HKA: The Hudson, Kreitman & Aguadé test for evolutionary neutrality. ►mutation neutral

H3K9: Lysine⁹ in histone-3; a common target of methylation and silencing of gene expression. ►histone methyltransferases, ►heterochromatin, ►epigenesis

HKR Oncogenes: HKR oncogenes were renamed GLI. ►GLI

HKT (high-affinity kalium transport) A membrane protein conferring the ability of potassium uptake. ►ion channels

HL60: A human granulocyte line. ►granulocyte

HLA: A human leukocyte antigen (see Fig. H51). The H2 gene cluster determines the corresponding functions in mouse. The development of congenic resistant lines in mice permitted, eventually, the determination of histocompatibility by serological tests rather than by tissue transplantation. The genes concerned with the determination of specificity are generally designated as the major histocompatibility complex (MHC). The HLA Class I molecules have two polypeptide sub-units. The 44-kDa highly variable heavy chain is coded within the MHC cluster in the short arm of human chromosome 6p21.31, whereas the invariable ~12-kDa β_2 -microglobulin is

Figure H51. Epitope fragments of about a dozen amino acids are positioned in a cleft of the MHC molecule located on an antigen presenting cell. These fragments are delivered to the T cell receptors and destroyed there by the enzymes secreted by the T cell

H

encoded at another location (15q21-q22) in the genome. Paralogous HLA clusters also appear in human chromosomes 1q21, 9q33-q34, and 19p131-p13.4. The heavy chain has three domains of about 90 amino acids each, and one of them interacts with the β_2 -microglobulin.

These proteins are transmembranic with about 30 amino acids extending within the cell and a larger portion is outside the cell. The heavy chain consists of three domains α_1 , α_2 and α_3 , encoded by genes HLA-A, HLA-B, and HLA-C. The Class I polypeptides were originally designated as transplantation antigens. HLA Class II antigens are heterodimeric composed of a 33- to 34-kDa α chain and a 28- to 29-kDa β chain. The human MHC Class II genes are HLA-DR, HLA-DQ, and HLA-DP. All of the HLA genes are interrupted by several introns. The α_3 and the β_2 -microglobulin of the Class I HLA genes and the β_2 and α_2 polypeptides of the Class II polypeptides are homologous with the heavy chain constant region of immunoglobulin M. The β_2 -microglobulin bears similarity to the V gene of immunoglobulins. Heterozygosity for both Class I and Class II genes can improve protection against some viral infections. The HLA cluster occupies about 3,600 kb in the DNA, including interspersed other genes (total of ~ 224 loci) not shown here:

The entire human HLA region has been sequenced and it includes 128 genes and 96 pseudogenes, some of the genes have paralogues in other chromosomes (Nature 401:921 [1999]). Within the Class II region there are about 20 multiple repetitive sequence families (retrotransposons, retrotransposons, human endogenous retroviruses [HERV]) occupying $\sim 20\%$ of the region. Retroelements seem to affect recombination within HLA. A detailed haplotype map of HLA

is available (Walsh EC et al 2003 Am J Hum Genet 73:580). A high-resolution linkage disequilibrium map to all three HLA regions, using single nucleotide polymorphism, facilitates fivefold increase in genotyping MHC linked diseases (Miretti MM et al 2005 Am J Hum Genet 76:634).

The DP cluster contains alternating 2 α and 2 β genes in opposite orientation; DQ also has the same arrangement of the 2 α and 2 β genes; DR has β_1 , β_2 , β_3 in the same left to right sequence and 1 α genes in opposite orientation. Both Class I and Class II genes appear to have pseudogenes. The HLA genes have a large number of alleles and certain alleles of some genes, e.g., A1 and B8, are in linkage disequilibrium, i.e., they are syntenic much more often than expected by random recombination.

The HLA genes display high polymorphism that may be correlated with the specificity of the immune reaction. In the N-termini of the A proteins there may be 7% differences. In exons 2 and 3 of the A genes the base substitutions generally result in amino acid replacements whereas in exon 4 half of the base substitutions are silent at the protein level. The β chains of DP, DQ, and DR are highly polymorphic but the α chains of DR and DP are conserved. The variations were suspected to be the result of gene conversion but some of the variation implicates interallelic recombination.

The amount of HLA gene products varies substantially in different cells. B lymphocytes display more A, B, and somewhat less C antigens whereas in T lymphocytes all three proteins are much less active. Interferons and tumor necrosis factors stimulate the expression of the Class I genes. Class II genes are expressed primarily on B lymphocytes, myelocyte resembling cells, and macrophages. When activated, T lymphocytes as well as skin fibroblasts and some endothelial cells may express them. Class II genes' transcription is induced only by γ interferon. If mouse lymphocytes are transformed with the HLA heavy chain genes of Class I, the heavy chain can function with the murine β_2 -microglobulin. It is detectable by monoclonal antibodies against HLA determinants while in transgenic cells cytotoxic lymphocytes did not attack the HLA determinants consistently. The heavy chain can function with the murine β_2 -microglobulin and it is detectable by monoclonal antibodies against HLA determinants while in transgenic cells cytotoxic lymphocytes did not attack consistently the HLA determinants. Genetically engineered HLA Class I indicated that the first two external regions of the heavy chain (α_1 and α_2) are critical for encoding serological determination. Class

II genes are expressed on the surface of mouse lymphocytes and the mouse cell can provide the invariant antigen chain.

Within the long DNA tract of the HLA cluster, several genes involved in disease susceptibility have been identified. 21-hydroxylase deficiency (in between DR and A) causes congenital adrenal hyperplasia (CAH1), hemochromatosis (HFE, either between B and A or distal to A) causing cirrhosis of the liver, diabetes, dark pigmentation, and heart failure. The gene for juvenile myoclonic epilepsy, JME (proximally to A), causes convulsions limited to certain areas, and is possibly involved in ragweed sensitivity, etc. The tumor necrosis factors TNF-A and TNF-B, cachectin (hormone-like protein product of macrophages) releasing fat and lowering the concentration of fat synthetic and storage enzymes and lymphotoxin (lyses cultured fibroblasts) are also coded within the HLA cluster.

The most important functions of the complex are in immune recognition, defense against bacteria and viruses. They also have a number of other not entirely clarified roles. The glycoproteins encoded by the HLA genes are deposited on the surface of the majority of cells. These surface antigens are the ID cards of the individuals. Their identity is determined by the inheritance of the specificity of the MHC alleles and not processed further as it is the case with the antibody transcripts. The Class I gene products are located on the cytotoxic T cells (CTC) that destroy the cells of the body when infected.

The Class II proteins are on the surface of B-lymphocytes and macrophages that are involved in binding humoral (circulating) antigens. Antigens are separated into polypeptides by cellular proteases and the polypeptides associate with specific compartments of the specific HLA protein molecule.

The CD8 (cluster of differentiation 8 protein, 34 kDa, encoded by a gene in human chromosome 2, product of differential processing of the transcript) becomes part of the T lymphocyte cytotoxic or suppressor molecule in association with Class I HLA proteins recognized by the T lymphocyte receptor (TCR) (see Fig. H51). [The TCR protein is a complex of different polypeptide chains encoded at 14q11.2 (TCR α), at 7q35 (TCR β), at 14q11.2 (TCR δ), at 11q23 (TCR ϵ) and at 7p15-p14 (TCR γ)]. CD4, a 55-kDa protein (encoded in human chromosome 12) is associated with TCR and with Class II HLA proteins on specific T lymphocytes. The CD8 and CD4 proteins also act as signal transducers in association with CD3 antigens (multiple cistrons encoded at 11q23), and the helper T lymphocytes secrete lymphokines that activate B cells to secrete antibodies. In addition, they turn on a protein tyrosine kinase to initiate signal transfers to the cell nucleus.

The human MR1 gene locus (1q25.3), also called HLALS, encodes a polypeptide that has similarities to the Class I major histocompatibility antigens. The human MHC-B and MHC-C duplicated 22.3 Myr ago and Old World monkeys diverged from the human lineages 27–30 Myr ago (Fukami-Kabayashi K et al 2005 Proc Natl Acad Sci USA 102:9230). ▶major histocompatibility complex, ▶H-2, ▶congenic resistant lines, ▶antibody, ▶T cells, ▶TCR, ▶CD8, ▶CD4, ▶CD3, ▶TAP, ▶adrenal hyperplasia, ▶hemochromatosis, ▶myoclonic epilepsy juvenile, ▶ragweed sensitivity, ▶ankylosing spondylitis, ▶Reiter syndrome, ▶lupus erythematosus, ▶psoriasis, ▶microcytotoxicity test, ▶mixed lymphocyte reaction, ▶endogenous virus, ▶RFX, ▶lymphochip; Hill AV 2001 Lancet 357:2037; Shiina T et al 2001 Genome Res 11:789; Hughes AL, Yeager M 1998 Annu Rev Genet 32:415; Ting JP-Y et al 2002 Cell 109[S02]:21; human-chimpanzee Class I region: Anzai T et al 2003 Proc Natl Acad Sci USA 100:7708; Wahl A et al 2006 Expert Rev Proteomics 3:641.

HLH: The amphipathic (both hydrophobic and hydrophilic sides) α -helices of proteins connected by a loop.

HLM Oncogene: A mosaic of various types of retroviral elements found in avian and mammalian viruses. Oncogene HLM2 was assigned to human chromosome 1. ▶retrovirus

HLP: A histone-like protein. ▶histones

HMBA (hexamethylene bisacetamide): HMBA causes genome-wide transient demethylation in mouse erythroleukemia cells while the DNA is not replicating. ▶methylation of DNA

HMCRC: Human-mouse conserved region in the DNA.

HMG: ▶high-mobility group of proteins

HMG Box: A high-mobility group domain of the SRY gene product and other proteins with high affinity DNA-binding but differing sequence specificity. ▶SRY

HMG-CoA Reductase: ▶cholesterol, ▶Niemann-Pick disease

HML and HMR: The left (α) and right (α) mating type gene cassettes, respectively, in chromosome 3 of yeast. These elements are expressed only when transposed to the mating type, MAT site. Both of these loci are flanked by HML-E and HML-I and HME-E and HMR-I silencing elements where binding sites exist for a combination of three proteins: ORC, a protein complex originating replication, Rap1, and Abf. HMR-I has the ORC and Abf binding sites (ACS) but has no Rap1 binding site. Rap1 binds the

silencer proteins Sir3 and Sir4. ORC recruits Sir1. HMR-I has both an origin of replication and a silencing function. ►mating type, ►ORC, ►Rap, ►Abf, ►silencer, ►mating type determination in yeast

hMLH1: A human DNA repair locus in chromosome 3p21 where mutations may lead to colorectal cancer. ►hereditary nonpolyposis colorectal cancer, ►DNA repair

HMM (hidden Markov model): ►Markov chain

HMMgene: A gene prediction program. ►gene prediction; <http://www.cbs.dtu.dk/services/HMMgene/>.

HMS: ►copia

HMSN (hereditary motor and sensory neuropathy): A group of hypomyelination diseases like the Charcot-Marie-Tooth disease, Dejerine-Sottas syndrome, and HNPP. ►hypomyelinopathies

HMS-PCI: High-throughput mass spectrometric protein complex identification. (See Ho Y et al 2002 Nature [Lond] 415:180).

HNF (hepatocyte nuclear factor): HNF proteins are transcription factors of liver-specific genes involved in carcinogenesis, atherosclerosis, hyperlipidemia, insulin resistance, hypertension, blood clotting, etc. HNF-1 α (human chromosome 12q22-t23, mouse chromosome 5) and HNF-4 α ([TCF14] human chromosome 20q12-q13.1) regulate insulin secretion and their defect may lead to non-insulin-dependent diabetes. HNF-3 α (human chromosome 14q12-q13, mouse chromosome 12) is a negative regulator of HNF-1 α and HNF-4 α whereas HNF-3 β has a positive regulatory effect on HNF-1 α , HNF-4 α , and HNF-3 α . HNF-3 α appears to compete for the binding site of HNF-3 β (human chromosome 20p11, mouse 2). HNF-3 γ is in human chromosome 19q13-q13.4 and in mouse chromosome 7. HNF3 may bind to nonacetylated nucleosomes. ►cancer, ►atherosclerosis, ►hyperlipidemia, ►diabetes, ►MODY, ►hypertension, ►blood clotting, ►plasmin, ►hepatocyte growth factor, ►glomerulocystic kidney disease hypoplastic familial, ►transcription factors; Shih DQ et al 2001 Nature Genet 27:375; Odom DT et al 2004 Science 303:1378.

HNGFR: A high molecular nerve growth factor receptor. ►LNGFR

HNPCC (human nonpolyposis colon cancer): A hereditary nonpolyposis colorectal cancer. ►colorectal cancer

HNPP (hereditary neuropathy with liability to pressure palsy, human chromosome 17p11.2): HNPP bears

similarity to hereditary motor and sensory neuropathies (HMSN), represented by the Charcot-Marie-Tooth syndrome and other hypomyelination diseases although it is distinguished from them in several ways. Its onset is during adolescence or shortly after. The hypomyelinated tomacula (sausage-like swellings) are diagnostic criteria. ►palsy, ►neuropathy, ►MLE, ►MITE, ►hypomyelination, ►HMSN, ►Charcot-Marie-Tooth disease

hnRNA: heterogeneous nuclear RNA; all the thousands of diverse species of RNA found in the eukaryotic nucleus, including primary transcripts and pre-mRNA in various stages of processing. The hnRNA includes introns and other transcribed but not translated RNAs. These RNAs may be associated with proteins ranging from 34 kDA to 120 kDA in size. There are about 20 different proteins within the particles. The six most common core proteins, A12, A2, B1, B2, C1, and C2 occur in multiple copies within each globular aggregate. The complex takes a beads-on-string like structure with each globular structure (about 20-nm in diameter) containing 100–800 nucleotides and having a sedimentation coefficient of about 40S. A gene in human chromosome 19q13.3 codes the U1AP protein. The U1-70K snRNP is the major antigen recognized by anti-(U1)RNP sera in autoimmune diseases. It has been estimated that only about 5% of the pre-mRNAs are exported from the nucleus to the cytoplasm. Most of the rest are degraded. ►snRNA, ►hnRNP, ►RNP, ►U1-RNA, ►autoimmune disease, ►KH domain; Roy-choi TS 1999 Crit Rev Eukaryot Gene Expr 9:107; Krecic AM, Swanson MS 1999 Curr Opin Cell Biol 11:363; <http://www.iscid.org/encyclopedia/hnRNA>.

H-NS: A histone-like nucleoid structuring protein abundant in prokaryotes; it participates in nucleoid structure, gene regulation, and silencing. It plays a key role in cell response to changes in temperature and osmolarity. H-NS can decorate DNA molecules at one H-NS dimer per 15–20 bp (Roee A et al 2003 Biophys J 84:2467).

hnRNP: Heterogeneous ribonucleoprotein. These proteins regulate gene expression at post-transcriptional levels. Some of the recognition motifs are RNP1 octamers and RNP2 hexamers, which are embedded in conserved regions of ~80 amino acids and are present in one to four copies. The K homology (KH) domains of about 60 amino acids may be present in up to 15 copies per protein. In the genome of *Arabidopsis*, 196 RNA recognition (RRM) and 26 KH proteins were found. These proteins are more complex in this plant than those found in metazoa. ►hnRNA, ►export adaptors, ►RNA binding proteins; Lorkovic ZJ, Barta A 2002 Nucleic Acids Res 30:623.

hobo: ►hybrid dysgenesis

Hodgkin Disease (HD): A malignant lymphoma with an unknown genetic determination because the familial nature of the condition is not sufficiently clear. WF Bodmer argued in favor of a gene linked with a HLA complex. In a two-marker case (A and A'), the distribution of 1AA:2AA':1A'A' would be expected in the progeny of heterozygotes without linkage. In a survey of 32 afflicted sib pairs, the actual proportions were 16:11:2, which were significantly different from 1:2:1 at the level of 0.005 probability. More recently, linkage to the pseudoautosomal region has been suggested. If it is assumed that the frequency of the gene *a* (Hodgkin) is 0.01 and all *aa* individuals become afflicted and only 0.05 of the *AA* individuals develop the disease and none of the *AA* do, then only about 0.01 of the Hodgkin patients will be homozygotes for *aa*. In a case of 32 two-offspring families with two afflicted children the expected frequency of *aa* was about 2.5×10^{-6} . This also assumed that the two-sib families had *AA* × *AA* parents (about 4×10^{-3}) and the frequency of two-child-afflicted families was about 2.5×10^{-3} . These latter figures thus point to the possibility that in some populations the frequency of the recessive homozygotes may indicate high familial expression of the disease due to drift/founder effect.

►ascertainment test, ►Hardy-Weinberg theorem, ►HLA, ►lymphoma, ►Epstein-Barr virus, ►leukemia, ►anaplastic lymphoma, ►MALT, ►IL-9, ►pseudoautosomal; Staudt LM 2000 J Exp Med 191:207.

Hoechst Stain 33258: The Hoechst stain 33258 is used for banding of AT-rich minor groove DNA sequences in the chromosomes and it is also an antibiotic. ►Harlequin staining of chromosomes, ►sister-chromatid exchange

HOG-1 (high osmolarity): A protein kinase of the MAPK family. ►signal transduction, ►osmosis, ►p38

Hogness Box (-Goldberg): (TATA box): A 7-8 base pair region of conserved homology rich in TA, preceding the transcription initiation of the mRNA by about 19–31 residues in the promoter region of eukaryotic genes:

Exceptionally, some promoter regions lack the TATA box, these are called *TATA-less promoters*

such as U1, U2, U4, and U5 RNA promoters. The TATA box (see Fig. H52) is generally surrounded by GC rich sequences (proximal and distal sequence elements, PSE and DSE). In these U promoters, PSE and DSE are still present. Transcription by RNA polymerase II requires the association of the TATA box with a TATA binding protein (TBP) or additional TATA associated factors (TAF). ►Pribnow box, ►TATA box, ►TBP, ►TAF, ►open promoter complex, ►transcription factors; Hernandez N 2001 J Biol Chem 276:26733.

hok-sok-mok: ►plasmid maintenance

Holandric Gene: The holandric gene is Y-chromosome linked. The mammalian Y chromosome appears largely heterochromatic under the light microscope and it carries few genes. The H-Y antigen gene has been assigned to the proximal region of the long arm of Y and the testis-determining factor, formerly called TDF, now SRF, is proximal to the centromere in the same arm in humans. The long arm also contains the pseudoautosomal region (PAS); this DNA sequence Yp (SMCY) is homologous to a X-chromosomal tract, Xp (SCX), the region where X and Y crossing over can occur. The gene for surface antigen MIC2Y was assigned to the euchromatic region Ypter - q1 of the Y chromosome. The homolog was assigned to a X-chromosomal band between Xp22.3 and Xpter. The azoospermia factor (AZF) Sp3 or HGM9 maps at the site of H-Y and may be identical with it. Genes controlling body height and tooth length were suspected to be in the Y-chromosome. An arginosuccinate and an actin pseudogene were located to the human Y chromosome. A gene for hairy ears was suspected to be in the Y chromosome but its status is not resolved with certainty. No hereditary disease gene is linked to the Y chromosome, although in aneuploids (XYY, XO), it may cause defects. ►Y chromosome, ►sex determination, ►differential segment, ►H-Y antigen, ►SRF, ►pseudoautosomal, ►azoospermia, ►pseudogene, ►actin, ►heterochromatin, ►surface antigen, ►hairy ear, ►imprinting; Jobling MA, Tyler-Smith C 2000 Trends Genet 16:356.

Holandric Inheritance: Genetic transmission (only) through the male. ►imprinting

Figure H52. Hogness box

Holin: The protein product of the *t* gene of phages that conducts the lysozyme into the periplasmic space of the bacteria conducive to lysis. ▶lysozyme, ▶periplasma, ▶endolysin, ▶lysis; Wang I-N et al 2000 Annu Rev Microbiol 54:799.

Holism: The view that organisms represent an integrated system of elements and mechanisms and that the integrated system is more than a collection of the parts and therefore cannot properly be understood on the basis of the separated components. ▶organismal genetics

Holliday Junction (Holliday junction): The points where the polynucleotides forming the Holliday structures are exchanged during homologous recombination as well as during phage lambda integrase mediated exchange at the *att* sites. In most eukaryotes and in budding yeast, Holliday junctions take place between homologous chromosomes (see Fig. H53). In contrast, in *Saccharomyces pombe*, single Holliday junctions form between sister chromatids and they are resolved by a specific (Mus81-Eme1) endonuclease (Cromie GA et al 2006 Cell 127:1167).

Peptides WRWYCR and KWWCRW inhibit recombination not just in the events mentioned, but

also in Cre-, Xer-, and Flp mediated processes indicating that inhibitor specificity is not in the amino acid sequence in the recombination proteins, but they are specific for the Holliday junction itself. The peptides interfere with the unwinding of DNA by *E. coli* RecG helicase and with the resolution by the RuvABC complex (see Fig. H54) (Kepple KV et al 2005 Proc Natl Acad Sci USA 102:6867).

This juncture may be bound by Rad1 protein in the presence of Mg^{2+} and cut by this endonuclease. Rad1 appears to be the catalytic subunit of the Rad1/Rad10 endonuclease. Rad54 promotes branch migration in homologous recombination (Bugreev DV et al 2006 Nature [Lond] 442:590).

The Bloom syndrome (BLM) and the Werner syndrome (WNS) helicases are involved in the processing of the junctures regulated by p53. ▶Holliday model, ▶Holliday structure, ▶RAD, ▶recombination molecular mechanism of, ▶integrase, ▶branch migration, ▶CRE, ▶Flp, ▶RecG, ▶RuvABC, ▶Bloom syndrome, ▶Werner syndrome, ▶p53; Bond CS et al 2001 Proc Natl Acad Sci USA 98:5509; Lilley DMJ, White MF 2001 Nature Rev Mol Cell Biol 2:433; Yang Q et al 2002 J Biol Chem 277:31980; McKinney SA et al 2003 Nature Struct Biol 10:93.

Figure H53. Electronmicrograph of a holliday juncture (Courtesy of Drs. H. Potter & D. Drechsler)

Holliday Model: The Holliday model of general recombination is best explained by Figure H55. (After Potter, H. and Dressler D 1976 Proc Natl Acad Sci USA:73:3000. The model was originally proposed by Holliday R 1974 Genetics 78:273). This is the most widely accepted model of both prokaryotic and eukaryotic recombination. ▶Holliday juncture, ▶Holliday structure, ▶single-end invasion, ▶dissolution; diagram.

Figure H54. Holliday juncture. (Courtesy of Drs. Wei Wang and Dietrich Suck; see also Biertümpfel et al. 2007 Nature [Lond] 449:616)

Figure H55. Holliday model of recombination. After Potter H & Dressler D 1976 Proc. Natl Acad. Sci USA 73:3000

Holliday Structure: A recombinational intermediate of DNA displaying a four-strand cruciform arrangement. (See ►[Holliday model](#) step I, Fig. 55). Its resolution requires a specific endonuclease, and depending on the manner, the resolution takes place either by crossing over (flanking marker exchange) or gene conversion (non-crossover), without outside marker exchange results (steps L). ►[model](#), ►[cruciform DNA](#); Allers T, Lichten M 2001 Cell 106:47.

Holocentric: In holocentric chromosomes found in several species of insects (*Lepidoptera*, *Hemiptera*, *Homoptera*), in the nematode *Caenorhabditis*, and in certain plants (*Luzula*) the spindle fiber attachment is not limited to the centromere (kinetochore), but the microtubules can be attached to many points along the chromosome (see Fig. H56), appearing as if the centromere would be diffuse.

Figure H56. Holocentric chromosome fragments. (From Hughes-Schrader S, Ris H 1941 J Exp Zool 87:429)

In some genotypes of maize and rye, additional spindle fiber attachment sites (neocentromeres) accompany the major centromere. This characteristic may influence the distribution of the chromosomes to the poles (preferential segregation, non-disjunction). Species with holocentric chromosomes may be subjected to high doses of chromosome-breaking agents and still a more or less orderly anaphase distribution may take place. This feature has been exploited for biological control *lepidopteran* of agricultural pests. Heavily irradiated individuals with broken chromosomes may survive and mate, but in their progeny the chromosomal fragments may fuse leading to multiple translocations and lethal offspring. ►[screwworm control](#), ►[genetic sterilization](#), ►[centromere](#), ►[neocentromere](#), ►[centromere activation](#), ►[translocation](#); Dernburg AF 2001 J Cell Biol 153(6):F33.

Holoenzyme: A functionally complete enzyme, including cofactors. ►[apoenzyme](#)

Hologenesis: A view that claims that humans originated at many locations of the globe.

Holography: A three-dimensional photography with the aid of split laser beams.

Holokinetic: Same as holocentric.

Holometabolous Insect: The homometabolous has a larval stage of development and the larvae include imaginal disks, which are the initials of the adult body parts and from which all the appendages emerge according to a determined plan. ►[imaginal disk](#); Yang AS 2001 Evol Dev 3(2):59.

Holoprosencephaly: Dominant with human chromosomal locations 7q36 (sonic hedgehog, SHH), 2p21, 13q32 (ZIC2, a homolog of the *Drosophila* odd-paired, Opa, Zn-finger protein), but possibly other locations affect the expression of this syndrome (21q22.3, 18p11.3 [Niemann-Pick syndrome], 2q35 [Indian hedgehog], 12q13). The anomalies involve cleft lip, cyclopia, hypotelorism (abnormal distance between organs), defective head and face, and mental defects due to neural tube anomalies. The SHH human gene's transmembrane receptors are smoothened (7q32) and patched (9q22.3). The TG-interacting factor (TGIF, 18p11.3) a homeodomain protein, interacts with Smad2, Nodal, and a sonic hedgehog protein, and repress transcription of genes, which control signaling to the neural axis pathway. Its incidence is 1/250 in conceptuses and ~1/16,000 in live-borns. Severely affected newborns usually die within days; the less-affected cases may survive for a few years. No cure is available. ►[head/face/brain defects](#), ►[cleft lip](#), ►[cyclopia](#), ►[sonic hedgehog](#), ►[hedgehog](#), ►[tumor suppressor pathway](#), ►[megalin](#), ►[Smith-Lemli-Opitz syndrome](#), ►[SMAD](#), ►[Nodal](#); Belloni E et al 1996 Nature Genet 14:353; Roessler E et al 1996 Nature Genet 14:357; Cohen MM Jr 2006 Birth Defects Res Clin Mol Teratol 76(9):658.

Holt-Oram Syndrome (HOS): A dominant or sporadic arm, thumb, and heart malformation associated with human chromosome 12q24.1. The defective transcription factor involved is homologous with the *Drosophila* gene *Serrate* and the *Brachyury* mouse gene family of T box. The prevalence of the syndrome is 1×10^{-5} . No evidence has indicated that the type or site of mutation within the TBX5 sequence can predict the severity of the heart or limb malformation, and most of the mutations truncating TBX5 have failed to display defects in these organs (Brassington A-ME et al 2003 Am J Hum Genet 73:74). A newer report indicates, however, that the transcriptional regulator of TBX5, TAZ is potent coactivator, and TBX5-dependent genes are important for cardiac and limb development in the HOS syndrome (Murakami M et al 2005 Proc Natl Acad Sci USA 102:18034). ►[heart disease](#), ►[polydactyly](#), ►[adactyly](#), ►[Brachyury](#), ►[thrombocytopenia](#),

►sporadic, ►Tabatznik syndrome, ►T box; Ghosh TK et al 2001 Hum Mol Genet 10:1983.

Homeoallele: Alleles in the homeologous chromosomes. ►homeologous chromosome

Homeobox: A conserved (183 bp) sequence within homeotic genes. ►homeotic genes

Homeodomain: The part of the protein that is coded for by the homeobox; it contains a DNA-binding helix-turn-helix motif protein domain. The homeodomain contains three α -helices and a flexible N-terminal arm. The third or recognition helix takes position in the major groove of the DNA. The N-terminus keeps contact with several bases in the minor groove of the DNA. The best-conserved part of the homeobox is the TAAT motif.

The homeodomain genes determine the anterior posterior pattern of development and they are usually clustered in the genome. The homeodomain proteins are transcription factors. ►homeotic genes, ►DNA-binding protein domain, ►helix-turn-helix motif, ►homeobox, ►pseudogenes, ►morphogenesis in *Drosophila*, ►anterior, ►posterior; Gehring WJ et al 1994 Annu Rev Biochem 63:487; Banerjee-Basu S, Baxevanis AD 2001 Nucleic Acids Res 29:3258; <http://genome.nih.gov/homeodomain/>.

Homeogene: ►homeotic gene

Homeogenetic Induction: In homeogenetic induction, cells or tissues start on a certain path of development by induced cell(s) and continue producing the same cell types. (See Tiedemann H et al 2001 Dev Growth Differ 43(5):469).

Homeologous: ►homeologous

Homeologous Recombination: Homeologous recombination may take place between DNA (chromosome) strands that are similar but not entirely homologous. Recombination between *E. coli* and *Salmonella* with about 16% non-homology is about 10^{-5} of that of recombination within the species. Mismatches within the species were found to affect recombination to a less dramatic extent. In mouse, 2/232 mismatches reduced recombination to about 5%. Mitotic recombination in budding yeast at a difference of about 17–27% resulted in reduced exchange by a factor of 13–180. Meiotic recombination is also much reduced in higher eukaryotes in case of sequence differences. ►illegitimate recombination, ►homologous recombination

Homeopathy: Administering to a sick person, small doses of a medicine that given in larger doses to a healthy individual would produce the symptoms of

the same disease, which, it intends to cure. Homeopathy's origin can be traced back to Hippocrates (~fourth–fifth century BC) and Paracelsus (sixteenth century AD). Homeopathy was elaborated upon by Hahnemann (1767). An analysis of 110 homeopathy and 110 matching conventional medications indicated that the effects of homeopathy are comparable to that of placebo (Shang A et al 2005 Lancet 366:726). Today in the USA, it is a largely discredited practice although there are some adherents worldwide. (See Barberis L et al 2001 J Altern Complement Med 7(4):337; ►placebo).

Homeosis: Changing a body part into the likeness of another body part. ►homeotic genes

Homeostasis: The property of a system to maintain its composition by a flexible adjustment of the function of its genes (genetic homeostasis), or a physiological, or developmental buffering capacity of cells or developing organisms under a range of conditions. ►logarithmic stability factor, ►stress, ►allostasis

Homeostasis, Genetic: The property of a population to equilibrate its genetic composition and resist mutational changes.

Homeotic Genes: Homeotic genes specify an alternative competence for differentiation of a part of the body, e.g., in *Drosophila*, legs in place of antennae, in plants, petals in place of stamens, (see Fig. H57) etc.; they contain a homeobox. Homeosis (term coined by Bateson in 1894) was recorded by the ancient world (King Midas, seventh century B.C. grew 60-petalled roses). The discovery of homeosis by Calvin Bridges in 1915 stimulated more interest in these genetically determined developmental anomalies. Subsequently, other such developmental genes were discovered both in *Drosophila* and all types of higher organisms. In *Caenorhabditis*, about 10% of the developmental genes contain homeoboxes. In the plant *Arabidopsis*, 35–70 homeogenes were estimated to exist. Homeotic genes are generally large complexes, the *BXC* complex occupies more than

Figure H57. Left: normal drosophila female, middle: antennapedia mutant. Right: homeotic shoot apex of *Arabidopsis* (Courtesy of Dr. K. Németh)

300-kb, and less than 1/10 of it codes for mRNA. They are interspersed with introns and intergenic DNAs required for the developmental regulation of the complex. In *Drosophila melanogaster*, the homeotic genes are basically continuous (only introns are wedged within), in *Drosophila viridis*, the *Ultrabithorax* complex is mapped to two different salivary chromosome bands in chromosome 2. The first molecular analysis conducted (in DS Hogness laboratory, 1983) on the *antennapedia* complex, *ANTC* (3-47.5), revealed that this complex spans 335-kb, and includes several transcription units. All homeotic genes have a 180-bp consensus sequence, the so-called *homeobox* that specifies the *homeodomains* of regulatory proteins. The structural features of the *Ant* gene of *Drosophila* represent the organization of the homeoproteins below (see Fig. H58).

The 7–8 amino acids at the amino termini are rather well conserved across taxonomic groups, except the one represented by (?). The homeodomain of this protein may form three helical units between amino acids 1 (Ser) and 22 (Glu), between 28 (Arg) and 38 (Leu), and between 42 (Glu) and 58 (Lys). The best-conserved amino residues are in bold italic. This homeodomain region has homology to the helix-turn-helix motif of prokaryotic repressor proteins and to the MAT $\alpha 2$ protein with repressor function at the mating type site in yeast. These three helical regions may fold into a helix-turn-helix DNA binding motif.

The homeoprotein may make (unspecific) surface contact with the phosphate backbone of the DNA in the major groove. The homeodomain's conserved residues, preceding the helices, attach to the minor groove of the DNA and for the more specific contacts,

probably helix III is responsible. These homeoproteins regulate processes of differentiation and either point or frameshift mutations may abolish their DNA-binding abilities and alter the pattern of differentiation. Binding can also take place at more than one DNA sequence as long as some basic similarities are shared in the base sequences. Therefore, one homeoprotein may regulate more than a single gene, although at a different degree. Homeoboxes display great similarities in sequence among different organisms. Mammals usually have four homeobox gene clusters, A, B, C, and D. Homeobox *HOX2* of the mouse is in chromosome 11, but its human homolog is in human chromosome 17 (containing in a 180-kb region altogether nine homeobox genes separated by a few units of recombination). *HOX1* of the mouse is in chromosome 6 but its homolog is in human chromosome 7p along with seven other homeoboxes. *HOX1* is also homologous to the *ANTC* homeobox of *Drosophila*. *Hox* genes in the mouse also occur in chromosome 11, 15, and 2. An additional homeobox gene cluster of three subgroups has been discovered in the X chromosome of mouse. The 12 *Rhox* genes (reproductive homeobox X-linked) control the development of the female and male reproductive tissues (MacLean JAH et al 2005 Cell 120:369). Each Hox/Hom contains a cluster of ~9–11 genes with an average length of about 10 kb, and thus the clusters are about 100 kb, each. The genes within the cluster show paralogy and most likely arose by serial duplications during evolution. The genes within a paralogous group also referred to as cognate. Some *trans-paralogous* genes (situated in chromosomes 6 and 2, respectively) of the mouse are

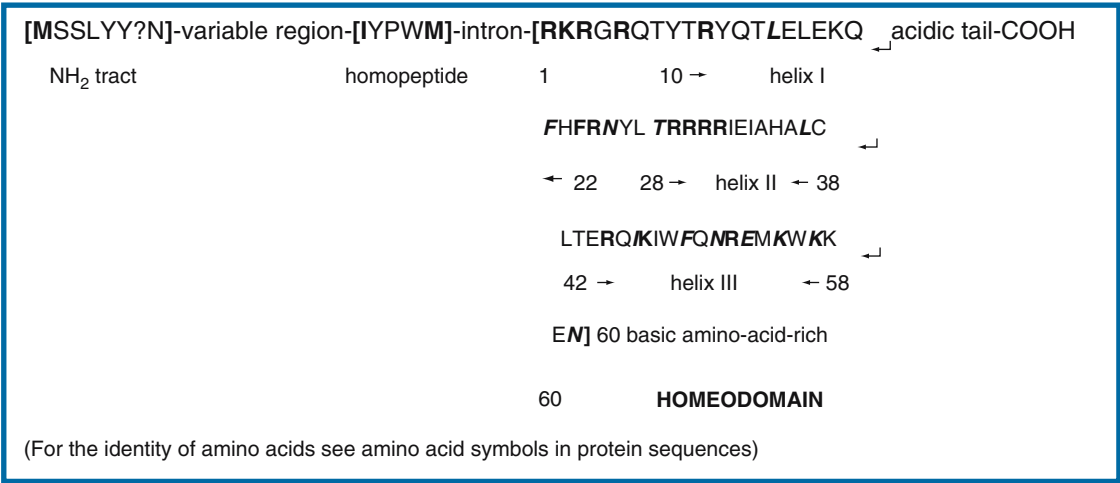

Figure H58. A homeodomain protein structure represented by the *Ant* gene product of *Drosophila*

capable of substituting for each other if one of them is deleted. Some similarities are apparent among the homeotic loci in different organisms and these are called *orthologous* because they appear to have common evolutionary origin. Statistical surveys of *Drosophila*, mouse, *Caenorhabditis*, humans, etc., indicate that the flanking areas of the homeotic gene clusters were conserved during evolution. Homeoboxes are regulated by cis- and trans-acting elements directly or indirectly. ►POU, ►developmental pattern formation, ►helix-turn-helix, ►mating type yeast, ►morphogenesis, ►Wolf-Hirschhorn syndrome, ►syndactyly, ►coordinate regulation, ►operon, ►paralogous loci, ►collinearity, ►heterochronic mutation, ►Polycomb, ►paralogous, ►orthologous, ►parahox genes ►[protohox genes]; Krumlauf R 1994 Cell 78:191; Ferrier DEK, Holland PWH 2001 Nature Rev Genet 2:33; Zákány J et al 2001 Cell 106:207; Galant R, Carrol SB 2002 Nature [Lond] 415:910; Ronshaugen M et al 2002 *ibid*: 914; <http://www.iephb.nw.ru/hoxpro>.

Homer: A 186 amino acid glutamate receptor binding protein with a single PDZ domain. ►PDZ, ►AMPA, ►GABA; Sal C et al 2001 Neuron 31:115.

Homing: Moving of insertion or other mobile elements within or into a genome. ►linotte

Homing Endonucleases: Homing endonucleases are encoded within mitochondrial and nuclear introns and catalyze the movement of introns and inteins. They have recognition sequences of 18 to 40 nucleotide pairs. The best studied representative of these enzymes is I-Sce. It is mitochondrially encoded within the ω^+ yeast factor (21S rRNA). After being spliced out, it is translated into Sce protein. The VDE endonuclease is within the intron of a vacuolar membrane ATP-ase. They are transcribed and translated together and when the protein is processed, the VMA1 ATPase and the VDE endonuclease are produced by evicting VDE and splicing the amino and carboxy-terminal amino acid sequences of VMA1.

The Sce system can be used for site-specific chromosome breakage and repair studies after introduction with appropriate vectors into the cells. The event can be monitored in a *S1neo* construct where the *neo* antibiotic resistance gene is interrupted by a 18 bp I-Sce I sequence and therefore *neo* is not expressed. The I-Sce I sequence is flanked by a CATG duplication: S1neo~~~~CATG~~CATG. After I-Sce I cleavage, two types of *neo* genes are found: (1) *neo*~~~~CATG expressed and *neo*~~~~Δ not expressed because of the Δ deletion. Other types of constructs can also be produced that can restore *neo*

activity by cleavage and repair. I-Sce I can be introduced into the cells also by electroporation and can bring about non-homologous repair. The double-strand breaks generated by the homing endonuclease were found to increase gene targeting up to a 1000-fold. They induce site-specific breaks within the 14-44 base pair recognition sequence. Four families of homing endonucleases are distinguished. These systems—although basically different from the Cre/loxP or FLP/FRT34; can be used for similar purposes. Insertion of *mobE* endonuclease into the *nrdA* gene of *Aeromonas hydrophila* phage Aeh1 creates a unique genes-in-pieces arrangement, where *nrdA* is split into two independent genes, *nrdA-a* and *nrdA-b*, each encoding cysteine residues that correspond to the active-site residues of uninterrupted NrdA proteins. Remarkably, the *mobE* insertion does not inactivate NrdA function, although the insertion is not a self-splicing intron or intein (Friedrich NC et al 2007 Proc Natl Acad Sci USA. 104:6176). ►mitochondrial genetics, ►Cre/loxP, ►FLP/FRT, ►intron homing, ►inteins, ►site-specific recombinases, ►chromosomal rearrangements, ►super-Mendelian inheritance, ►marker exclusion, ►LAGLIDADG; Dujon B et al 1989 Gene 82:115; Jurica MS, Soddard BS 1999 Cell Mol Life Sci 55:1304; Edgell DR, Shub DA 2001 Proc Natl Acad Sci USA 98:7898; Chevalier BS, Stoddard BL 2001 Nucleic Acids Res 29:3757; Wessler SR 2005 Trends Plant Sci 10:54.

Hominidae: The family of humans *Homo sapiens*, *Homo erectus*, *Homo habilis*, and other most closely related, now extinct, genera that are more highly evolved than the closest family of *Pongidae* that includes the orangutan, chimpanzee, gorilla and other great apes. The brain size in modern humans varies, the Australian aborigines have a brain volume over 1,200 cm³ whereas that of *Homo erectus* was over 1,000, *Homo habilis* above 700, *Australopithecus* 400 to 500, gorilla 500, and orangutan and chimpanzee just below 400. (The word australis means southern; pithekos indicates ape in Greek). Apparently, brain size has changed very little in the last 300,000 years. Sequencing 53 intergenic, non-repetitive DNA segments (24,234 bp) from humans, chimpanzees, gorillas, and orangutans revealed a very low average sequence divergence. The divergence for human–chimpanzee is 1.24%, human–gorilla 1.62%, and for chimpanzee–gorilla 1.63%. On the basis of a molecular evolutionary clock, humans separated from chimpanzees 4.6 to 6.2 million years ago (Chen F-C, Li W-H 2001 Am J Hum Genet 68:444). Newer analysis of chromosome human 21 and the corresponding sequences in chimpanzee revealed

very small differences in coding (0.51%), in promoter (0.88%) and exon-intron junctions (0.85%), by sequencing 127 genes (Shi J et al 2003 Proc Natl Acad Sci USA 100:8331).

The taxonomic classification and evolutionary descent of *Primates* is not entirely clear. The majority of anthropologists favor the idea that *Homo sapiens* evolved in Africa (about 1 million years [Myr] ago) and then spread to Asia and Europe in relatively recent time. One incomplete tree of hominid descent is shown below.

There is fossil indication that *H. habilis* and *H. erectus* coexisted for about half a million years and therefore *habilis* did not convert directly into *erectus* and therefore there might not have been a simple direct line of descent as shown in the figure (see Fig. H59) (Spoor F et al 2007 Nature [Lond] 448:688). Human evolution from primates will be revealed by the completion of the genome projects. At this time the actual steps and course of human evolution are not entirely clear because of the scarcity of paleontological remains (Dalton R 2006 Nature [Lond] 440:1100).

It is already known that the DNA base composition of humans and chimpanzees is almost 99% identical. Therefore, morphological and brain differences may be accounted for by different regulation of the basically identical genetic material. The lower human chromosome number appears to be due to chromosome fusion (e.g., human chromosome 2). Pericentric inversions of human chromosome 18 and chromosome 3 show major differences from the corresponding ape chromosomes (Muzny DM et al 2006 Nature [Lond] 440:1194). Rearrangements frequently alter regulation of genes. The human genus (Hominini) has been reclassified on the basis of new criteria and because of the inherent problems of scanty anthropological remains; modifications are likely to be proposed. Mandibular ramus morphology (a projection of the lower jaw) on a recently discovered specimen of *Australopithecus afarensis* closely matches that of gorillas. This

finding was unexpected in the view that chimpanzees are the closest living relatives of humans. Because modern humans, chimpanzees, orangutans, and many other primates share a ramal morphology that differs from that of gorillas, the gorilla anatomy must represent a unique condition, and its appearance in fossil hominins must represent an independently derived morphology. The absence of this morphology in modern humans has cast doubt on the role of *Au. afarensis* as a modern human ancestor (Rak J et al 2007 Proc Natl Acad Sci USA 104:6568).

►hologenesis, ►Primates, ►Eve foremother of molecular mtDNA, ►Y chromosome, ►out-of-Africa, ►genome projects, ►inversion, ►language, ►chimpanzee, ►bonobo, ►*Homo floresiensis*; Wood B, Collard M 1999 Science 284:65; Stone AC et al 2002 Proc Natl Acad Sci USA 99:43; Wood B 2002 Nature [Lond] 418:133; Carroll SB 2003 Nature [Lond] 422:849; White TD et al 2003 Nature [Lond] 423:742; Cela-Conde CJ, Ayala FJ 2003 Proc Natl Acad Sci USA 100:7684; <http://www.mnh.si.edu/anthro/humanorigins>; <http://www.talkorigins.org/faqs/homs>.

Hominins: The various evolutionary ancestors at the separation of human and ape lineages. They include *Homo*, *Australopithecus*, and the more ancient *Paranthropus* and *Ardipithecus*. By some definition hominins include primates up to human lineage and the associated subfamilies of *Pan* and *Gorilla* ►hominidae, ►Pongidae; Underdown S 2006 Nature [Lond] 444:680.

Hominoid: Hominoids includes gibbons, great apes, and hominids (and extinct species). ►primates, ►hominids, ►pongidae, ►great apes

***Homo sapiens* (man):** $2n = 46$. ►hominidae, ►human races, ►primates

***Homo floresiensis*:** An extinct human race that lived in the late Pleistocene period in Indonesia. Its body size

Figure H59. New skeletal mtDNA analysis of Neanderthal remains supports the view that these people represent an evolutionary dead end as shown at left

was comparable to that of the African pygmy. Its brain volume $\sim 380 \text{ cm}^3$ is comparable to the chimpanzee's. The first skeletal remains were discovered in 2003. (See Lieberman DE 2005 Nature [Lond] 437:957).

Homoalanine: $\text{C}_4\text{H}_9\text{NO}_2$.

Homoalleles: Homoalleles differ at the same nucleotide site of a codon, and therefore only four different alleles can be produced, containing at a particular site either A or T, or C or G, and within the nucleotides recombination is impossible. Such an allele can be changed by intracodon (between nucleotides) recombination or base substitution.
▶ [homoeoalleles](#), ▶ [heteroalleles](#)

Homocaryon: ▶ [homokaryon](#)

Homocitrullinuria: ▶ [urea cycle](#)

Homocystinuria: Homocystinuria may occur due to different causes: (i) recessive deficiency of cystathionine synthetase [human chromosome 21q22.3], (ii) defects in vitamin B12 metabolism, (iii) poor intestinal absorption of B12, (iv) deficiency of methylenetetrahydrofolate reductase (1p36.3). Within group (i) different forms were also found; some responded also to vitamin B6 (pyridoxine). The phenotypes may resemble that of the Marfan syndrome. In some instances, deletion of the 145 amino acid carboxy terminal of cystathionine synthase alleviates the metabolic problems. It seems that this segment negatively controls the catalytic activity and it is under regulation by AdoMet. The general symptoms involve dislocation of the eye lens (ectopia lentis), thromboembolism (obstruction of the blood vessels), bone abnormalities, mental retardation in 2/3 of the afflicted, psychological disorders, etc. Prevalence is $\sim 2 \times 10^{-6}$ although in Ireland it is much more common. The diagnostic test to determine elevation of homocysteine (see Fig. H60) and methionine in the urine is carried out by the cyanide-nitroprusside reaction. Prenatal and carrier identification is practical. Types (ii) and (iii) respond favorably to vitamin B12 (hydroxycobalamin), and

Figure H60. Homocystin

cultured cells require methionine. Type (iv) individuals respond favorably to pyridoxine and folic acid. Defects in methionine synthase reductase (MTRR, 5p15.3-p15.2) may also increase the blood homocystine level. In Down syndrome, the level of cystathionine and cysteine is increased, the level of homocysteine is reduced, folate-dependent methionine synthesis is diminished, and folate deficiency may occur.

Homoeoalleles: Evolutionarily and functionally closely related genes in polyploid species. ▶ [homoalleles](#)

Homoeobox: ▶ [homeobox](#), ▶ [homeotic genes](#)

Homoeologous Alleles: Homoeologous alleles occur in the homoeologous chromosomes of allopolyploid species; also called homoeoalleles.

Homoeologous Chromosomes: Nonidentical yet related chromosomes derived from a common ancestor, and despite some evolutionary divergence, show partial homology like the A, B, and D genomes of wheat.
▶ [homologous chromosomes](#), ▶ [nullisomic compensation](#)

Homoeotic: Related by evolutionary descent but modified during the course of evolution; similar but not entirely identical (recent usage is generally homeotic although homoeotic would be the etymologically correct spelling).

Homogametic Sex: (XX) produces only X-chromosome-containing gametes, in contrast to the heterogametic (XY) individual, which can have both X- and Y-chromosome-bearing gametes. The homogametic sex can be either female (XX) or male (ZZ).
▶ [chromosomal sex determination](#), ▶ [heterogametic](#)

Homogamy: Mating between similar types or self-fertilization in plants.
▶ [autogamy](#), ▶ [assortative mating](#), ▶ [heterogamy](#)

Homogeneity Test: The homogeneity test (see Table H2) can be used to determine whether different sets of data are statistically homogeneous enough to be considered a part of the same population, and whether the information is homogeneous enough to permit pooling. This test is basically a chi square procedure but the use of the Yates correction is not allowed. Without testing the homogeneity of separate sets of experiments, the information should not be pooled, even when the combined data fit well to a null

Table H2. Homogeneity test (using pea data of Mendel)

hypothesis. The use of this test is best explained by the tabulated example shown. ►chi square, ►null hypothesis, ►Yates correction

Homogeneously Stained Region (HSR): Due to amplification in cancer cells, extended chromosomal bands are detectable by light microscopy. ►double minutes

Homogenote: ►endogenote

Homogenotization: The production of homozygosity for knockout, either by targeting both chromosomes in the somatic cells, or culturing the heterozygous knockout cells under highly selective conditions favoring the knockout chromosome. ►knockout, ►targeting genes

Homogentisic Acid: ►alkaptonuria

Homograft: In a homograft, there is no known genetic difference between the transplanted and host tissues.

Homohistont: A non-chimeric tissue derived from a chimera. ►chimera

Homohybrid DNA: The annealed product of two methylated or unmethylated DNA sequences.

Homoio-genetic Induction: Homoio-genetic induction is passed on by cells that have been previously induced. (See Nieuwkoop PD 1999 Int J Dev Biol 43(7):615).

Homokaryon: ►dikaryon

Homolog: Homologs have similar primary and three-dimensional structures (3D) and functions. In homologous proteins, the 3D structure is commonly better preserved during evolution than the amino acid sequence. Thus, they have common motifs. Similarity does not necessarily mean homology. Homology indicates relationship by common evolutionary descent. ►orthologous loci, ►paralogous loci; Homologene database of homologous genes (over 165,491 groups by 2005) of sequenced eukaryotes: <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=homologene>).

Homologous Chromosomes: Homologous chromosomes contain the same cytological gene loci, and form bivalents in meiosis. The homology may not be perfect and the difference may be up to several hundred kilobases. The nonhomologous chromosomes may display substantial telomeric homology among several chromosomes. In molecular evolutionary terms, homology may exist among certain chromosomes or chromosomal regions or sites of different taxonomic groups if they carry similar nucleotide sequences. ►homoeologous chromosomes; Mefford HC et al 2001 Hum Mol Genet 10:2363.

HomoloGene: The homologene detects homologs of annotated genes among 18 sequenced eukaryotic organisms. ►homologous genes; <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=homologene>.

Homologous Genes: Homologous genes carry out basically the same function, and are descended from common ancestors, yet their primary structure may not be entirely the same. ►analogous genes; <http://www.ncbi.nlm.nih.gov/HomoloGene/>.

Homologous Incompatibility: In homologous incompatibility, the pathogen cannot cause disease because a particular, race-specific gene of the host conveys resistance to it.

Homologous Pathogen: A pathogen that is genetically qualified to cause disease in a particular host.

Homologous Proteins: Homologous proteins occur in different species and display similar structure and function such as the various globins, the majority of metabolic enzymes, etc.

Homologous Recombination: Genetic exchange between essentially identical chromosomes (polynucleotide chains). Homologous recombination can be used for gene disruption and studying the consequence of lack of function of a particular locus (see Fig. H61). For this, a plasmid is constructed that carries in between the flanking sequences of the target gene, other nucleotide sequences such as an antibiotic resistance gene. The flanks permit homologous pairing and recombination and may take place within the boundary of an interrupted DNA stretch (e.g., the target):

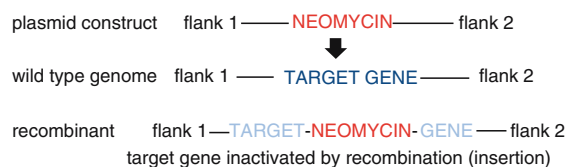

Figure H61. Homologous Recombination

Such a manipulation is useful in animal cell cultures and the resistance to the antibiotics can select the recombinant cells. Extremely rare double crossovers can thus be recovered. Cutting within the target by an appropriate restriction endonuclease can enhance homologous recombination by about 10 fold. The frequency of somatic homologous recombination in mammalian cells may vary within the range of 10^{-8} to 10^{-6} per cell per generation. One may note that this term “homologous recombination” has gained a new meaning because classical genetics recognized recombination as always homologous. In yeast, homologous recombination usually requires

a homology of at least 30 bp. Single-stranded DNA about 30-nucleotides-long may promote recombination by promoting annealing to complementary sequences. *Non-allelic homologous recombination* occurs between duplicated sequences and contributes to genetic variations by nucleotide loss and gain, common in human populations (Hinds DA et al 2006 Nature Genetics 38:82). ►illegitimate recombination, ►recombination, ►crossing over, ►targeting genes, ►Cre/loxP, ►FLP/FRT, ►excision vector, ►recombination molecular mechanisms eukaryotes, ►recombination molecular mechanisms prokaryotes, ►ectopic recombination, ►heterochromosomal recombination, ►deletion, ►I-SceI; Hiom K 2001 Curr Biol 11:R278; Sonoda E et al 2001 Proc Natl Acad Sci USA 98:8388; Bollag RJ et al 1989 Annu Rev Genet 23:199; Court DL et al 2002 Annu Rev Genet 36:361; recombination proteins in yeast: Krogh BO, Symington LS 2004 Annu Rev Genet 38:233; mechanisms: Sung P, Klein H 2006 Nature Rev Mol Cell Biol 7:739.

Homolog-Scanning Mutagenesis: Homolog-scanning mutagenesis is applicable to gene families coding for structurally related proteins. Homologous domains of the proteins (7 to 30 amino acids) are substituted for each other, and in the substituted domain amino acids are replaced by another amino acid, e.g., alanine. Then the binding of the substituted domains to the protein receptor (e.g., growth hormone, protein kinase) is analyzed. Such an analysis may reveal any change in receptor binding and function. A simpler procedure is the “charged-to-alanine scanning mutagenesis” in which blocks of amino acids (4 to 8) are replaced by alanine. ►site-specific mutation, ►oligonucleotide-directed mutagenesis, ►cysteine-scanning mutagenesis, ►Kunkel mutagenesis; Vik SB et al 1988 J Biol Chem 263:6599; Kunkel TA et al 1991 Methods Enzymol 204:125; Griffith KL, Wolf RE Jr 2002 J Mol Biol 322:237.

Homology: Similarity based on nucleotide sequences in the DNA and RNA or amino acid sequences in the protein. It also indicates evolutionary relationship. Information on homology of human and yeast genes can be obtained at <http://www.ncbi.nlm.nih.gov/>

XREFdb. The discovery of homology sometimes appears puzzling. *Saccharomyces* yeast contains a gene homologous to the *NifS* gene of nitrogen fixing *Azotobacter*, although yeast does not fix nitrogen.

Further studies revealed that this gene actually inserts sulfur into metal—sulfur centers of metal-loenzymes using pyridoxal phosphate as cofactor. The reliance on homology for understanding genetic functions is of great importance. Yeast, *Drosophila*, and *Arabidopsis* are relatively simple organisms and can genetically be manipulated by mutation, recombination, transformation, etc (see Table H3).

They can help shed light on the series of gene functions in a genomic context in other organisms, e.g., humans, in whom the application of these laboratory techniques (e.g., controlled mating) is limited or impossible. Evolutionists distinguish between *repetitive homology*, such as the multiplicity of legs in the millipedes, and *non-serial homology*, e.g., the leaves of a plant. Usually, a 25% or higher homology is considered as evidence for common evolutionary relationship. The evolution of homology of morphological traits such as legs of mammals and wings of birds or fins of fishes is not straightforward and it has been suggested that it is based not on particular genes, but rather on “character identity networks” (Wagner GP 2007 Nature Genet 8:473).

The amino acid sequence homology of cytochrome C protein is shown in 35 different organisms (see Fig. H62). The shaded areas indicate complete identity at the alignments. (Courtesy of Margaret Dayhoff, ed. Atlas of Protein Sequence and Structure, 5. Natl. Biomed. Res. Found. Georgetown Univ. Washington, DC). Alignment of nucleotide sequences provides more critical information because the amino acid sequences do not distinguish among synonymous codons. Among bacteria, the homologous genes, except members of operons, are not in identical orders. Apparently, replication may rearrange the gene positions in the various genomes. A conservative estimate of the sequenced human and mouse genomes revealed 3,920 orthologous gene pairs. ►analogy, ►DNA sequence alignment, ►indel, ►orthology, ►paralogy, ►xenology, ►congruence analysis, ►phylogenetic weighting, ►URF, ►illustration

|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|--|

Homology-Dependent Gene Silencing: ► [co-suppression](#), ► [RIP](#), ► [post-transcriptional gene silencing](#), ► [anti-sense technology](#); Cogoni C 2001 Annu Rev Microbiol 55:381.

Homomeric Protein: Protein built from identical subunits.

Homomultimeric Protein: Protein consisting of more than two identical subunits.

Homonomous: Similar in structure and function; the metameric body parts of insects have developed in a similar homonomous manner in different species. ► [metamerism](#), ► [homeogenes](#), ► [homeobox](#)

Homopeptide: Single amino acid repeats in proteins; they occur in 4.3% of the human proteins. (See database of 13 species: http://repeats.med.monash.edu.au/genetic_analysis/).

Homophila: A database that correlates human disease genes with their *Drosophila* homologues. About 74% of the human genes associated with disease have one or more strong matches with *Drosophila* sequences. (See <http://superfly.ucsd.edu/homophila/>; Chien S et al 2002 Nucleic Acids Res 30:149).

Homoplasmy: In homoplasmy within a cell, tissue, or organism, the organellar genomes (mitochondrial, plastid) do not show genetic differences. Despite the usually large number of organelles per cell and the high rate of mutation, homoplasmy is the most common situation. Low level of heteroplasmy is difficult to detect, however, if the number of organelles is large. In cancer cells, high degree of mutant mtDNA homoplasmy is common. Homoplasmy for mtDNA defects may cause lethality in the offspring of a clinically normal mother who is a carrier. ► [heteroplasmy](#), ► [sorting out](#), ► [heteroplastidy](#), ► [mtDNA](#), ► [mitochondrial diseases in humans](#); Collier HA et al 2001 Nature Genet 28:147; McFarland R et al 2002 Nature Genet 30:145.

Homoplastidic: A cell is homoplastidic if all the plastids/chloroplasts are identical within that cell. ► [heteroplastidy](#), ► [chloroplast genetics](#)

Homoplasy: Parallel evolution (similarity is not based of common ancestry). In other words, two alleles or genes are identical or near-identical in state and/or in function, but they do not share common ancestry. ► [convergent evolution](#), ► [microinversions](#); Collard M, Wood B 2001 J Hum Evol 41(3):167.

Homoploid Speciation: Hybrid speciation without a change in chromosome number.

Homopolymer: A synthetic polynucleotide chain built from only one type of nucleotides, e.g., AAAA or CCCC, etc.

Homopolymeric Amino Acids: Homopolymeric amino acids may occur in proteins due to increased numbers of trinucleotide repeats. The best known among them are the polyglutamine stretches that lead to a variety of diseases. Although rare, polyleucine and polyalanine sequences are even more toxic. ► [trinucleotide repeats](#); Dorsman JC et al 2002 Hum Mol Genet 11:1487.

Homopolysaccharides: Polysaccharides built of one type of sugar subunits.

Homoproline: ► [pipecolic acid](#)

Homoscedasticity: Homogeneity (equality) of the variances in a group of samples.

Homoselection: In small populations, selection may favor homozygotes and this increases the specialization to the unique environmental niche. ► [heteroselection](#), ► [selection](#)

Homoserine: (2-amino-4-hydroxybutyric acid): An analog, antimetabolite of threonine (see Fig. [H63](#)). ► [threonine](#), ► [serine](#)

Figure H63. L-Homoserine

Homoserine Lactone: An autoinducer (see Fig. [H64](#)). At the NH site, different molecular groups may join to assure specificity for signaling. ► [autoinduction](#)

Figure H64. Homoserine lactone

Homosexual: An individual who is attracted to the same sex identifies himself/herself as homosexual, develops sexual fantasies about the same sex, and practices homosexuality. Various studies estimate the prevalence of homosexuality from 2 to 10% in human populations. Homosexual orientation occurs in other mammals also, especially under conditions when the opposite sex is not available.

In some primitive human societies, magical powers are attributed to homosexuals, however, in the majority of societies and religions, homosexuality is disapproved. The ancient Greeks accepted it as an abnormal condition. Base reliefs in the tombs from the Fifth Dynasty of Old Kingdom Egypt discovered in the 1960s depict men in intimate poses expected only in conjugal relations (Reeder G 2000 World of Archeol. 32:193).

Most homosexuals may begin same-sex orientation between age 5 to 30, most commonly by puberty. The bases of homosexuality are not entirely clear.

Homosexuality has been attributed to hormonal, psychological, anthropological, genetic, and moral causes, or to a combination of part or all of these factors. The exact scientific study of homosexuality is difficult because generally a multitude of factors influence the development of all behavioral traits and homosexuality may also have different categories from obligate homosexuality to bisexuality and primarily heterosexuality. Recent anatomical studies attributed brain differences concomitant with homosexual orientation. Many great artists, including the Russian composer Pyotr Tchaikovsky, the painter Leonardo de Vinci, and the famous writer Oscar Wilde and others were homosexuals.

Twin studies suggested higher concordance of this type of sexual orientation between monozygotic twins than between dizygotic ones. One study concluded (on the basis of 4600 individuals) that female relatives of homosexual males have higher fecundity than female maternal relatives of heterosexuals. This information explains why homosexuality does not disappear from the populations (Camperio-Ciani A et al 2004 Proc Roy Soc Lond B Biol Sci 271:2217). The observation that male homosexuals have more homosexual males than lesbian females in their kindred may indicate either that the genetic bases of female homosexuality may not be identical to that of males or may also point to some environmental causes. One study involving 114 families of homosexual index cases found an increase of same-sex orientation among maternal uncles and cousins in comparison to paternal relatives, suggesting the possibility of sex-linked transmission of the gene(s) concerned. Empirical correlation indicates an increased tendency toward homosexuality in younger brothers who were preceded by gestation of their shared mothers. This observation indicates that homosexual tendency in males (but not in females) is affected by prenatal condition(s) rather than postnatal environmental influences (Bogaert AF 2006 Proc Natl Acad Sci USA 103:10771). It has been hypothesized that male histocompatibility antigen (H-Y) of older brothers sensitizes their mother and that increases homosexuality of younger brothers (Blanchard R, Klassen P 1997 J Theor Biol 185:373). This theory does not have, so far, experimental proof.

In 40 families where at least two homosexual males occurred, in approximately 64% of the sib-pairs tested, an apparent linkage was observed to the DNA marker Xq28 with a multipoint lod score of 4, indicating a higher than 99% probability for syntenicity. Another study (Rice G et al 1999 Science 284:665)

failed to confirm linkage to Xq28 by studying 52 gay male siblings. The heritability of male homosexuality was reported to be 0.50, but the inheritance of female homosexuality seems more complex. Researchers debate some of this human information. There is some indication that high fetal androgen levels may favor the development of both male and female adult homosexuality. In *Drosophila*, the *satori* (*sat*) mutants of males do not court or copulate with females but have sexual interest in males. The locus co-maps and is allelic with *fru* at 91B chromosomal band. The *fru^{sat}* flies lack the male-specific Lawrence muscle (MOL). The *fru^{sat}* protein, expressed in some brain cells, is probably a transcription factor with two Zinc-finger domains. The female flies produce two double bonds (dienes) with 27 and 29 carbons and these excite males. The male flies make monoenes (one double bond) of 23 and 25 carbons of the pheromones. The transformer gene (*tra*) regulates these two pheromones. When the *tra* gene is ubiquitously expressed, a mixture of the two pheromones is produced in the males and elicits homosexual courtship by normal males.

Heterosexual men and heterosexual females responded differently to putative pheromones, a testosterone derivative and an estrogen-like odor, respectively. Homosexual men's response resembled that of heterosexual women, rather than that of heterosexual men. Maximum activation in all three groups was observed in the medial preoptic area/anterior hypothalamus. These areas of the brain are involved in sexual behavior of animals (Savic I et al 2005 Proc Natl Acad Sci USA 102:7356). The social status of human homosexuals is an ethical, rather than a biological problem, yet the ethical solution may be facilitated by better biological information. ▶lod score, ▶sibling, ▶twinning, ▶kindred, ▶ethics, ▶behavioral genetics, ▶sex determination, ▶behavior genetics, ▶pheromones, ▶sex reversal; Hammer DH et al 1993 Science 261:321; Hu S et al 1995 Nature Genet 11:248; Yamamoto D, Nakano Y 1999 Cell Mol Life Sci 56(7–8):634.

Homosexual Cross: The mitochondrial genome of yeast appears to have sex-factor-like elements ω^+ and ω^- and the crosses between $\omega^+ \times \omega^-$ are called heterosexual, while the crosses $\omega^+ \times \omega^+$ or $\omega^- \times \omega^-$ are homosexual crosses. ▶mtDNA, ▶mitochondrial genetics

Homothallism: The same individual (thallus) of lower eukaryotes produces both *plus* and *minus* or A and a mating type spores that can fuse into a zygospore. The homothallism bears similarity both to monoecy and autogamy in higher plants. These spores are not necessarily immediate meiotic products. ▶monoecious, ▶dioecious, ▶zygospore, ▶heterothallism, ▶pseudohomothallism

Homotopic Transplantation: Homotopic translation transfers cells or tissue(s) to an identical site but in a different individual.

Homotropic Enzymes: Allosteric enzymes acting on the same substrate and usually regulated by their substrate. ►allostery

Homozygosity in a Randomly Selected Individual: At a locus for an allele, under equilibrium conditions between mutation and genetic drift, homozygosity is approximately $F = \frac{1}{1+4N\mu}$, where N = population size, μ = mutation rate. Homozygosity estimator in a population is obtained by $\frac{2(H_w - H_b)}{1 + H_w - 2H_b}$, where H_w = proportion of homozygosity within an individual and H_b = proportion of homozygosity between individuals. In outbreeding populations of dioecious species, homozygosity for the majority of loci is expected to be low. A study of short tandem repeats in human families in CEPH revealed that on the average more than 10 cM homozygous tracts occur. The longest 77-cM segment included 118 homozygous markers. Apparently, there is a substantial degree of autozygosity or relatedness in these populations. The linkage disequilibrium can be preserved only in the absence of recombination and low mutation rate. Actually, the long homozygous segments also indicate that these families are of relatively recent origin and mutation and selection did not have a chance yet to break up the linkage. ►genetic equilibrium, ►genetic drift, ►autozygosity, ►linkage disequilibrium, ►CEPH; Broman KW, Weber JL 1999 Am J Hum Genet 65:1493.

Homozygosity Mapping: Homozygosity mapping locates autosomal recessive genes in consanguineous families by identity of descent in the pooled records. The information may be collected by determining the restriction fragment length polymorphism (RFLP, Lander ES, Botstein D 1987 Science 236:1567) or on the basis of genome sequence data (Leutenegger A-L et al 2003 Am J Hum Genet 73:516). ►IBD, ►consanguinity, ►mapping, ►autozygosity mapping, ►human genome, ►RFLP; <http://www.broad.mit.edu/ftp/distribution/software/>.

Homozygous: In a homozygous organism, diploid or polyploid, the alleles at a locus are identical, e.g., *aa* or *aaaa* or *AA* or *AAAA*. In a new mutant line, the mutation is generally heterozygous but homozygosity may be obtained if selectable marker(s) are available by screening for rare somatic non-junction.

Honeybee: *Apis mellifera* 2n = female 32, male n = 16, diploid workers and 2n female (queen) and haploid males (drones, 1n) (see Fig. H65). Bees do not have sex chromosomes and sex determination is by

haplodiploidy. The genome of >10,000 genes has been sequenced in 2006 (Nature [Lond] 443:931). The A + T content and the CpG sequences are relatively high. Major transposon families are absent. The difference between workers and queen is developmental, due to difference in nutrition. A complex of pheromones secreted by the mandibular glands and the tergite glands of the queen are required for the many functions to assure the biological order within the colony (Keeling CI et al 2003 Proc Natl Acad Sci USA 100:4486). Homovanillyl alcohol (a dopamine-like compound) (see Fig. H66) is the key component of the queen mandibular pheromone that affects changes in the brain, resulting in specific behavior (Beggs KT et al 2007 Proc Natl Acad Sci USA 104:2460).

Figure H65. Honey bee

Figure H66. Dopamine (left), homovanillyl alcohol (right)

The workers are generally highly heterozygous because the queen mates with many drones and this conveys an advantage to the colony. The ovaries of the Asian honeybee (*A. florea*) workers are activated after the queen dies and lay eggs from which only drones hatch leading to demise of the colony. These egg-laying workers develop primarily by workers non-natal (nonindigenous) for the colony that are intruders, parasitizing queenless nests and eggs (Nanork P et al 2005 Nature [Lond] 437:829).

Honeybees have rich, map-like organization of spatial memory and that helps them to return to feeder areas (Menzel R et al 2005 Proc Natl Acad Sci USA 102:3040). Communication of the bees is a waggle dance of considerable efficiency for the new recruits that can find the feeder area direction, although in the final stages they depend on odor and visual signs of the target (Riley JR et al 2005 Nature [Lond] 435:2005). The brain of a honeybee is ~1 mm³ and contains 950,000 neurons. ►social insects,

Hoogsteen Pairing: Hoogsteen pairing refers to nucleotide pairs, by an association different from that proposed by Watson and Crick. The A—T pairs have an 80° angle between the glycosylic bonds and a 8.6 Å distance between anomeric carbons (differing in configuration about C). In the *reversed Hoogsteen* pairs, one base is rotated 180° relative to the other. Hoogsteen pairing takes place between nucleotides of a third strand of DNA in the major groove of the duplex. This happens when in the duplex one strand is polypurine and the other is polypyrimidine; the third strand is most commonly polypyrimidine in the triplex DNA. ►Y-family DNA polymerases, ►DNA polymerase, ►Watson and Crick model, ►triple helix formation; see Fig. H67; Soliva R et al 1999 Nucleic Acids Res 27:2248; Aishima J et al 2002 Nucleic Acids Res 30:5244.

Figure H67. DNA triple helix and Hoogsteen base pairing

Hookworm (*Ancylostoma*): A parasitic nematode posing substantial health hazard to humans and animals. ►AcAP

HOP (*Humulus lupulus*): A climbing dioecious plant (see Fig. H68) with $2n = 20$ chromosomes although forms (*H. japonicus*) with $2n = 16$ females and $2n = 17$ males have also been reported. Its main use is for brewing beer but it may be mixed in bread in some areas of the world. The soft resins and essential oils of the flowers add a typical bitter flavor to the brew and have some preservative effect. It is related to hemp (*Moraceae*). Some extracts have pharmaceutical value.

Figure H68. Hop plant leaf, flower and fruit

Hopeful Monster: Neo-Darwinism assumes that evolutionary changes take place by accumulation of minor mutations that favor fitness of an organism. An alternative suggestion raised the possibility that some major mutations conveyed distinctive alterations to an individual, transcending conventional taxonomic boundaries, and such an individual was called a hopeful monster. ►saltation, ►saltatory replication, ►gradualism; Richards E 1994 Isis 85(3):377.

Hopping: Movement from one location to another by a transposable or insertion element. Hopping also occurs in translation when the peptidyl-tRNA passes further downstream to a similar or same codon. ►transposable elements, ►insertion elements, ►re-coding, ►translational hopping

Hopsigen: Processed pseudogene database. ►pseudo-gene, ►processed pseudogene; <http://pbil.univ-lyon1.fr>; <http://pseudogene.org/human/index.php>; pseudogenes shared by human and mouse: http://pbil.univlyon1.fr/databases/hopsigen_orthologs.html.

Hordeum bulbosum: A wild barley; it exists in diploid and tetraploid forms ($x = 7$). It gained particular attention because when crossed with the common barley (*Hordeum vulgare*, $2n = 14$) or with wheat ($2n = 42$), its chromosomes are eliminated from the zygote and thus haploids are produced at a high frequency. ►haploids, ►chromosome elimination

Hordeum vulgare: Cultivated barley ($2n = 14$). It is used for animal feed, human food, and for the industrial production of malt and beer. The global production of barley is about half of that of maize and about 40% of that of wheat. It evolved probably from the wild *H. spontaneum* ($2n = 14$), a species with which it is readily crossable and forms fertile hybrids. *H. spontaneum* has 2 dominant genes (*Bt* and *Bt₁*) that make the ear brittle. The two-rowed barley develops fertile flowers in the central part of the spikelets, whereas in the six-row barley all three flowers are female-fertile under the control of gene *v*. In the naked barley, the glumes (husks) are not attached to the kernel because of a gene. It is an autogamous species. ▶databases, ▶crop plants, ▶barley

H

hORF: An open reading frame, which has a function identified only by homology. ▶ORF

Horizontal Gaze Palsy, Familial (with progressive scoliosis, 11q23-q25): Rare recessive anomaly of the movement of the external eye muscles (myokymia) associated with abnormal deviation from straightness of the spine, caused by mutation in axon guidance in the brain. ▶ophthalmoplegia, ▶scoliosis; Jen J et al 2002 Neurology 59:432; Jen JC et al 2004 Science 304:1509.

Horizontal Transmission (HGT, horizontal gene transfer): ▶transmission, ▶transfer lateral

Horizontal Resistance: In horizontal resistance, the host is resistant to all races of a pathogen.

Hormesis: Increased growth by irradiation at low doses or by other stress factors. It is a controversial idea that very low doses of radiation make human cells more resistant to subsequent exposure to higher doses. Hormetic U-shape response is characteristic also against some toxic agents. Recent analysis indicates, however, no-threshold (NLT) for potential radiation damage. ▶radiation; Macklis RM, Beresford B 1991 J Nucl Med 32:350; Holzman D 1995 J Nucl Med 36:13n, Calabrese EJ 2002 Rev Mut Res 511:181.

Hormonal Effects on Sex Expression: Although sex-determination is under the control of genes within the sex-chromosomes, the expression of sex characteristics may be influenced by natural hormones or those administered through medical treatment. Human females treated by steroid hormones to prevent miscarriage may give birth to females who may become somewhat masculinized after puberty.

The bovine freemartins also display some virile features, presumably caused by intrauterine exposure to male sex hormones. Genetically determined subnormal production of the pituitary growth hormone

(human gene assigned to chromosome 17q23-q24) may involve recessive sexual anomalies. Castration and ovariectomy lead to intersex phenotype that can be further enhanced by grafting ovaries into male or testes into female chickens (see Fig. H69). The plant hormone gibberellin may affect sex ratio in some species, and can restore fertility in some genetic dwarf plants. ▶hormones, ▶testicular feminization, ▶animal hormones, ▶growth hormones, ▶freemartins, ▶plant hormones, ▶sex determination, ▶gonads

Hormone Receptors: Hormone receptors are located on the surface or within target cells and transmit their signals to the genes that are set into action when the signals reach them. In *Caenorhabditis elegans*, hormone receptors represent about 1.5% of the coding sequences of the entire genome.

The general structure of the Zn-fingers of the steroid and thyroid (peptide) hormone receptors are shown (see Fig. H70). Steroid hormones are not readily soluble in aqueous media like blood and require special carrier serum proteins to be carried to the plasma membrane. The glucocorticoid receptor is usually situated in the cytoplasm and moves to the nucleus after binding with a ligand. The estrogen and progesterone receptors are mainly in the nucleus and the thyroid receptors are present only in the nucleus. The hormones combine with hormone receptor proteins. These complexes then may bind also to other complexes of hormones and navigate to the hormone response elements (HRE) in the upstream regulatory regions of the genes. The HREs are found in either the promoter or in the enhancer regions where they regulate the transcription of particular genes. These HRE elements vary from hormone to hormone specificities but all have a consensus sequence of dyad symmetry, sometimes palindromic and frequently separated by 3 or more non-conserved bases. The most important functional parts of the hormone receptors are the 66 to 68 conserved and basic amino acid rich tracts that bind to the DNA. The binding may require that a ligand be associated with the receptor or the removal of the ligand-binding domain. The DNA binding region of the hormone receptor forms two Zinc fingers by cross-linked to Zn. The two fingers are coded for by two separate

H

Figure H70. Zinc fingers of the estrogen receptor DNA-binding protein. The most conserved residues are shown in bold. Nuclear localization is specified by the carboxy terminus. The amino acid symbols in protein sequences are given by the single-letter code. Three different hormone response consensus sequences are shown at the lower part of the diagram. The hormone response element is generally about 200 bases upstream from the transcription initiation site

exons, and the entire DNA-binding region is separated by introns from other coding regions of the receptor gene. The structure shown represents the estrogen receptor but it is characteristic for many transcription factors. Thus the hormone receptors are hormone-inducible transcription factors. For the DNA binding, the 3 amino acids following the last Cys residue of the right finger appears most important. The palindrome-like structure of the HRE in the DNA indicates that the hormone receptor protein works as a dimer. The function of the receptor as a transcription factor requires hormone binding. Primarily, the residues near the C terminus determine the hormone binding. This hormone-binding region is critical for specificity. If a chimeric protein is constructed that replaces this binding region with the amino acid sequences of another hormone receptor, then the chimeric protein activates transcription of genes normally receptive to the first segments of the chimera in response to the latter hormone, but not to the hormone that normally activates these genes. The receptor protein does not bind to the HRE unless it is linked to the hormone. Yet, if the hormone-binding domain is deleted, the receptor can bind to the cognate HRE. When the

human estrogen response element (HRE) is transfected into yeast along with a functional estrogen receptor gene, estrogen can promote the expression of yeast genes even if their normal UAP (upstream activating sequence) has been deleted. In some instances, all the components of transcriptional activation by hormones are present, yet no activation is observed because an inhibitor may tie up the system and may prevent, e.g., dimerization of the receptor. These basic molecular genetic studies have found medical applicability. The proliferation of breast cancer depends on a continuous supply of estrogen. The drug tamoxifen can compete for the estrogen-binding site but this complex is not capable of activating transcription. Thus, it may be used as an antineoplastic drug in combination with surgery, irradiation, and chemotherapy if clinical evidence indicates that the tumor has estrogen and progesterone receptors. The steroid analog, RU486, developed in France, is a progesterone analog (antiprogesterone) and can block the implantation of the fertilized ova because of the depletion of normally functional receptors. It is also beneficial for the treatment of endometriosis and leiomyoma. Thus, it is used—in countries where it is approved—as an “after morning

pill” for prevention of pregnancy. The most commonly used birth control pills contain a combination of estrogen and progesterone and their elevated level shuts down the production of the pituitary hormones, thus preventing ovulation. The levonorgestrel pill (Plan B) contains only progestin and interferes with ovulation. It is 80–90% effective if taken within 3 days or less after unprotected sex. None of these drugs protect against sexually transmitted disease. ▶[hormones](#), ▶[transcription factors](#), ▶[signal transduction](#), ▶[breast cancer](#), ▶[testicular feminization](#), ▶[hormone-response elements](#), ▶[hormones](#), ▶[tamoxifen](#), ▶[DNA-binding protein domains](#), ▶[nuclear receptors](#), ▶[RU486](#), ▶[endometriosis](#), ▶[leiomyoma](#); Zhu T et al 2001 Cell Signal 13:599; Chang C, Stadler R 2001 Bioessays 23:619; Robinson-Rechavi M et al 2001 Trends Genet 17:554; pharmacist refusal to dispense contraceptives: Greenberger MD, Vogelstein R 2005 Science 308:1557.

Hormone-Response Elements (HRE): Short DNA sequences flanking genes that respond rapidly to activation by steroid or peptide hormones. Steroid hormones, retinoic acid, thyroid hormone, and vitamin D₃ interact with ligand activated transcription factors (see Fig. H71). The receptors for this steroid/nuclear receptor superfamily are bound to the interspaces of the “half-sites” (n) between the tandem repeats of six base pairs:

These six nucleotide pairs are unchanged but the number of bases (n) between the boxes varies. These are recognized by heterodimers of receptor proteins. The binding domains may include Zn fingers. ▶[glucocorticoid response elements](#), ▶[estrogen response elements](#), ▶[thyroid hormone response elements](#), ▶[RAR](#), ▶[RAX](#), ▶[Zn fingers](#), ▶[regulation of gene activity](#), ▶[ethylene](#), ▶[retinoic acid](#), ▶[nuclear receptors](#); Klinge CM 2001 Nucleic Acids Res 29:2905.

Hormones: Peptides (polypeptides), amino acid-derivatives, and steroids synthesized in a gland of animals and carried by the blood to the site of their action(s) where they control the local function (first messengers). They are not nutrients. Animal hormones are, e.g., somatotropin (growth hormone), corticotropin (in adipose and kidney tissues), thyrotropin (stimulates thyroids), follitropin and lutropin

(in gonads), prolactin and lipotropin (in mammary glands), insulin (regulates sugar metabolism), serotonin (in nervous system), testosterone, estrogen (in most cells), progesterone (in uterus), prostaglandins (in smooth muscles), etc. Plants synthesize five different groups of hormones that are quite different (except the brassinosteroids) in chemical nature from animal hormones. These control primarily cell elongation (auxins), cell divisions (cytokinins), elongation, germination (gibberellins), abscission of leaves and fruits, dormancy, germination (abscisic acid), elongation, ripening, and morphogenesis (ethylene). These plant hormones display numerous types of interactions and are involved in complex manners in signal transduction. ▶[steroid hormones](#), ▶[animal hormones](#), ▶[hormone receptors](#), ▶[hormone-response elements](#), ▶[plant hormones](#), ▶[brassinosteroids](#)

Horse Threadworm: ► *Ascaris*

Horseradish (*Armoracia rusticana*): A perennial pungent condiment; $2n = 4x = 32$. The pungent substance is allyl isothiocyanate (AIT) and may cause pain, inflammation, and extreme sensitivity to heat. The same substance is present in other cruciferous plants that contain mustard oil. AIT depolarizes a subset of the primary sensory neurons and activates ANKTM1, a member of the transient receptor potential ion channel. Capsaicin and Δ^9 -tetrahydrocannabinol (in marijuana) function through the same path. ► [capsaicin](#), ► [cannabinoids](#), ► [ion channels](#); Jordt S-E et al 2004 Nature [Lond] 427:260.

Horsetail Movement: During meiotic prophase of yeast, the nucleus—under the direction of the spindle pole body and with the aid of the microtubules—slowly oscillates in a manner reminiscent of how the horse moves its tail. The telomeres are then clustered and the chromosomes are paired. (Hiraoka Y 1998 Genes Cells 3:405).

Horsetail Stage: In fission yeast (but not in budding yeast), meiosis before intimate pairing the 3 chromosomes aggregate to the spindle pole body (SPB) by their telomeres and are moved back and forth until the homologous regions find each other along the string. This stage bears similarity to the bouquet stage in the majority of eukaryotes. ► [spindle pole body](#), ► [bouquet](#)

Host-Mediated Assay: The host-mediated assay tests whether the host metabolism can convert a compound (a pro-mutagen) into a mutagen, detectable by the cells passed through the host, e.g., yeast, bacterial, or animals cells injected into and then withdrawn from the abdominal cavity of a mouse previously exposed to a potential mutagen. Forward or back-mutation frequency in the cells is assessed after withdrawal from the abdominal cavity of the test animal and then plating the cells onto selective solid media or growing them in liquid media. Such a rapid assay was designed for substituting it to the slow and expensive direct mammalian assays of promutagen. (See Fig. H73); ► [Big Blue](#), ► [Muta Mouse](#), ► [bioassays in genetic toxicology](#)).

Host-Pathogen Relations: Host-pathogen relations are based on susceptibility or tolerance/resistance genes in the host and virulence and avirulence genes in the

Microbial or cultured animal cells are injected intraperitoneally into a mammalian host for proliferation.

After a period of 1 to 3 days a test chemical dissolved in saline or in saline plus a solubilizer is injected subcutaneously once or more into the mouse or rat. The control animals are treated with the solvent solution only. This mutagenic exposure lasts for a few hours or a few days.

A sample of the injected cell population is withdrawn from the abdominal cavity into centrifuge tubes in preparation for assaying the mutagenic effectiveness of the test chemical in comparison with the control.

The recovered cells are plated on Petri dishes or incorporated into soft agar culture tubes to screen the mutants produced withing the host as a consequence of the treatment.

Figure H73. Host-mediated mutagen test (Modified after Fischer GA et al. 1974 Mutation Res. 26:501)

pathogen, respectively. The development of the disease depends on the appropriate genetic determination and expression of genes in the two organisms. In order to display resistance, plants usually carry *R* (dominant gene[s] for resistance) and the microorganism has *avr* (virulence) gene[s]. The several plant disease resistance genes (*R*) interact with RAR1 and the SGT1 complex of SKP1, Cul1 subunits of SCF (Skp1 – Cullin – F box) and have ubiquitin ligase function (Azevedo C et al (2002 Science 295:2073). In *Arabidopsis*, SGT1b has two genetically separable functions in the plant immune system. SGT1b antagonizes RAR1 and negatively regulates R protein accumulation before infection. SGT1b also regulates independently of RAR-1 function apoptosis of cells during infection. The balance between RAR1 and SGT1, also in concert with the chaperone HSP90 (heatshock protein), modulate R protein accumulation and signaling competence (Holt III BF et al 2005 Science 309:929).

Other allelic combinations lead to disease susceptibility. In plant breeding, successful efforts were made to transfer disease resistance genes from wild relatives to the cultivated varieties (e.g., the *Ry* dominant genes of the wild potato, *Solanum stoloniferum*, conveys resistance against the potato Y virus (PVY) or leaf rust (*Puccinia triticina*) from *Aegilops umbellulata* (new name *Triticum umbellulatum*) to the cultivated bread wheat, etc. The leaf-rust-resistance locus (Lr10) of hexaploid wheat has been isolated by map-based cloning (Feuillet C et al 2003 Proc Natl Acad Sci USA 100:15253). A mildew (*Blumeria graminis*) resistant variation in barley (mlo-11) involves a truncated gene regulatory sequence plus a coding sequence of the normal locus. Apparently interference with normal transcription of *Mlo* results in resistance (Piffanelli P et al 2004 Nature [Lond] 430:887).

The classical methods of breeding for resistance have had to overcome problems of linkage of the resistance to agronomically undesirable genes present in some primitive species. Some viral plant pathogens have lines with extra genomic *satellite RNA* and the presence of the latter may suppress the expression of the full-scale disease (*attenuation*). The disease symptoms may be prevented in some cases also by the simultaneous presence of another related plant virus (*cross protection*). It has been shown that 25-nucleotide viral RNA may target a 25-kDa protein involved in viral movement and may generate a posttranscriptional silencing signal and protection against other viruses. This phenomenon, also called *preimmunity*, can be exploited by transferring through transformation into the plant species a coat protein gene of some of the RNA viruses. Another molecular

plant breeding approach is to introduce into the plants antisense mRNA of the viral protein that would prevent the synthesis of viral proteins within the plants. The latter method may be coupled with a ribozyme expression system that would degrade the viral RNA. Plant resistance or tolerance to viral infection may be based also on transcriptional or posttranscriptional silencing bearing similarities to co-suppression by transgenes. In some plants, the silencing may take place also without the presence of transgenes. A transgenic oligopeptide fused to a carrier may interfere with the viral capsid and thus confers resistance to several viruses (Rudolph C et al 2003 Proc Natl Acad Sci USA 100:4429).

Various genetic mechanisms are known to be involved in resistance against bacterial and fungal pathogens. The *hypersensitivity reaction* of the plant tissues restricts infection by death of the surrounding host cells resulting, in addition, in the liberation of antimicrobial cellular substances. A collection of chemically diverse substances, called phytoalexins, regulate the synthesis of plant cellular compounds that are involved in the defense mechanisms or are the consequences of the infection process. Various genes involved in the synthesis of phenol-derivatives may be regulatory targets. The activation or enhancement of the transcription of genes determining cell wall components (polysaccharides, lignin, suberin, saponin, etc.) may provide a barrier to infection. Cinnamoyl-CoA-reductase is an effector of small GTPases in plants and mediates lignin production in response to NADPH oxidase generated hydrogen peroxide and lignin production (Kawasaki T et al 2006 Proc Natl Acad Sci USA 103:230). The activation of plant enzymes (*pathogenesis-related proteins*) such as various glucanases, chitinases, and proteases may lead to continued breakdown of the cell walls of the pathogens, and thus facilitates the escape of potential hosts from microbial infection. Upon infection, the plants may produce reactive oxidative species (ROS), which may damage or destroy the infectious agents. Plants ectopically expressing ferritin may become tolerant to oxidative damage and pathogens (Deák M et al 1999 Nature Biotechnol 17:192). Plants do not have an immune reaction—like that mediated by antibodies of animals—to invading agents yet some type of systemic resistance may be induced by exposure to necrosis-causing microorganisms, with certain chemicals such as nicotinic acid-derivatives, etc. Some microorganisms secrete or contain in their cell walls organic molecules (proteins, glucans, glucosamines, fatty acid-derivatives, etc.) that provoke the defense mechanisms of plants or the plants themselves may produce such molecules upon contact with the pathogens. These compounds are

called *elicitors*. Elicitors come in much different chemical compositions and display substantial specificity for different hosts and pathogens. Many of these substances seem to reach the plant cell nucleus through the various ion channels or the signals are transduced through the membrane systems to activate the appropriate plant cells and functions. Recently several plant genes have been cloned that are involved in the disease-resistance-tolerance mechanisms (*RPS1*, *RPS2*, *Pto*, [*Pseudomonas syringae*], *Cf-9* [*Cladosporium fulvum*], *L⁶* [*Melampsora lini*], *N* [tobacco mosaic virus], *Hm1* [*Cochliobolus carbonum*], etc. It is believed that these genes act by activating the plant defense system through responding to the elicitors of the avirulent pathogens or by producing enzymes that degrade the fungal toxin. *P. syringae* avirulence protein AvrPtoB, when secreted into plant cells, inhibits apoptosis in the plant tissue. This protein has ubiquitin ligase activity whereby it inactivates host defenses (Janjusevic R et al 2006 Science 311:222).

Plants may contain intracellular or plasma membrane-associated proteins RPS2 that behave like an immune receptor to the bacterial pathogen's effector protein (AvrRpt2 in *Pseudomonas syringae*). AvrRpt2, when delivered to the plant cell, is cleaved near the amino terminus and its carboxyl terminus (a putative cysteine protease) then incites the cognate RPS2-dependent defense. The 21 kDa bacterial AvrRpt2 protease causes the disruption of the plant RPS2-RIN4 complex, and RIN4 is eliminated as long as three of this carboxyterminal fragment do not contain mutations at three critical amino acid sites. RIN4 (resistance-interacting negative protein) possess two sequences similar to AvrRpt2. The cleavage of AvrRpt2 requires another plant cofactor, cyclophilin, a single-domain peptidyl-prolyl cis-trans isomerase (Coaker G et al 2005 Science 308:548). Similar mechanisms exist in *Arabidopsis*, tomato, and yeast (Schulze-Lefert P, Bieri S 2005 Science 308:506).

In some instances, inorganic antimicrobial compounds accumulate. *Arabidopsis* roots exude numerous antimicrobials (butanoic acid, *trans*-cinnamic acid, coumaric acids, indolepropanoic acids, ferulic acid, vanilic acid, methyl-*p*-hydroxybenzoate, *p*-hydroxybenzamide, syringic acid) in response to various strains of *Pseudomonas syringae* and the bacterial strains may or may not cause damage to the roots according to their specificities (Bais HP et al 2005 Nature [Lond] 434:217). Green plants emit C6-aldehydes, C6-alcohols, and their acetates, and these so-called green leaf volatiles (GLVs) are biosynthesized via the lipoxygenase/hydroperoxide lyase (HPL) pathway. *Arabidopsis* plants, whose GLV biosynthesis had been modified by the larvae of

the cabbage white butterfly, *Pieris rapae*, and a fungal pathogen, the gray mold *Botrytis cinerea*, develop a defense system. *Cotesia glomerata*, a parasitic wasp that attacks *P. rapae* larvae, was attracted to at least two GLVs, (*E*)-2-hexenal and (*Z*)-3-hexenyl acetate, which were emitted by *Arabidopsis* in response to herbivore damage. Also, GLVs induced several defense genes in *Arabidopsis*, resulting in higher resistance to *B. cinerea* (Shiojiri K et al 2006 Proc Natl Acad Sci USA 103:16672).

In *Theobroma cacao*, cyclooctasulfur accumulation in the xylem walls was observed in *Verticillium dahliae* resistant plants. Salicylic acid is generally considered as an agent for improving plant resistance probably through its stimulating action of hydrogen peroxide release from the cells. *S*-nitrosoglutathione reductase generates nitrosothiol that enhances plant salicylic acid production (Feechan A et al 2005 Proc Natl Acad Sci USA 102:8054). Plant mutants with reduced ability to synthesize salicylic acid or phytoalexins become more susceptible to pathogens. These latter compounds are credited for systemic acquired resistance (SAR). The *Xa21* (*Xanthomonas oryzae*) gene of rice conveys resistance to this plant pathogen. DNA sequence analyses indicate a leucine-rich repeat, characteristic for serine/threonine kinases. It has been suggested that this protein is a signal transducer to alert the plant cell defense system. In some pathogenic bacteria (*Pseudomonas*) the same virulence factors mediate pathogenicity in plants (*Arabidopsis*) and in animals (mouse). It is assumed that a signal transduction path in general mediates plant disease resistance. A pathogen-generated ligand, produced by an avirulence gene, is recognized by an extra- or intracellular receptor, encoded by a plant receptor gene and the recognition sets into motion the process of defense. Different plant species and different resistance reactions indicate the involvement of a leucine-rich repeat (LRR) and leucine zipper binding sites shared by many resistance genes. The majority of isolated disease resistance genes display a nucleotide-binding domain, a common feature of many ATP- and GTP-activated protein families involved in signal transduction. The nucleotide-binding leucine-rich repeat (NB-LRR) resistance genes (R) and pseudogenes are present in multiple (about 150) copies in *Arabidopsis*. They are present in all five chromosomes as singletons or multiple clusters. The R genes may recognize more than a single type of avirulence factors and protect against different types of pathogens, e.g., fungi and viruses or virus and nematode. Great diversity may exist among the different R genes; some have lost the LRR sequences, yet they may be involved in some types of signal transduction.

Plant disease resistance genes may be classified into five structural groups and some of their domains reveal homologies to innate immunity genes of animals (e.g., the Toll-like receptors [TLR]). The criteria for classification of resistance genes involve their location or location of some of their domains, e.g., cytoplasmic or transmembrane or membrane association or the combinations of these features. Salicylic acid, jasmonic acid, and ethylene and similar plant compounds monitor and regulate responses to pathogens. The pathogen surveillance proteins of plants respond to invaders by PAMP-triggered immunity (PTI). [PAMP stands for pathogen-associated molecular patterns]. PAMPs include bacterial lipopolysaccharides and flagellin mediating bacterial movements. Insects present chitin and fungi display ergosterol. Plant receptor-like kinases (RLK) sense also the first 18 amino acids of the bacterial elongation factor EF-Tu. ETI (effector triggered immunity) recognizes the PTI and responds to this effector with some delay after MAP kinase pathway signaling to the nucleus. Te WRKY transcription factors are attracted to the resistance genes. The plant then transcribes genes responsible for reactive oxygen species (ROS) and attempts to prevent further microbial growth by reinforcing cell walls by callose.

Some bacteria can subvert the PAMP-triggered defense by type III secretion system (TTSS)-generated effectors. *Pseudomonas syringae* can secrete 20–30 effectors. The pathogen is protected against the effectors (Chisholm ST et al 2006 Cell 124:803). *P. syringae* subverts the plant immune system by secreting a virulence protein, HopM1 (712 amino acids) and targeting it against the AtMIN7 protein of *Arabidopsis*. The bacterial protein recruits the aid of host proteasomes to destroy immunity (Nomura K et al 2006 Science 313:220). In *Arabidopsis*, microRNAs repressing auxin signaling restrict *Pseudomonas syringae* growth (Navarro L et al 2006 Science 312:436).

The *Pto* serine/threonine protein kinase of tomato and the closely linked *Prf* gene seem to bind directly to the *Pseudomonas syringae* avirulence gene (*AvrPto*), conveying susceptibility to the pathogen. A single amino acid substitution in the plant resistance gene *Pto* may be sufficient to develop resistance to the *Pseudomonas*. Several bacterial species rely on acyl-homoserine lactones (AHL) for quorum sensing and, with its aid, to select a host plant to invade and eventually infect. If AHL can be inactivated by breaking special bonds of the molecule (quorum quenching), the disease symptoms can be prevented (Dong Y-H et al 2001 Nature [Lond] 411:813). Plants can protect themselves by hypertensive reactions but some pathogens learn how to counteract this reaction by special effectors.

Some pathogens develop ubiquitin ligase function to prevent the hypersensitive/apoptotic functions of the host or to alter critical defense proteins by desumoylation. Some fungal effectors include cysteine-rich protease inhibitors for host evasion. Plants may defend themselves against viral RNA by RNAi systems but some plant viruses have already developed effectors against this type of defense (Soosar JL et al 2005 Nature Rev Microbiol 3:789).

Many of the putative resistance genes cloned may lack the stringent criteria to be the principal determinants of resistance to a particular pathogen. Some plant pathogenic fungi (*Helminthosporium victoriae*) can be infected with double-stranded RNA viruses (totivirus) and cause lytic disease to the fungus. Recently in a wild relative of the cultivated beets, a membrane protein was identified that conveys resistance against a nematode (a lower eukaryotic animal). The defense of animals relies on innate and adaptive immunity systems. Posttranscriptional gene silencing may control resistance to viral diseases.

Plant defense gene expression profiles can be monitored by microarray hybridization. The gene expression profile can be evaluated by the LCK (local context finder) procedure (Katagiri F, Glazebrook J 2003 Proc Natl acad. Sci USA 100:10842).

Although insect resistance and herbicide resistance were successfully incorporated into plants by the methods of molecular engineering, disease resistant transgenic plants so far appear to be of less economic success.

In animals, the immune system of the host is the primary defense. In recent years it has become clear that viral pathogens have the potentials of rapid evolution due to their high rate of mutation and short generation time. Thus, the jumping across the species boundaries by HIV and corona viruses are frightening examples (Grenfell BT et al 2004 Science 303:327). Animal and human host transcriptional responses to various pathogens and 5042 genes were summarized by Jenner RG, Young RA. in 2005 (Nature Rev Microbiol 3:281). ▶immune system, ▶infection, ▶infectious diseases, ▶innate immunity, ▶stoma, ▶antisense RNA, ▶RNAi, ▶signal transduction, ▶alien substitution, ▶transformation, ▶Floor's model, ▶ribozyme, ▶hypersensitive reaction, ▶apoptosis, ▶ubiquitin, ▶virulence, ▶avirulence, ▶SAR, ▶biological control, ▶antimicrobial peptides, ▶secondary metabolism, ▶plant defense, ▶guard hypothesis, ▶wound response, ▶chitin, ▶plantibody, ▶2,5-A, ▶salicylic acid, ▶jasmonic acid, ▶ethylene, ▶pathogen-derived resistance, ▶silencer, ▶flagellin, ▶co-suppression, ▶parasitoid, ▶methylation of DNA, ▶post-transcriptional gene silencing, ▶quorum sensing, ▶ROS, ▶oxidative burst, ▶pathogenicity island, ▶octadecanoic acid, ▶PTGS, ▶RdRP, ▶caspase,

Host-Range: The host-range implies that an infectious agent (virus, bacterium, fungus) can grow in some but not in other individuals depending on genotype of the agent and its target. (See da Silva ACR et al 2002 Nature [Lond] 417:459).

Host-Range Restriction: As per the host-range restriction, the same oncoprotein may not transform different species because the host cellular machinery does not favor its function. Some viruses infect or fail to infect other species. (See Oto T, Kawaoka Y 2000 Vet Microbiol 74(1–2):71).

Host-Resistance Genes: Host-resistance genes in mammals are generally quantitated on the basis of the length of survival after infection by viruses, bacteria, or protozoa or on the basis of the density of the pathogen in the infected foci. The inheritance is assessed on the basis of crosses with recombinant inbred strains in mouse. Most of the resistance genes are linked to the H-2 complex (MHC) but other locations as source of resistance have also been identified. The bacterial pathogen *Listeria monocytogenes* induces a dramatic dephosphorylation of histone H3 as well as a deacetylation of histone H4 during early phases of infection. This effect is mediated by the major listerial toxin listeriolysin O in a pore-forming-independent manner. Strikingly, a similar effect is also observed with other toxins of the same family, such as *Clostridium perfringens* perfringolysin and *Streptococcus pneumoniae* pneumolysin. The histone modifications correlate with a reduced transcriptional activity of a subset of host genes, including key immunity genes (Hamon MA et al 2007 Proc Natl Acad Sci USA 104:13467).

Several resistance genes have been cloned. Comparative analyses assist in the use of the information for human and livestock research. ►host-pathogen relations, ►pathogenicity island, ►*Listeria monocytogenes*, ►*Clostridium perfringens*, ►*Streptococcus pneumoniae*, ►histones; Staskawicz BJ et al 2001 Science 292:2285).

Hot Spot: Highly mutable site within a gene or high-frequency recombination site in chromosomes. Recombinational hot spots are generally expressed as cM/kb (map unit/kilobase). Within the *a'* gene of maize the recombination frequencies varied between 5×10^{-3} to 8×10^{-2} cM/kb, whereas in the 140 kb distance between *a'* and *sh2* 6×10^{-4} cM/kb was observed. Within the pseudoautosomal site (*PAR*) of *Drosophila*, 1 cM/53 kb was found. Within the mammalian histocompatibility locus, recombination frequencies of 1 cM/0.6 kb to 1 cM/400 kb have been reported. The frequency of recombination shows great variation along the length of the chromosomes. In humans, 50% of the recombination occurs in less than 10% of the sequences and the local rate of variation may exceed four orders of magnitude (McVean GAT et al 2004 Science 304:581). Usually, a number of hot spots are recognized and there is no equivalence between genetic and physical length. In the vicinity of minisatellites, recombinational hot spots may be found by molecular analyses. In humans and chimpanzees, the recombination hot spots occurred at different chromosomal locations and indicated rapid evolution of hot spots (Winckler W et al 2005 Science 308:107). In human chromosome 22, recombination is increased between long, tandem GT repeats. ►chi elements, ►cold spot, ►coefficient of crossing over, ►mariner, ►MITE, ►coefficient of crossing over, ►recombination hot spots, ►recombination, ►HLA, ►recombination frequency, ►genotyping, ►mutation rate; Lichten M, Goldman ASH 1995 Annu Rev Genet 29:423; Majewski J, Ott J 2000 Genome Res 10:1108; Gerton JL 2000 Proc Natl Acad Sci USA 97:11383).

Hot-Start PCR: Hot-start PCR is used to detect allele-specific changes in the mtDNA. The reaction begins at relatively high temperature but subsequently the temperature is reduced during the cycling (touch-down PCR) in order to improve the specificity of the amplification. ►polymerase chain reaction, ►PCR allele-specific, ►TULIPS-PCR; Ailenberg M, Silverman M 2000 Biotechniques 29:1018.

Hot-Stop PCR: A method for quantitation of allele ratios. (See Uejima H et al 2000 Nature Genet 25:375).

Housefly: *Musca domestica*, 2n = 12. Genome size bp/n = 9×10^8 . (See anatomy: <http://www.ento.csiro.au/biology/fly/fly.html>).

Housekeeping Genes: Housekeeping genes are functional throughout the life of a cell and in the majority of cells and tissues. In the promoters the TATA and CAAT boxes are not present. Their 5' CpG islands are not methylated. ►asparagine synthetase, ►TATA box, ►CAAT box, ►transcription illegitimate, ►methylation of DNA, ►capping enzymes, ►CpG islands

HOVERGEN (homologous vertebrate genes): A database that facilitates identifying homology between nucleic acid and protein sequences. ►evolution, ►databases; <http://pbil.univ-lyon1.fr/databases/hovergen.html>.

HOWDY: An integrated human genome database. It permits also cytogenetic localization. See <http://www.alis.tokyo.jst.go.jp/HOWDY/>.

H

Hox: Proteins (transcription factors) that control differentiation along different paths in the anterior-posterior axis of the body. Mammalian cells are endowed with 39 HOX genes in four clusters (HoxA to HoxD) that belong to 13 paralogous groups. Truncation of the human HOXA may lead to abnormal development of the central nervous system (Tischfield MA et al 2005 Nature Genet 37:1035) resulting in multiple phenotypic defects (deafness, hypoventilation, cardiac and vascular defects, mental retardation and autism). In *Drosophila*, Hox proteins work in cooperation with two segmentation proteins, Sloppy paired and Engrailed. The two proteins repress the Hox target *Distalless* gene in either anterior or posterior compartments (Gebelein B et al 2004 Nature [Lond] 431:652). The expression of other members of the differentiation proteins downstream is generally activated in 3' → 5' direction within the group. Some of the *Hox* genes influence a series of others in different differentiation processes (Lei H et al 2005 Proc Natl Acad Sci USA 102:2420). ►homeotic genes, ►duplication, ►PAX; Gehring WJ et al 1994 Annu Rev Biochem 63:487; Moconochie M et al 1996 Annu Rev Genet 30:529; Shen W et al 2001 Mol Cell Biol 21:7509; Wellik DM, Capecchi MR 2003 Science 301:363; evolution of Hox gene clusters: Lemons D, McGinnis W 2006 Science 313:1918.

Hox Clock: As per the hox clock, the temporal activation of the homeotic hox gene clusters determines the spatial/axial pattern of differentiation. ►hox, ►homeotic genes; Kmita M, Duboule D 2003 Science 301:331.

HP1 (HP-1): A small protein with an amino-end chromodomain and a C-terminal chromoshadow domain. ►heterochromatin, ►chromodomain, ►chromoshadow

HpaII: is a restriction endonuclease enzyme with recognition site C↓CGG.

HPBP: The human platelet basic protein is a member of a large cytokine family. ►cytokines; Zhang C et al 2001 Blood 98(3):610.

HPFH: ►thalassemia

HPFN: The human plasma fibronectin is a cell adhesion molecule. ►CAM; Poulouin L et al 1999 Protein Extr Purif 17:146.

HPLC (high performance liquid chromatography): HPLC is suitable for the separation (among other molecules) of oligonucleotides up to 20 residues by partitioning them between a stationary phase (such as a chromatography column) and a mobile phase (such as solvents) forming a gradient pumped through a system, carefully monitored. ►sequenator, ►electrophoresis, ►high-performance liquid chromatography

HPRT: The hypoxanthine phosphoribosyl transferase is controlled in humans by a recessive gene (map location Xq26-q27.2, 57 kb). Its deficiency causes the Lesch-Nyhan syndrome involving choreoathetoses (involuntary, uncoordinated movements), spasticity (high muscular tension), mental retardation, tendency to self-mutilation, overproduction of uric acid, renal damage, etc. It can be detected prenatally. The molecular basis of the defect is an interruption of the salvage pathway of nucleotides because the guanosine and hypoxanthosine cannot be phosphorylated. The defects of this enzyme have been extensively exploited for *in vitro* selective isolation of fused mammalian cells and for the isolation of mutations. Prenatal diagnosis and carrier identification of defects is feasible. ►salvage pathway, ►HAT medium, ►Lesch-Nyhan syndrome, ►HGPRT, ►epilepsy

HPV: Human papilloma virus. ►papilloma virus, ►bovine papilloma virus

HR: Hypersensitive reaction. ►hypersensitive reaction, ►host-pathogen relationships

hr: Human recombinant in abbreviation, e.g., hrEGF, human recombinant epidermal growth factor.

hRAS (HRAS): RAS proto-oncogene of humans. ►RAS

HRE: ►hormone-response elements

HRF (homologous restriction factor, synonym (C8bp): ►membrane attack complex

HRI (hemin regulated inhibitor, EIF2AK3, human chromosome 2p12): Hemin apparently interferes with the function of this specific protein serine/threonine kinase involved in translational activation; in the absence of hemin the protein kinase is active and protein synthesis may be shut off leading to cell death. Hemin inactivates it by forming disulphide-linked homodimers. Functionally it is similar to the

yeast GCN2 and the PKR-endoplasmic reticulum elongation factor kinase, PEK/PERK. ►hemin, ►protein kinase, ►GCN2, ►GCN4, ►PKR; Crosby JS et al 1994 Mol Cell Biol 14:3906.

HRP-A: A human homolog of the single-strand binding protein involved in genetic recombination. It is required for in vitro replication of SV40 DNA and growth. ►SV40; Baumann P, West SC 1999 J Mol Biol 291(2):363.

hs: A prefix that stands for *Homo sapiens*, e.g., hsDNA, human DNA or hDNA.

HS Site: ►DNase hypersensitive site

HSA: Human serum albumin.

HSA (human sequence assembly): HSA7 is the assembled nucleotide sequence of human chromosome 7.

Hsc (heat shock cognate): A form of a heat-shock protein in the normal cytosol. ►heatshock protein, ►Hsp70

Hsc66: A 615 amino acid *E. coli* protein, encoded by *hscA*, member of the Hsp70 family. It is induced by cold shock. It lacks the ATP-binding domain of Hsp70. It is co-transcribed with *hscB* (encoding a DnaJ-like protein) and *fdx* (encoding ferredoxin). ►cold shock, ►heat shock, ►DnaK, ►ferredoxin; Silberg JJ et al 2001 J Biol Chem 276:1696.

hsdR: Some mutations in *E. coli* that eliminate restriction function but not the modification in the restriction-modification system. ►restriction enzyme, ►restriction-modification; Doronina VA, Murray NE 2001 Mol Microbiol 39:416.

HSE: Heatshock elements located in the upstream region of eukaryotic heatshock responding genes and recognized by heat-shock protein transcription factors. A typical heatshock element is an about 14 bp palindromic sequence with a GAA core: 5'-CTN-GAANN TTCNAG-3' 3'-GANCTT NNAAGNTC-5' ►heat-shock proteins, ►transcription factors inducible, ►HSTF, ►Hsc

HSF: Heat shock transcription factor, which activates the transcription of heatshock proteins. ►heat-shock proteins, ►HSE

Hsj1a, Hsj1b: Neuron-specific chaperones of the DnaJ family. Alternative splicing of the same RNA transcript produces them. They do not have intrinsic ATPase activity, yet they increase this function of Hsp70. ►chaperone, ►DnaJ

HSP (heat-shock proteins): HSP110 of mammals are similar to the SSE proteins of yeast and they are related to Hsp70. The 40-kDa-mammalian chaperone Hsp40 (J protein) facilitates the folding

of the polypeptides coming off the ribosomes. These are also stress proteins highly inducible by heat, although may be formed constitutively. The sea urchin egg carries a HSP that serves as a receptor for the sperm. Another related protein is Osp94/APG-1 formed in response to heat, high osmotic, and other stresses. The GRP glycoproteins of diverse molecular sizes are also heat-inducible and function in the spleen, lymph nodes, and Peyer's patches in connection with the immune responses. The HSP40 family members are co-chaperones of the Hsp70 family of proteins resembling DnaJ. The HSP40 members interact with nucleic acid and proteins in concert with Hsp70, and occur in the nucleus, mitochondria, endoplasmic reticulum, and on the membrane surfaces mediating chaperon functions (protein folding, translocation, renaturation of proteins of wrong conformation, proteolysis), signal transduction, and formation of macromolecular complexes. The Hsp100 (Clp) family of proteins is generally involved in aggregation and disaggregation of proteins of different sizes. Hsp104 is another stress protein controlling also the Psi^+ prion-like protein of yeast. Hsp47 is the serpin family stress protein of vertebrates, found in the endoplasmic reticulum where it binds to procollagen. Hsp101 is a plant chaperone closely related to Hsp104. Hsp78 is a soluble mitochondrial chaperone of yeast. Hsp26 is a sHsp of yeast with major role in stress and cytoskeletal control. ►heat-shock proteins, ►HSE, ►HSTF, ►Hsc, ►Hsp70, ►Hsp83, ►Hsp90, ►constitutive gene, ►spleen, ►lymph nodes, ►Peyer's patches, ►immune system, ►DnaJ, ►conformation, ►signal transduction, ►chaperones, ►chaperonins, ►Clp, ► PSI^+ , ►sHSP, ►serpin, ►pro-collagen, ►endoplasmic reticulum; J proteins: Sahi C, Craig EA 2007 Proc Natl Acad Sci USA 104:7163.

HSP60 (CPN60, chaperonin 60): ►chaperonins

Hsp70: A heat-shock protein gene (activated by elevated temperature); it is a chaperone. These proteins are widely distributed among diverse species, prokaryotes and eukaryotes, and have been found in various subcellular compartments. The proteins are endowed with multiple functional domains required for peptide and co-factor binding and a weak ATPase activity. Hsp70 functions involve control of protein folding, lytic phage infection of bacteria, un-coating of clathrin-coated vesicles and thereby selective endocytosis, and assist proteases in degradation of abnormal proteins, etc. ATP hydrolysis and polypeptide binding activity of Hsp70 depends on two different domains of the protein. Hsp70 also needs the cooperation of Hsp40 (DnaJ). The human homologs (HSPA) are encoded in chromosomes 6p21.3, 14q22, 14q24.1, 5q31.1,

9q34, 1q, 14q24, and at other locations. Mouse homologs were identified in chromosomes 17, 12, 2 and 18. Male mice lacking Hsp70 homologs are unable to produce spermatids and mature sperm and show dramatic increase of apoptosis of the spermatocytes. Female mice of the same constitution did not show meiotic disturbances or infertility. The four *SSA* genes of yeast are highly homologous (80%) members of this family of proteins (~70-kDa). *SSA2* is essentially constitutive, the others are heat-inducible. The *SSA* gene products negatively regulate their own and each other's synthesis. The *SSA* genes are essential for normal cell viability. The *SSB* gene products of yeast are associated with the ribosomes. The *Ssc* yeast proteins occur in the mitochondrial matrix and envelope, aid the translocation between the cytosol and the mitochondria, and are also involved in general protein folding and lysis in that organelle. *Ssc* proteins are weakly inducible by heat. *Ssh1* protein is encoded in chromosome 12 of yeast and located in the mitochondria where it may be involved with DNA replication and protein processing. *Ssi* (100-kDa) protein controls endoplasmic reticulum traffic, particularly when the *KAR2* gene of yeast is defective. *Kar2* protein (682 amino acids) in the endoplasmic reticulum of yeast mediates translocation and folding of proteins and also nuclear fusion after mating. *BiP* is an essential endoplasmic reticulum chaperone present in fission yeast, several plant species, *Trypanosomas*, and mammals. The *Hsc4* proteins of *Drosophila* are also Hsp70-related. *Hsc3* in *Drosophila* is homologous to *Kar2* and *BiP*. The Mammalian *Prp73* is 73-kDa chaperon recognizing the S-peptide (residues 1-20 of ribonuclease A). *Pbp74* (74-kDa) peptide-binding protein in the mammalian and yeast mitochondria aids peptide import and processing within the mitochondrial matrix. *Stch* chaperone (471 amino acids) is encoded in human chromosome 21q11.1 and the protein is located in the microsomal fraction of the cell and has ATPase activity. ▶[heat-shock proteins](#), ▶[HSE](#), ▶[HSTF](#), ▶[apoptosis](#), ▶[chaperone](#), ▶[clathrin](#), ▶[endocytosis](#), ▶[ATPase](#), ▶[Prp73](#), ▶[HSTF](#); Hartl FU 1996 Nature [Lond] 381:571; Bukau B, Horwich AL 1998 Cell 92:351.

Hsp83: ▶[Hsp90](#)

Hsp90: A chaperone protein family including heat-inducible and constitutive chaperones involved with the signal transduction kinases and steroid receptors. In yeast, a study of the function of 4,700 viability genes revealed 198 putative physical interactions and 451 genetic and chemical-genetic interactions with the Hsp90 chaperone (Zhao R et al 2005 Cell 120:715). Homologs occur in prokaryotes (*HtpG*), *Drosophila* (*Hsp83*), mammals (*Grp94*), yeast, and

plants. Hsp90 and its homolog Hsp83 may cause transmissible epigenetic alterations in plants (Queitsch C et al 2002 Nature 417:618) and in animals (Sollars V et al 2003 Nature Genet 33:70). Hsp90 chaperones are regulators of cell circuits and may mediate protein folding in response to environmental variations. After several generations it may reassort genetic variations and leads to the expression of traits that were cryptic in the progenitors. Fungal drug resistance may develop as a consequence of its action on new or old mutations (Cowen LE, Lindquist S 2005 Science 309:2185). The structure of Hsp90 displays dramatic conformational change dependent on ADP nucleotide association (Shiau AK et al 2006 Cell 127:329). ▶[heat-shock proteins](#), ▶[chaperones](#), ▶[protein folding](#), ▶[Grp94](#); Kumar P et al 2001 Cell Stress Chaperones 6:78; crystal structure of Hsp90 domains in association with ATP and co-chaperones: Pearl LH, Prodromou C 2006 Annu Rev Biochem 75:271.

HSR: ▶[homogeneously stained region](#)

HSSB (human single-strand binding protein): The same as replication protein A; see it there.

HST Oncogene: The HST oncogene was assigned to human chromosome 11q13; originally identified in stomach cancer but it was also found in Kaposi sarcoma. Its product is a heparin-binding protein with homology to the fibroblast growth factor (FGF). It is also called K-FGF. ▶[FGF](#), ▶[oncogenes](#), ▶[growth factors](#), ▶[Kaposi sarcoma](#)

HSTF: The heatshock transcription factor regulates about 20 heatshock genes by binding cooperatively to more than one heat shock element. It is activated by phosphorylation. ▶[HSE](#), ▶[HSP](#); Tanguy RM 1988 Biochem Cell Biol 66(6):584.

Hst1p (homolog of Sir2): The protein involved in mating type determination in yeast. Rusche LN, Rine J 2001 Genes Dev 15(8):955.

HSV (Herpes Simplex Virus): ▶[Herpes](#)

HTC: A database for high-throughput not yet definite genomic sequences.

HTDV (human teratocarcinoma derived virus): An endogenous human retrovirus family occurring in about 25–50 copies per genome. About 10,000 solitary LTRs are also present. They are well expressed in different organs. ▶[retroviruses](#), ▶[solitary LTR](#)

hTERT: The catalytic subunit of human telomerase. ▶[telomerase](#)

HTF Islands: 1–2 kb sequences around the 5' region of genes where the Hpa II restriction endonuclease cleaves Tiny Fragments because the cytidines are not

methyated. At most other regions, because of methylation, only larger fragments are cut. The mammalian genome may display 30,000 HTFs. (See Bird AP 1986 Nature [Lond] 321:209; Zardo G, Caiafa P 1998 J Biol Chem 273:16517).

H1TF2: A histone transcription factor binding to CCAAT box. ▶ [histones](#); Martinelli R, Heintz N 1994 Mol Cell Biol 14:8322.

HTG/HTGS (high throughput-genomic sequences): Division of gene banks permitting the search for unfinished nucleotide sequences. ▶ [databases](#), ▶ [genome projects](#), ▶ [GenBank](#); <http://www.ncbi.nlm.nih.gov/HTGS/>.

Human Artificial Chromosome (HAC): HACs are not yet equivalent to similar constructs in *Saccharomyces* or *Schizosaccharomyces* and their closest counterparts are the minichromosomes that may be less than 1/10 of the size of the chromosome before truncation yet are mitotically quite stable. Human minichromosomes can be generated in vitro by mixing alphoid, telomeric, and carrier DNAs. These structures transfected into human cells are maintained, and segregate and bind centromeric proteins. Current evidence indicates, however, that neither the alphoid DNA nor the CENP-B protein may be required for normal centromeres. Neocentromeres have been analyzed and apparently lack alphoid DNA and are not suitable for the construction of human artificial chromosomes. Despite earlier assumptions that human artificial chromosomes may not function normally if they are introduced into somatic cells because under normal conditions the cells are disomic rather than trisomic although the extra chromosome (HAC) would not carry genes that are already present in one or two doses in the genome. This problem might even further be aggravated if the cell would undergo meiosis. Current evidence indicates, however that the new technology facilitates the overcoming of these difficulties and mammalian artificial chromosomes are useful vectors. They can be transmitted through generations and can have important role in biotechnology and in the pharmaceutical industry (Duncan A, Hardlaczky GY 2007 Curr. Opin Biotechnol. 18:420). In cell culture, human artificial chromosomes have been used as genetic vectors to introduce specific genes and have demonstrated the potentials of complementing deficiencies of hypoxanthine guanine phosphoribosyl transferase. HACs may be exploited also for the transfer of genes from humans to other mammals. Human artificial chromosome vectors equipped with chromosome 17 alphoid DNA generated 32–79% artificial minichromosomes but the alphoid DNA of the Y chromosome generated only 4%. The stability of the minichromosomes decreased when the guanine phosphoribosyl locus (HPRT1) was included. ▶ [minichromosome](#), ▶ [HAC](#), ▶ [YAC](#), ▶ [BAC](#), ▶ [PAC](#), ▶ [alphoid DNA](#), ▶ [α-satellite](#), ▶ [neocentromere](#), ▶ [disomic](#), ▶ [trisomy](#); Harrington JJ et al 1997 Nature Genet 15:345; Ikeno M et al 1998 Nature Biotechnol 16:431; Tyler-Smith C, Floridia G 2000 Cell 102:5; Mejia JE et al 2001 Am J Hum Genet 69:315; Mejia JE et al 2002

Human Chromosome Maps: Linkage and mapping information until the 1960s were obtained mainly by studying family pedigrees. This procedure was very inefficient both because in human populations controlled mating is not feasible and because of the small populations available, crossing over frequencies can not be used the same manner as in, e.g., *Drosophila*. Some of the gene locations were determined by deletion mapping, but until 1956 even the number of human chromosomes was uncertain. In the late 1960s and early 1970s, new chromosomal staining techniques made possible the recognition of chromosome bands, permitting the more precise location of genes relative to these beacons. During the 1960s, the culture of isolated mammalian cells had been improved and in 1960 fusion of somatic cells was accomplished, followed in 1965 by the production of mammalian somatic cell hybrids. It was discovered that in human-mouse somatic cell hybrids, human chromosomes are preferentially lost, facilitating the assignment of particular genes to specific

human chromosomes. Only those human genes were expressed in the cultures that were present and their expression ceased when the critical chromosome was eliminated. By induced breakage, the location of genes could be further specified when it was seen that the retention of particular cross bands was essential for the expression of a particular gene. In 1960, nucleic acid hybridization was discovered and by the mid 1960s, nucleic acid hybridization was used for localizing genes in cultured human HeLa cancer cells. Somatic cell hybridization permitted the chromosomal assignment of three times as many genes within a few years as family analysis accomplished over half a century. By 1970, methods were developed to assign mouse DNA fragments to chromosomal location by in situ hybridization. In situ hybridization also facilitated the location of about twice as many genes than the pedigree analysis. Discovery of restriction endonuclease enzymes in the late 1960s and 1970's opened in genetics a new era of physical mapping and localizing cloned genes or just "anonymous DNA" sequences to chromosomal positions. Isolated DNA sequences could be ordered on the basis of the overlapping fragments by the use of chromosome walking and jumping first employed

in *Drosophila* in 1983. The use of isolated genes from other species (*Drosophila*, mouse, yeast, etc.) as probes permits now the identification of the position of homologous genes and DNA sequences. By the extension of these techniques, individual human genes can be isolated, cloned, and sequenced; thus, the technology is in use for the ultimate mapping of the human genome at the nucleotide level, to recognize the structural bases of functions, regulation, and organization of the genome. The detailed mapping is assisted now by sophisticated computer programs to determine the order of several gene loci on the basis of the maximum likelihood principle. This information, sought by the human genome projects, will contribute to evolutionary information as well to medical applications of gene therapy. The 2002 (Kong A et al Nature Genet 31:241) genetic map includes 5,136 microsatellites (AC/TG) markers based on 1,257 meiotic events. The 'complete' nucleotide sequence of the human genome available by 2000 facilitates the determination of the position of most human genes. By 2004, an almost complete map of the euchromatic sequence was published containing a reevaluated gene number of 20,000–25,000 protein-coding genes (Nature [Lond] 431:931). Although the physical map of the human genome is 'practically' complete (Science 291, 15 Feb. 2001, Nature [Lond] 409, Feb. 15, 2001), the full functional annotations will have to wait.

A compendium of the gene expression pattern of normal human tissues is available (Hsiao LL et al 2001 Physiol Genomics 7:97). The genetic and the nucleotide sequence based physical maps are not entirely consistent because of technical ambiguities (DeWan AT 2002 Am J Hum Genet 70:101). Human chromosome 1 contains 3,141 genes and 991 pseudogenes (Gregory SG et al 2006 Nature 441:315), 2 has about 1,346 protein-coding genes and 1,239 pseudogenes, whereas chromosome 4 has 796 and 778, respectively (Hillier LW et al 2005 Nature [Lond] 434:724). Chromosome 8 has 793 genes and 301 pseudogenes (most of them reprocessed); the average chromosome-8 gene is 3,056 bp with 9.9 exons and 4.1 transcripts. The gene density (5.6/Mb) is almost half of the genome average 10/(Mb). The most distal part of chromosome 8 of humans shows high divergence from chimpanzees and other mammals. This region includes the defensin genes controlling innate immunity and gene MCPH1 (microcephaly) involved in brain development (Nusbaum C et al 2006 Nature [Lond] 438:331). [Microcephaly genes occur also in human chromosomes 19.13.1, 15q15, 9q33, 1q31, 13q12.2]. Chromosome 15 has high number of duplications in the centromere-proximal and -distal regions. It has a total (including putative and gene fragments) of 695

genes and 250 pseudogenes (Zody MC et al 2006 Nature [Lond] 440:671). H

Human Dignity: Human dignity is part of universal human rights of self-determination. From it flows the views on the sanctity of human life, euthanasia, abortion, death penalty, prisoners' rights, torture, political freedom, and various principles concerning the use of biotechnology (cloning, stem cell research), informed consent, sale of human body parts, experimentation with human subjects, prostitution, gene patenting, social equality, lack of discrimination, etc. For some of these concepts there is complete or nearly universal support in all enlightened, free societies, while for others there is no consensus. (See also Caulfield T, Brownsword R 2006 Nature Rev Genet 7:72).

Human Evolution: The study of human evolution has gained in recent years important tools by the application of molecular markers of mtDNA (of skeletal remains) and mtDNA and Y chromosomes to the survey of dead and living populations, respectively. These methods permit the separation of the gene flow also by the sexes. Commonly in migrating populations, mixtures of immigrant men's and native women's gene pools seem to prevail because the invading men eliminated or reduced the number of the native men but begot offspring with the women and among the immigrants females were not always represented equally to males. The information may be biased by the size of the admixing populations. The entire human species has essentially the same amount of DNA, the same number of genes in the same order in the chromosomes. Yet, differences among human races are also obvious. These differences seem to be based on a few minor deletions or additions to the genome. The spread of infectious diseases may contribute to human evolution. Malaria and HIV infections and high mortality may select for tolerance

Figure H75. Continued

Figure H75. REFERENCE POINTS FOR MAPPING GENES OR DNA SEQUENCES TO HUMAN CHROMOSOMES

(above) Each chromosome is numbered; 1 is the longest by cytological evidence. Since the metaphase length is somewhat ambiguous because the condensation, due to genetic and other causes, may vary and length is not an absolutely consistent feature of the karyotype. The approximate minimal DNA content (Mb) of each chromosome is shown in parenthesis under each diagram. The centromere is represented by constrictions and the pericentromeric region is diagonally hatched. The short arms (shown above the centromere) are designated by p (for petit) and the long arms are designated by q. Each arm has cross-bands corresponding to observations by Giemsa, q and c banding techniques. The fine hatching indicates heterochromatic regions. Each chromosome, starting at the centromere, is divided into domains and subdomains designated by numbers. if we see that the location of TNFR-2 (encoding tumor necrosis factor 2, a 75-KDA protein) is at 1p36.3-p36.2, we know that it is in the terminal region of chromosome 1, either in the first black band or above. The telomeric region is usually designated by ter. Acrocentric chromosomes (13, 14, 15, 21, 22) and their heterochromatic areas and satellites are finely cross-hatched. The large number of genes is impossible to represent on a single page. the location of the physical markers occupied, by 1996 (Nature 380, suppl.), about 138 pages in fine print. (Illustration is based partly on the New Haven Human Gene Mapping Library Chromosome Plots. Number 4. HGM9.5, constructed by Spence MA and Spurr NK) by 2001 after the completion of the finished the human genome (Nature [Lond] 431:932, 2004) the length of the individual chromosomes required revision compared to the data seen in this illustration. Thus the latest length in Mbp of the euchromatic sequences of the chromosomes is: **1 223.9, 2240.0, 3 199.3, 4 188.4, 5 177.7, 6 170.0, 7 155.6, 8 145.6, 9 120.4, 10 133.0, 11 134.5, 12 132, 13 96.3, 14 88.3, 15 82.1, 16 78.9, 17 78.8, 18 76.12, 19 60.1, 20 60.7, 21 34.2, 22 35.2 X 151.8, Y 26.7** These figures ignore the unsequenced gaps and heterochromatin.. The total euchromatic length is about 2.88 billion bp out of the total of ~3.08 billion. (For publicly available genome data see Nature [Lond] 409:860 (2001). Physical maps of the human chromosomes can be found in some details in Nature [Lond] 409:942–958 (2001), Nature [Lond] 431:931 (2004). The cytogenetic map shown here is still used but one must remember that its resolution is not sufficient for the precise location of the large number of protein-coding genes, estimated to about 20,000–25,000 in the euchromatic sequences. Therefore the same cytogenetic map sites often accommodate several functionally different genes.

or resistance because of the differential survival to reproductive age. A refined map of human chromosome 17q21.31 displays a 900-kb inversion in two different orientations, H1 and H2. The H2 lineage is rare in Africans, almost absent in East Asians but is represented in 20% among Europeans. These two structural rearrangements did not recombine. In Icelandic populations, the H2 lineage seems to have positive selective value as indicated by the higher number of children of the carrier females and higher genetic recombination than the non-carriers (Stefansson H et al 2005 Nature Genet 37:129). ▶mtDNA, ▶Y chromosome, ▶hominidae, ▶chimpanzee, ▶language, ▶Eve foremother of mitochondrial DNA, ▶Y chromosome; Jones S, Martin R, Pilbeam D eds 1992 Human Evolution, Cambridge Univ. Human Experimentation: Human experimentation must be limited to cases where other methods or means of study are not available. The subject(s) of the study should consent and be fully informed of the implications of the experiments. No experiment should be conducted which, by existing knowledge, is likely to involve injury, death, or unnecessary suffering. The experimenter must have the highest qualification. The experiments must be terminated any stage when

the subject so desires or when the experimenter expects harm. ▶ethics, ▶informed consent, ▶privacy rules, ▶genetic privacy; Foster C 2001 The Ethics of Medical Research, Cambridge Univ. Press, New York.

Human Gene Index: Human gene sequences, annotations, etc. <http://www.tigr.org/tigr-scripts/tgi/Tindex.cgi?species=human>.

Human Gene Mutation Database: <http://www.hgmd.org/>.

Human Gene Transfer: In human gene transfer, the vectors can be replication-deficient retroviral or adenoviral vectors. The retroviral vectors may integrate 9-kb passenger DNAs into the chromosomes and may destroy tumor suppressor genes or activate oncogenes if inserted nearby, and thus may permanently alter the genome either favorably by inserting the desired genes or undesirably as mentioned above. Adenoviral vectors have a carrying capacity of about 7.5-kb DNA. These enter the cells by special receptors. Adenoviral vectors do not integrate into the chromosomes and do not replicate indefinitely but have to be reapplied after a few weeks or months. They are well suited for in vivo use because they may be efficient in replicating and non-replicating cells and may have high titer (10^{13} virion/mL). The adenoviral vectors may involve inflammation of the tissues and may encounter antivector

cellular immunity. New vectors are continuously developed for greater efficiency.

Plasmid-liposome carriers also have been explored under in vivo conditions. Human gene transfer may be used to insert selectable markers into T cells, stem cells, tumor-infiltrating lymphocytes, neoplastic cells in hematopoietic lines, and sarcoma cells, etc. Gene transfer may have also therapeutic goals. Most of the human gene transfer experiments were plagued with inconsistent results and the expectations based on animal model experiments were not entirely fulfilled. The vectors need further improvement regarding "homing-specificity" (targeting), side effects (inflammation), elimination of the possibility of insertional mutations, and eliminating possible immunological reactions against the vectors. ►transformation genetic, ►vectors, ►gene therapy, ►cancer gene therapy, ►adenovirus, ►liposomes; Factor PH ed 2001 Gene Therapy for Acute and Acquired Diseases. Kluwer, Boston.

Human Genetics: Basic genetics using human (cells or individuals) as the subject of study. The human genome contains approximately 30,000 to 25,000 genes and their physical mapping and sequencing is near completion. In general, the function of several physically identified gene is discovered weekly. Human genetics is relying more and more on the methods of reversed genetics and bioinformatics (Botstein D, Risch N 2003 Nature Genet 33 [Suppl.]:228). ►BodyMap, ►clinical genetics, ►medical genetics, ►pharmacogenetics, ►OMIM, ►HGMD; Hawly RS, Mori CA 1999 The Human Genome: A User's Guide. <div data-bbox=)

Human Genome: About 90% of the genome, 2.91 billion bp of the euchromatic portion was sequenced by the whole-genome shotgun approach using the DNA of five individuals of different ethnicity, and published by the Celera group on Feb. 16, 2001 and on Feb. 15 by the Human Genome Sequencing Consortium. 25% of the genome is in scaffolds of over 10 million basepairs and 90% is in assemblies of 100,000 bp or more. Celera found 25,588 protein coding transcripts and computational analysis and mouse information indicated the presence of ~12,000 additional genes. The Consortium estimated ~31,000 protein-coding genes. The definitive number of genes is still uncertain; the best current estimates are ~25,000. About 75% of the DNA is intergenic. About 740 genes are transcribed into RNA but not translated into protein. Only 1.1% is in exons and 24% is in introns. On the average, there was found 1 bp variation per 1250 bp among genomes, and less than 1% of the SNPs were found to alter the amino acid sequences in the proteins. Mate pairs using BAC clones arraigned the megabase size sequences. The high throughput automation and computational technology made possible rapid progress beyond expectation. The gene density of the chromosomes varies, and generally the genes are not distributed uniformly along the length of the DNA. There are more genes in the GC-rich tracts than in the AT-rich sequences. Chromosomes 11, 17, 19, and 22 are relatively gene-rich whereas X, 4, 18, 13, and Y are poor. The highest numbers of genes are in chromosomes 1, 2, 19, and 11, in this order. Recombination frequencies per Mb are higher in the telomeric region and also higher in females than in males. The first coding exons appear to have high CpG proportions. There is a high proportion of processed

pseudogenes, especially for ribosomal proteins (67%), lamin receptors (10%), and to smaller extent in others. 107 blocks contain repeated genes, 781 of them five or more. Duplications are extensive over the entire genome, especially in chromosome 2 and 14. The latter is duplicated in over 70%. Some of the genes responsible for diseases (bleeding disorders, developmental regulation, and cardiovascular conduction) are in paralogs of duplicated segments. Interestingly, these duplications are similar to those in mice, indicating that their origin predated the evolutionary divergence. The nucleotide diversity based on SNIPs for the autosomes was found to be 8.94×10^{-4} and for the X chromosome 6.54×10^{-4} . The transition: transversion rate varied from 1.59:1 to 2.07:1, depending of the analytical methods. The distribution of SNIPs deviates from the Poisson expectation. In the coding sequences, the missense nucleotide substitutions are relatively rare (0.12–0.17%), indicating that conservatism for the integrity of the proteins is favored by selective evolution. The intergenic and intron regions harbor most of the SNIPs. About 40% of genes had no identified function by 2001. The annotation remains of central interest (Hubbard T 2002 Bioinformatics Suppl. 2: S140). Some inconsistencies and errors turned up on reexamination of the draft completed by 2000. The largest categories are nuclei acid metabolism (7.5%); transcription factors (6%), hydrolases (proteases), signal transduction (G proteins), receptors, kinases, phosphatases, transporters, cytoskeletal proteins, ion channels, motor proteins, cell adhesion molecules are common. Human-*Drosophila* orthologs were 2,758, and the human-*Caenorhabditis* orthologs appeared to be 1,523. The nucleic acid metabolic enzymes, polymerases, helicases, ligases, nucleases, and ribosomal proteins were best preserved during evolution. The lower animal genomes (*Drosophila*) are devoid of the human genes mediating acquired immunity. The human nervous system is controlled by a much larger number of genes than the similar functions in *Caenorhabditis* or *Drosophila*. Intracellular signaling, hemostasis, apoptosis, translation, and ribonucleoprotein genes are substantially expanded in humans compared to other, lower organisms. The number of genes is about only twice that of *Caenorhabditis* because with the more elaborate regulatory system in humans the higher complexity of functional needs can be taken care of. ▶draft genome sequence, ▶shotgun sequencing, ▶scaffolds in genome sequencing, ▶clone-based mapping, ▶exon, ▶intron, ▶mate pairs, ▶BAC, ▶fingerprinting, ▶acquired immunity, ▶paralogous loci, ▶gene number, ▶SNIPs, ▶diversity, ▶polymorphism, ▶Poisson distribution, ▶missense mutation, ▶transposition, ▶transversion, ▶rough draft, ▶gene,

Human Genome Diversity Project (HGDP): The HGDP studies 52 populations including African, Europeans, Western Asians, Southern Asian, Eastern Asians, Oceanians and Native Americans. It contained (in 2004) 1064 cell lines and provided free samples to 56 laboratories and collected the largest, diverse DNA samples of the species. Its goal includes information on world-wide distribution of human genetic disease genes. It provides information also on the origin of human populations. ▶MAPMAP, ▶human evolution; Cavalli-Sforza LL 2005 Nature Rev Genet 6:333.

Human Intelligence (IQ): Human intelligence is not a simple qualitative trait but is generally defined as

the composite index of a variety of scores each of which is expected to have different genetic determination. The intelligent quotients (IQ) also vary, depending on the variety of test batteries used for the analysis, such as cognitive, verbal, mathematical, logical, performances, among others. Since intelligence is such a complex trait, it must be under the control of many genes. All polygenic traits have genetic and environmental components, so does intelligence. As a consequence it is impossible to separate clearly ability from achievement, and the tests involve generally the latter. Nevertheless, it is obvious that all traits are expressed on the basis of a genetic blueprint in the DNA, and “intelligence” cannot be an exception. Shortly before the end of the nineteenth century, Francis Galton, the father of statistical genetics, came to the conclusion that the apparent mental abilities of parents and children are correlated. Galton found that 36% of the sons of the 100 most distinguished men were still eminent but only 9.5% of their grandsons and 1.5% of their great grandsons were such. Also, 23% of the brothers of eminent men were also eminent. Since then several studies confirmed the existence of such general correlations. These correlations may be biased to a great degree because the environmental conditions of parental and offspring population is also highly correlated. Before World War I, intelligence quotients were introduced for standardized quantitative measurements of intelligence. The Binet test had been widely used for determining scholastic performance and predictions. According to these quotients, children scoring according to the average of their age group were classified with a score of 100 and whose performance corresponded to two years behind or two years ahead of their peers were assigned IQ values 80 or 120, respectively. Within similar socio-economic and educational groups, these figures were meaningful. Comparisons between mono- and dizygotic twins reared together and apart, as well as those between adopted children and foster and birth parents were studied for the inheritance of IQ.

These studies have proven by objective measures the existence of a significant hereditary component of the IQ indexes. Some studies attribute great influence to maternal effects through the womb environment. The IQ values should be very cautiously considered if different ethnic or socio-economic groups are compared. Also, the developmental rate of individuals may vary a great deal. Some of the children are early or late “bloomers” and this condition limits the predictive value of the indexes. There can be no question that certain genes, concerned with the nervous system, are responsible for mental retardation. The IQ indexes should not be used, however, for ethnic or social group-discrimination because the

statistical ranges of individual IQ values are highly overlapping in human populations, e.g., of blacks and whites in the USA. Although the averages of the two groups displayed a 15% difference, such information does not serve any useful purpose (see Fig. H76, drawn on the basis of data by AR Jensen 1998 The 3 g Factor. Praeger, Westport, CN). Racial gaps in

Figure H76. IQ distribution according to AR Jensen

achievement can be substantially reduced by appropriate social-psychological intervention involved in boosting self-confidence (Cohen GL et al 2006 Science 313:1307). Also, humans can be judged only individually. Furthermore, diverse individual values of athletes, business people, laborers, physicians, geneticists, theoretical physicists, etc., are all important for the good functioning of human societies. Anyhow, IQ data are statistical and do not have rational neurobiological bases. Sex differences in mental test scores have been examined repeatedly in large representative populations. Although the overall differences between the sexes appear small, the males' abilities in mathematical and mechanical performance appeared higher whereas in associative memory, reading comprehension, and perceptual speed the females were at advantage. The genetic meaning of these data is not clear. Males and females share the same chromosomal complement, except the Y-chromosome, which by current knowledge contains minimal information beyond what is located in the pseudoautosomal segment and the genes related to sex determination and male fertility. Fragile sites in several human chromosomes are associated with trinucleotide repeats. The C residues of these variable-length repeats may be methylated to a variable extent and the increase of methylation is correlated with a decrease of intellectual abilities of the individuals. The range of IQ of dull individuals is 20–84, of the feeble-minded is 50–70, the imbecile is 20–50, and the idiot is < 20. These three lower types combined represent 2–3% of the general population, but are substantially higher in consanguineous sibships, especially when one or both of the parents are subnormal. IQ represents a good example of regression. Children of higher IQ people (IQ 140) display values about 121, whereas the IQ of low IQ (85) people's offspring may exceed (92) the parent's. Although various IQ tests have been widely used for psychological and clinical studies, general cognitive abilities can be better assessed by Spearman's *factor*

analysis based on the *g* test (general factor test) developed at about the same time as the Binet test. The *g* test uses correlation matrices of various abilities, e.g., study of classics, modern languages, mathematics, pitch, music, etc. The basic idea is that one single ability is expected to be correlated with diverse other abilities and the *g* score can express it all in a single numerical manner (*factor loading*). The *g* test generates a composite index that weighs the separate tests by the overall correlation with all other component tests. Since the 1910s, Cyril Burt proposed the more complex *group factor* approach as a refinement of the *g* test. The IQ tests are also numerical but the final score is derived from the summation of the average individual scores (e.g., reading, memory, judgement, etc.). Recently, the availability of methods for the study of quantitative gene loci and multivariate genetic analyses permit the study of genetic correlation among numerous genes. Also, the heritability of cognitive abilities can be assessed with much better resolution. The progress in neurobiology (neuroimaging) sheds also some light on the spatial organization and cooperation of the sites of these separate cognitive centers in the brain. The availability of chromosome and genome sequence information along with microarray hybridization techniques is expected to further reveal how the cognitive index of *g* is controlled by molecular factors. Since in a human population the individual genes may be represented by different alleles, the fine differences may be revealed by single nucleotide polymorphism (SNIP). With the progress of the proteome analysis, eventually better treatment may be feasible for the mentally retarded or those who are afflicted by affective disorders. The molecular genomics of behavior will certainly raise many ethical problems. The progress in biology and genetics must go ahead even in some of the delicate areas. Application of the new technology requires, however, different types of moral and ethical decisions. One must keep in mind the lack of a generally agreed upon definition of what constitutes intelligence. ►polygenes, ►heritability, ►behavior genetics, ►behavior in humans, ►genius, ►mental retardation, ►microcephaly, ►cognitive abilities, ►euteleogenesis, ►myopia, ►fragile sites, ►FMR1 mutation, ►trinucleotide repeats, ►autism, ►dyslexia, ►QTL, ►multivariate analysis, ►heritability, ►microarray hybridization, ►DNA chips, ►SNIP, ►mental retardation, ►affective disorders, ►proteome, ►Spearman rank-correlation test, ►brain human, ►covariance, ►behavior genetics, ►imaging, ►admixture in populations, ►chimpanzee; Macphail EM, Bolhuis JJ 2001 Biol Rev Camb Philos Soc 76(3):341; Dickens WT, Flynn JR 2001 Psychol Rev 108:346; Plomin R, Craig I 2001 Br J

Human Mutagenic Assays: Humans cannot be subjected to mutagenic treatments and a mutagenic risk to human populations is determined largely by indirect means, using microbial, and animal and plant bioassays of genetic toxicology. Other methods may involve epidemiological efforts involving dominant mutations, survey of chromosomal aberrations in blood samples, testing cell cultures for mutability, and biochemical and molecular methods to assay genetic repair in cell culture, monitoring changes in DNA by restriction fragment polymorphism using appropriate probes, SNIPs, etc. Increase in recessive mutations are difficult to detect because the human mating system does not favor homozygosis. Although the populations of Hiroshima and Nagasaki were exposed to very high doses of ionizing radiation as a consequence of the atomic explosion during World War II, no statistically significant increase in gene mutation could be detected. Developmental defects and incidence of neoplasia, however, increased. Similarly, although the meltdown of a nuclear reactor in Chernobyl in 1986 caused a significant increase in birth defects and cancer, it is too early to tell whether these were only teratological effects or genetic causes are also involved. More recent data seems to indicate that genetic alterations were also caused. ►atomic radiations, ►bioassays in genetic toxicology, ►host-mediated assays, ►substitution mutation, ►mutation detection, ►mutation rate in humans, ►SNIP; human mutation database: <http://www.hgmd.cf.ac.uk/ac/index.php>.

Human Origins: Anthropologists and paleontologists are not in agreement about how *Homo sapiens* populated the world. The earliest human relics—based on $^{40}\text{Ar}/^{39}\text{Ar}$ dating—in Africa appear to be $195 \pm \text{kyr}$, substantially older than the earlier estimate (McDougall I et al 2005 Nature [Lond] 433:733). Some scientists claim that Europe was invaded from Africa 40,000–50,000 years ago during the Paleolithic period. Others favor the demic-diffusion hypothesis according to which during the Neolithic period (10,000 years ago) humans migrated to Europe from the Near East bringing with them early agricultural practices. Others postulate that agriculture moved to Europe without actual migration of people. According to some views, these waves of immigrants failed to interbreed with the earlier settlers. According to others, the origin was not supposed to be multiple but multiregional (Wolpoff MH et al 2000 Am J Phys Anthropol 112:129), yet *Homo erectus* continuously interbred with the different geographically dispersed populations of *H. sapiens*. These different concepts are based on fossil, skeletal morphology, mtDNA, and

Y chromosome and classic gene frequencies. Ancient migration from Africa via Southeast Asia might have taken place southward to Australia and northward to China and Japan. Indians and Eskimos populated the Americas about 10,000 years ago through a land bridge across the Behring Strait from North Asia. The ancestral size of the original human population (about 10,000) was inferred from DNA sequence variations using statistical methods (Yang Z 2002 *Genetics* 162:1811). ▶hominoids, ▶radiocarbon dating, ▶argon dating, ▶Out-of-Africa, ▶Y chromosome, ▶Eve foremother; Lell JT, Wallace DC 2000 *Am J Hum Genet* 67:1367; Tishkoff SA, Verelli BC 2003 *Annu Rev Genomics hum Genet* 4:293.

H

Human Population Growth (Modified after Biraben JN 1980 *Population* 4:1): Some calculations indicate a 2/3 probability that the world's population will not double during the twenty-first century (see Table H4). Probabilistic forecast indicates 85% chance that the world population will cease growing by the end of the twenty-first century and the probability is 60% that it will not exceed 10 billion by the end of this century. After that there is a 15% chance for decline. The United Nations currently predicts 8.9 billion by 2050. ▶age-specific birth and death rates, ▶human origins; Lutz W et al 2001 *Nature [Lond]* 412:543; tragedy of the common: <http://www.un.org/popin/data.html>.

Table H4. Human Population Growth

| Years | 400 | 1 | 500 | 1000 | 1500 | 2000 |
|--------------------|-----|-----|-----|------|------|-------|
| Millions of people | 160 | 250 | 200 | 250 | 460 | ≈6000 |

Human Protein Atlas (www.proteinatlas.org/): Expression, localization and classification of proteins (antibodies) in human tissues and cancers. It displays the encoding genes according to chromosomes, homologies with other species, references, etc.

Human Races: Human races are distinguished by anthropologists on the basis of anthropometric traits. Geneticists delineate the races on the basis of *gene frequencies* shared within the group and as different from other “racial” populations. The classification of “races” is compounded by social and cultural factors. The main human races are Caucasoid, Mongoloids (including Chinese, Japanese, Koreans, and American Indians, etc.), and Negroid. Khoisanoids or Capoids (Bushmen and Hottentots) and Pacific races (Australian aborigines, Polynesians, Melanesians, and Indonesians) may also be distinguished. Many other subgroups within the larger ethnic groups may be classified. There is no genetic incompatibility among the various human races and there is no

well-founded scientific evidence that interracial marriage would lead to the disruption of co-adapted gene blocks resulting in biological or mental deterioration in the offspring. The three major human races are genetically closely related as indicated by determination of evolutionary genetic distance. There is a controversy in the biomedical community as to what extent race would have any meaning for therapy. Different alleles are represented by different frequencies among ethnic groups and there may be differences in response to medication and a different need for social services. The human race is extremely closely related on the basis of DNA sequences to primates, primarily to chimpanzees, yet the genetic isolation is complete. ▶allelic frequencies, ▶evolutionary distance, ▶genetic isolation, ▶racism, ▶SNIPs, ▶miscegenation, ▶interracial human hybrids, ▶primates, ▶*Homo sapiens*, ▶human evolution; Barbuji G et al 1997 *Proc Natl Acad Sci USA* 94:4516; Roychoudhury AK, Nei M 1988 *Human Polymorphic Genes: World Distribution*. Humanics: Combination of genetics and social sciences.

Humanin: A short polypeptide that prevents neuronal death in Alzheimer disease. ▶Alzheimer diseases; Hashimoto Y et al 2001 *Proc Natl Acad Sci USA* 98:6336.

Humanized Antibody: A chimeric molecule with the variable region of the mouse fused to the constant region of the human antibody. This molecular chimera retains its binding specificity and some characteristics of the human antibody. Some humanized antibodies have been tried as immunosuppressors of lymphatic, breast, and other tumors. Hyperchimerization and civilization are synonyms of humanized antibody. Humanized mouse antibodies (mAb) reduce allergic response. Making alteration in the Ab amino acids can also mask mouse epitopes. For therapeutic mAb it is important that it be effective in cytotoxicity. The Fc in mouse may make this effector function insufficient. The humanized form produced in non-human cells may alter the expected glycosylation pattern and may make it less effective. If mAb is produced in human B-lymphocytes, the

immunogenic risk can be reduced. Either human B cells are immunized *ex vivo* in the presence of human antigens and then immortalized by cell fusion, or donors are selected with high immunoreactivity to the specific antigen. By such procedures mAbs are generated with specificity for human mesothelin and granulocyte-macrophage colony-stimulating factor (GM-CSF), which are now in preclinical trial (Li J et al 2006 Proc Natl Acad Sci USA 103:3557). ▶antibody, ▶immune system, ▶HAMA, ▶veneering of antibody, ▶epitope, ▶monoclonal antibody, ▶GM-CSF, ▶mesothelin; Vaswani SK, Hamilton SG 1998 Ann Allergy Asthma Immunol 81(2):105.

Humor: Body fluid, like the serum. It contains important solutes.

Humoral Antibody: The humoral antibody is made by the B lymphocytes and circulates in the bloodstream rather than being attached to the surface of T lymphocytes. ▶immune system, ▶antibody

Humoral Antigen: The humoral antigen is secreted into the bloodstream. ▶B cell, ▶T cell, ▶immune system

Humunculus: A seventeenth–eighteenth century preformationist figment that either in the human egg or sperm a miniature version of a human adult resides that eventually develops into a human embryo. ▶preformation

Humus: Decaying organic matter in soil.

Hunter Syndrome: ▶mucopolysaccharidosis (MPS II)

Hunter-Thompson Chondrodysplasia: ▶chondrodysplasia

Huntingtin: ▶Huntington's chorea

Huntington's Chorea (Huntington's disease, HD): A dominant, gain-of-function, genetic disorder (chromosome 4p16.3) with a prevalence of 4 to 9×10^{-5} live births of Western European descent. The deletion of this chromosomal area leads to the Wolf-Hirschhorn disease. It is a progressive degeneration of the basal ganglia (spinal cord) and the brain cortex causing uncoordinated (choreic) movements and loss of mental abilities (dementia). It exists in the juvenile (akinetetic/rigid) form with an onset in the teen years or with the late onset at age 30 to 50. Expectancy of survival, after the first symptoms appear, is about 20 years. Motor disorders (jerkiness) in the carriers may be observed years before the onset of the disease. The late onset form is generally inherited through the mother and the early onset through the father. Although this difference of the gene with a near-perfect penetrance was attributed initially to a mitochondrial co-factor, it appears to be determined by differential methylation (imprinting). Repression of

PGC-1 α by huntingtin leads to mitochondrial dysfunction and neurodegeneration (Cui L et al 2006 Cell 127:59).

Prenatal testing is feasible because of a very closely linked DNA marker, D4S10 (G8). Because the onset is frequently delayed beyond the reproductive period, early analysis of risk on the basis of linkage to this tight molecular marker is desirable. Various biochemical alterations (GABA, glutamic acid decarboxylase, choline acetylase deficiency) may be associated with the disease. Among Huntington patients 322 mRNAs showed significant alterations in expression. On this basis—by microarray hybridization—presymptomatic individuals were distinguished from healthy individuals and Huntington patients. Alterations in mRNA correlated with the progression of the disease (Boroveczki F et al 2005 Proc Natl Acad Sci USA 102:11023). In mice, HD is frequently associated with diabetes because of deficiency of pancreatic β -cell mass and reduction in the number of insulin-containing secretory vesicles (Björkvist M et al 2005 Hum Mol Genet 14:565). It has been shown that the 'huntingtin' protein (≈ 350 -kDa) in the basal ganglia and cerebral cortex displays 37 to 121 glutamines (CAG) repeats vs. the normal protein, which have only 6–34 repeats. Amino-terminal mutant fragments accumulating in the striatal neurons are the principal cause of neuropathy. Huntingtin cleavage at the caspase-6 site mediates neuronal dysfunction (Graham RK et al 2006 Cell 125:1179).

SUMOylation of *Drosophila* huntingtin exacerbates neurodegeneration, whereas ubiquitination abrogates the process. Both SUMO and ubiquitin bind to identical lysine residues (Steffan JS et al 2004 Science 304:100). PKR binds preferentially to CAG repeats in mutant huntingtin RNA and this may be important in pathogenesis. When the mismatch repair enzyme MSH2 is deficient, the trinucleotide instability increases. Glucocorticoid receptor (GR) localizes the repeat into the nucleus. Deletion or mutation in the C-terminal of GR was found to suppress aggregation and nuclear localization. Surprisingly, mutation in the DNA-binding N-terminal domain increased aggregation and nuclear localization by GR. The chemical disruption of the aggregation may alleviate the disease (Apostol BL et al 2003 Proc Natl Acad Sci USA 100: 5950). The genetic transmission of the normal range of the repeats is stable whereas in the abnormal it is unstable. The longer repeats hasten onset and increase severity of the condition. Homozygosity may result in embryonic lethality. The polyglutamine aggregates compromise cellular viability. When in a mouse model the HD gene was turned off during development by an antibiotic in the drinking water of 18-weeks-old puppies, the extranuclear polyglutamine aggregates

were gradually reduced or disappeared and concomitantly the neurological motor disorder was alleviated. The huntingtin protein resembles neuronal nitric oxide synthase. It has been assumed that it is a transcription factor. The mutant huntingtin and atrophin-1 seem to interfere with transcription through CREB-binding protein CBP. Increased histone deacetylase activity may play a role in the accumulation of the polyglutamine tracts and the neurodegeneration. The ~10-kb normal Huntington gene is transcribed into two mRNAs of 13.5- and 10.5-kb and it is essential for embryo survival. Huntingtin binds to dynein and acts in a complex along with dynactin and huntingtin-associated protein-1 to facilitate vesicular transport (Caviston JP et al 2007 Proc Natl Acad Sci USA 104:10045). The presence of the wild type huntingtin is required for the normal production of the brain-derived neurotrophic factor (BDNF), a requisite for the survival of striatal neurons in the brain. By neural transplantation, both the cognitive and the motor system deficits may be alleviated. Mice mutant for the huntingtin gene can be normalized by introduction of the wild type HD transgene. The huntingtin-interacting protein (HIP14) is a palmitoyl transferase that controls neuron function by palmitoylation of multiple neuronal proteins (Huang K et al 2004 Neuron 44:977). The polyglutamine-induced cell death is dramatically decreased in *Drosophila* lacking the Dark/Apaf-1 protein, which regulates caspases/apoptosis (Sang T-K et al 2005 Hum Mol Genet 14:357). In *Drosophila*, single-chain Fv antibodies that bind huntingtin intrabodies reduce cellular aggregation and toxicity (Wolfgang WJ et al 2005 Proc Natl Acad Sci USA 102:11563). RNAi is a potential means for controlling HD abnormalities (Harper SQ et al 2005 Proc Natl Acad Sci USA 102:5820). Yeast has genes that appear homologous to that in humans. In a yeast test, 28 deletions suppressed toxicity of a mutant huntingtin fragment. The suppressors apparently affected vesicle transport, vacuolar degradation, transcription, and prion-like aggregations. The globular aggregates of different sizes may be the major cause of the Huntington disease (Mukai H et al 2005 Proc Natl Acad Sci USA 102:10887; ►inclusion body). One of the most potent suppressors involved kynurenine 3-monooxygenase, an enzyme mediating tryptophan degradation and reactive oxygen species (ROS), and this finding suggests a new type of therapeutic intervention in Huntington disease (Georgini F et al 2005 Nature Genet 37:526). In vitro analysis of huntingtin-mediated transcriptional repression indicates multiple transcription factor targets, particularly TFIID, TFII (Zhai W et al 2005 Cell 123:1241). ►genetic screening, ►DNA marker, ►inclusion body, ►mental retardation, ►epilepsy,

Hurler Syndrome (mucopolysaccharidosis I, MPS I, 4p16.3): Also called Scheie syndrome or Hurler-Scheie phenotype. It is due to the deficiency of α -L-iduronidase. The symptoms range from severe mental retardation, enlargement of the liver and spleen (hepatosplenomegaly, bone diseases (dysostosis multiplex), opacity of the cornea, hearing loss, and heart problems, but there is usually normal intelligence and life span. Aminoglycoside antibiotics, (geneticin, gentamycin) by suppression of nonsense mutation, may alleviate the symptoms. ►mucopolysaccharidosis, ►mucopolidosis, ►Hunter syndrome, ►hypertrichosis, ►iduronic acid, ►aminoglycosides; Keeling KM et al 2001 Hum Mol Genet 10:291.

hut Operon: Histidine utilization genes. Histidine is synthesized from three precursors ATP and phosphoribosyl-pyrophosphate (PRPP) and glutamine, and it is involved in the regulation of other amino acids by yielding both glutamate and ammonia. The operon includes five structural genes, *hutH*, *hutU*, *hutI*, *hutG* and *hutM*, and *hutP*, and regulates histidine utilization and degradation. *hutP* is just downstream of the promoter and an overlapping nucleotide sequence controls antitermination/termination of transcription. Antitermination requires L-histidine and Mg^{2+} . ►histidine operon, ►antitermination; Zalieckas JM et al 1999 J Bacteriol 181:2883, *hutP* crystal structure: Kumarevel T et al 2005 Nature [Lond] 434:183.

Hutchinson-Gilford Syndrome (progeria, HGPS): A rare very precocious aging of either recessive or dominant inheritance (human chromosome 1q) leading to heart defects and death by the second decade of life. The disease is usually accompanied by multiple heat-labile protein defects. The basic defect seems to be in lamin A. In 80% of the cases, at G608 there is a GGC→GGT transition in exon 11 of lamin A (McClintock D et al 2006 Proc Natl Acad Sci USA

103:2154). A mouse model is available for the study the progressive defect of the vascular smooth muscles (Varga R et al 2006 Proc Natl Acad Sci USA 103:3250). Lamin A precursor, prelamin, terminates with C-terminal motif CaaX (where *C* stands for cysteine, *a* for aliphatic amino acids, and *X* for a variety of amino acids). Prelamin normally is farnesylated at the C residue and the three terminal amino acids are removed by endoproteolytic cleavage. The farnesylated cysteine is carboxy-methylated. During biogenesis by a second proteolytic event, a zinc metalloprotease (Zmpste 24) removes the terminal 15 amino acids, including farnesyl and the carboxymethylated CaaX modifications. As a consequence of lamin defect, the nuclear membrane is deformed. The progeria seems to be associated with mutation of the CaaX motif (SaaX; S being serine) and abnormal farnesylation due to alteration at the cleavage site and the internal deletion near the C terminus. It appears that farnesyltransferase inhibition (see Fig. H77) may alleviate or remove some of the lamin-related progeroid symptoms (Toth JI et al 2005 Proc Natl Acad Sci USA 102:12873; Mallampalli MP et al 2005 Proc Natl Acad Sci USA 102:14416). In the great majority of cases, “Progeria of Childhood” a single nucleotide mutation (1824 C→T) in the *LMNA* gene, which encodes lamin A and C, nuclear intermediate filaments that are important components of the nuclear lamina is responsible for the anomaly. Short hairpin RNA (shRNA) constructs were designed to target by lentivirus vector the 1824 C→T mutations in pre-spliced or mature *LMNA* mRNAs. One of the shRNAs targeted to the mutated mRNA reduced the expression levels of Δ50 lamin A to 26% or lower and improved the disease symptoms including senescence of cells (Huang S et al 2005 Human Genet 118:444).

Figure H77. Progeria. Left: farnesyltransferase-inhibitor reversed nuclear damage. Right: untreated cells. (Courtesy Dr. Brian C. Capell, NHGRI)

In HGPS patients with a mutant lamin, loss of facultative heterochromatin was observed. This loss was associated with loss of histone H3 trimethylated lysine (H3k27) in the inactive X chromosomes of

human females. In constitutive pericentric heterochromatin, trimethylation of histone 3 lysine 9 (H3K9) and levels of heterochromatin protein HP1α and the CREST antigen were also reduced. The reduction was accompanied by an increase of trimethylation in H3K20, a biomarker for constitutive heterochromatin. These epigenetic alterations seem to be the molecular bases of the rapid aging caused by the disease (Shumaker DK et al 2006 Proc Natl Acad Sci USA 103:8703). ▶aging, ▶lamins, ▶CREST, ▶histones, ▶epigenesis, ▶heterochromatin; Eriksson A et al 2003 Nature [Lond] 423:293; Goldman RD et al 2004 Proc Natl Acad Sci 101:8963.

HUVEC: Human umbilical vein endothelial cells.

HVEM (herpes virus entry mediator): HVEM may block the entry of herpes virus into T cells but not into other cells. The 283-276 residue protein participates together with its receptor, LIGHT, in TNF function. ▶LIGHT, ▶TNF

HVR: Hypervariable regions in the DNA. ▶DNA fingerprinting, ▶somatic hypermutation

H-Y Antigen (6p23-q12, structural gene): A histocompatibility antigen controlled by another gene on the X chromosome (Xp22.3, HYR), the H-Y regulator. The HYA histocompatibility Y antigen is located in the long arm of the Y chromosome (Yq). It was recognized by rejection of skin grafts of male donors by female recipients, but the male recipients did not reject the grafts donated by females. The mice involved in these studies were inbred for many generations and were supposed to be isogenic, except for factors in the Y-chromosome. Therefore, the rejection was attributed to a male-specific antigen. Thereupon it was hypothesized that the H-Y male-specific cell surface antigen is also a male (testes) determining factor. Another gene, SMC, encoding an H-Y epitope on both the X and the Y chromosomes was located near the centromere in the long arm of the Y-chromosome encoding an 11-peptide residue of the SMCY protein of 1539 amino acids. The X-chromosome has a homolog SMCX with about 200 amino acid site differences scattered along the entire length, except in the 11 residue H-Y antigen where there is only a single amino acid difference between the SMCY and SMCX. In the mouse, the H-Y controlling gene (*Hya*) in the short arm of the Y chromosome and the epitope is defined by the octamer Thr-Glu-Asn-Ser-Gly-Lys-Asp-Ile. Exceptional individuals with XY chromosomal constitution displayed female phenotype and cytological analyses revealed a deletion at the tip of the short arm of the Y-chromosome. Also, chromosomally XX exceptional males carried a translocated terminal segment of the short arm of the Y-chromosome in one

of the X-chromosomes. This terminal segment was thus identified as the testis-determining factor (TDF) and thus the H-Y antigen has a true histocompatibility role, but it is apparently not responsible for testis differentiation. The H-Y antigen is the product of several genes. The current name of *TDF* is *SRY* (sex-determining region Y). ▶chromosomal sex determination, ▶sex determination, ▶sex reversal, ▶SRY, ▶gonadal dysgenesis, ▶azoospermia, ▶testicular feminization, ▶freemartins, ▶pseudohermaphroditism; Wolf U 1998 Cytogenet Cell Genet 80:232.

Hyacinth (*Hyacinthus orientalis*): Bulbous, monocot, fragrant spring flower (see Fig. H78), $2n = 16$.

Figure H78. Hyacinth

Hyaline: A transparent membrane and cartilage protein.

Hyalinosis, Infantile Sistematic: ▶fibromatosis

Hyaloplasm: The very finely granulated part of the cytoplasm. ▶cytoplasm

Hyalurodinase Deficiency (3p21.3-p21.2): A recessive hyaluronic acid (see Fig. H79) storage disease. Short stature and excess hyaluronate occur in the fluid of the joints. ▶mucopolysaccharidosis, ▶glucuronic acid, ▶glucosamine

Hybrid: Progeny of two genetically not identical parents. ▶F₁

Hybrid Antibody: Hybrid antibodies have more than one epitope-binding site because they are produced by genetic or chemical modification. ▶hybrid hybridoma, ▶humanized antibody, ▶antibody; Chintalacheruvu KR et al 2001 Clin Immunol 101:21.

Hybrid Arrested Translation (HART): When a mRNA is hybridized with a cDNA, only those sequences can be translated in vitro that are not base-paired. The pairing prevents translation of the paired sequences. On this basis the coding sequence for a particular polypeptide can be identified. Hybridization of mRNA by antisense RNA also prevents translation. ▶antisense RNA, ▶cascade hybridization, ▶hybrid-released translation; Paterson BM et al 1977 Proc Nat Acad Sci USA 74:4370; Nagy E et al 1987 Virology 158:211.

Hybrid, Asymmetric: After somatic cell fusion some chromosomes of one of the “parental” cells were eliminated. ▶alien addition, ▶cell fusion, ▶somatic cell genetics

Hybrid Breakdown: Reduced viability of the F₂ generation compared to the F₁. The most likely cause is homozygosity of deleterious recessive genes or negative recessive epistasis. ▶epistasis

Hybrid Capture: A commercial (Digene Corp. Silver-spring MD) DNA solution hybridization method for testing viral cancer risks. (See Clavel C et al 1999 Br J Cancer 80:1306; Lörincz AT 1996 J Obstet Gynecol Res 22:629).

Hybrid Depletion: Hybrid deletion identifies any cDNA that encodes a subunit of a multimeric protein. It is managed by preparing an mRNA pool coding for the protein of interest. The mRNA is hybridized to a cDNA cloned in a single-stranded vector, and the hybrids are fractionated by CsCl equilibrium centrifugation providing at the bottom of the centrifuge tube the unhybridized, i.e., the antisense RNA. When it is injected into *Xenopus* oocytes along with the coding mRNA of the original pool, it may block the translation of the complementary mRNA. ▶mRNA, ▶density gradient centrifugation, ▶antisense technology

Hybrid Dysgenesis: A historical term for various genetic phenomena caused by transposable elements in *Drosophila*. It entails mutations and chromosomal rearrangements in hybrids of two genetic stocks. *P-M* system: The *P*-strains carry a transposable element and a suppressor of transposition. In the other strains (*M*), there is a genetic factor that derepresses the transposase and thus the hybrid becomes genetically unstable, while both the parental forms are stable. (The *P* and *M* originally indicate paternal and maternal conditions, respectively.). In *Drosophila*, over 30 different hybrid dysgenesis systems have been identified. The best known among them is the *P-M* system. The physical structure of a complete *P* element is shown in the diagram (see Fig. H80).

Some *P* elements have internal deletions, duplications, and substitutions (such as $\pi 2$, $Pc[ry]$). The *P* element can be *autonomous* (transpose by their own power) and *nonautonomous* (requires a more complete [helper] element to move it). The autonomy of an element has been successfully tested by introduction through transformation of an in vitro engineered *P* element ($Pc[ry]$) carried on a plasmid along with the *rosy* gene (*rosy* is the structural gene for xanthine dehydrogenase [map position 3–52] and mutants have rosy eyes). The wild type allele introduced into *ry*[−] homozygotes have normal eyes and are capable of moving into the *sn* (*singed*, map location 1–21, responsible for bristle [microchaetae] deformations), and this fact can easily be monitored.

The movement of *P* is controlled by the transposase function that is encoded by the four exons that extend to almost the entire length of the element (see diagram). The transposase begins transcription at

base 85 and terminates at 2696, thus the transcript includes about 2.5 kb. The transposase enzyme is an 86.8-kDa protein. The *P* element can excise almost completely and leave behind the original genomic sequence or it may delete internal sequences, sometimes including even flanking nucleotides, involving genes with a total length rarely exceeding 7 kb. The imprecise excisions generate the defective elements. The frequencies of these excisions vary, ranging from 0.4 to nearly 2% per generation of the dysgenic flies. The mutability at the *sn* locus varies from 20 to 60%, but may reach up to 90% when two reverse oriented *P* elements (*double P*) are present at the target site. The targets for insertion are not distributed at random and *P* is inserted by several orders of magnitude more frequently in the *sn* locus than into the alcohol dehydrogenase (*Adh*) gene. Also, there is a tendency for *P* elements to become clustered. For insertion, the non-translated upstream regions of genes are favored compared to the coding regions. Insertion into euchromatic sites is favored over heterochromatin. Interbands appear more likely targets over chromosomal bands. *P* elements integrate with preference for 5'-end of the genes. The integration does not seem to have base-specificity, rather some structural properties of DNA are the basis of choice for insertion. The 8-bp target site duplication created by the *P* insertion is situated within a 14-bp palindromic sequence. Also, transposition in the germline is much more frequent than in the somatic cells. The suppression of transposition of the *P* chromosomes may only partially be relieved in the strains designated as *M'*. These transposable elements induce a variety of genetic events, including

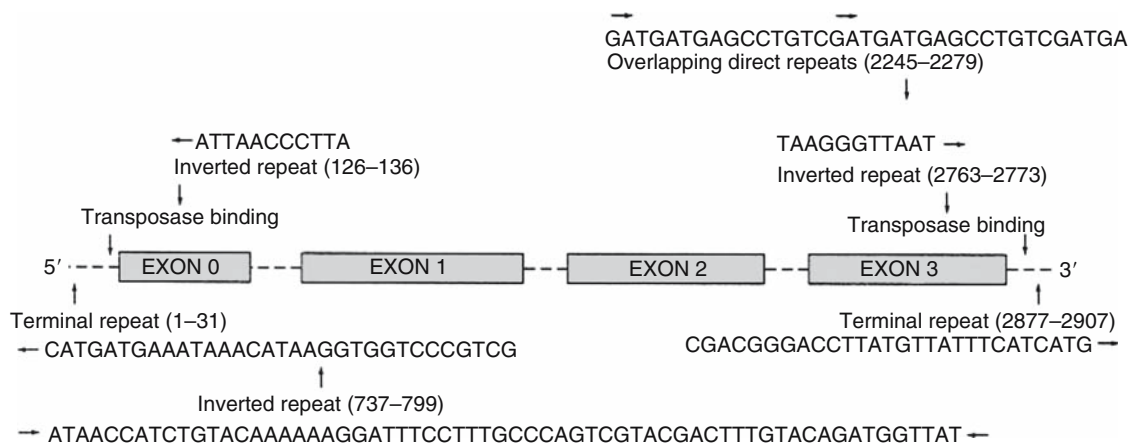

Figure H80. The structure of a complete *P* element of *Drosophila* (2,907) flanked in the genomic DNA target site by 8 bp direct repeats. The numbers in parenthesis indicate the nucleotide positions (beginning with the 5' end). The horizontal arrows indicate the direction of the repeats; the vertical arrows point toward the positions in the linear sequence of the *P* element. (After Engels WR 1989. *Mobile DNA*, Berg DE & Howe MM, eds., pp. 437–484. American Society of Microbiology, Washington, DC.)

recombination in the male *Drosophila*, mutation, and chromosomal rearrangements. P elements carrying visible markers or the molecularly defined insertions can be used for chromosome mapping (Zhai RG et al 2003 Proc Natl Acad Sci USA 100:10860). The *P-M* system slightly boosts the effect of other mutagens. The frequency of X-chromosomal rearrangements was estimated to be 10% per generation and the second breakpoint tends to stay within the same chromosome. The active transposable elements also cause segregation distortion because the transmission of the *P* chromosomes is reduced compared to the *M* chromosomes. The transposons are also associated with gonadal abnormality and (GD) sterility at temperatures particularly above 27° C. The cytological sites and cis-effects too may affect the activity of the *P* elements. Various mutations induced by *P* are subject to suppressors. This transposon, similar to others, can be used for gene tagging and isolation, particularly its special constructs carrying selectable markers such as neomycin resistance so they can be screened efficiently (smart ammunition). The element *pogo* (about 2.2-kb) is somewhat similar to *P*, and it has either 23-bp inverted terminal repeats and no target site duplication, or a 21-bp inverted terminal repeat flanked by duplication of TA. The transposable element *hobo* (variable up to 3-kb) with up to 50 copies and 8-bp targets site duplication. Some (H) *hobo* elements are located in euchromatic regions and others are empty (E) sites. Reciprocal crosses do not activate *Hobo* but its presence is associated with high degree of instabilities. “*HB*” is a small (1.6-kb) element with 20 copies and 8-bp target site duplication. *HB* contains one reading frame of 444 bp that shares 25% homology with the amino acids of the *Tc* element of *Caenorhabditis elegans*.

The other best-studied transposable system of *Drosophila* causing hybrid dysgenesis is the *I-R* system. The complete *I* element is 5.4-kb (5–15 copies/genome scattered among the chromosomes) and has many features of a retrotransposon (its transposition is via an RNA intermediate), but it does not have long terminal repeats. Thus, it is structurally quite different from *P*, yet some of its functions warrant its description. The counterpart of the *M* cytotype of the *P-M* system is the *R* (responsive) cytotype. Hybrid dysgenesis is observed in the crosses of *R* females with *I* males. These sterile/semisterile females are called SF (stérilité femelle) whereas the reciprocal non-dysgenic ones are RSF. The female sterility of *I-R* does not involve gonadal anomalies (in contrast to GD in *P-M*) but hatching of the eggs is reduced. Eventually, the *R* strains may be converted to *I* by “chromosome contamination”, i.e., accumulation of chromosomes derived from an *I* strain by crossing and segregation. *I* factor activity

involves mutations (recessive and dominant) that are frequently clustered, indicating their occurrence shortly before or at meiosis. The frequency of mutation varies at different loci and does not follow the same pattern as with *P*. The molecular structure of the complete *I* element of 5,371 bp is known. It does not have terminal repeats, however, four TAA reiterations are near the 3'-end of one strand and in the genomic DNA there are 12-bp duplications at the target site. One of the strands of *I* has open reading frames (ORF) I (1,278-bp) and II (3,258-bp), separated by 471 bases. There is probably another ORF of 228-bp. The base sequences in ORF II are similar to viral and virus-like transposases and reverse transcriptases. There are apparent coding sequences at the COOH-end for RNase H (ribonuclease digesting RNA in RNA-DNA hybrid molecules as required in reverse transcription). Elements similar to *I* have been detected in the mammalian *L1*, *Drosophila* non-viral retrotransposable elements (*F* family), *R2* ribosomal insertions in silk worm, *Cin4* element in maize, and in the *ingi* elements of *Trypanosoma brucei*. Near the 3' end of ORF II and the longest ORFs of *L1* and *Cin4* code the amino acid sequence: Cys-Pro-Phe-Cys-Gln-Gly-Asp-Ile-Ser-Leu-Asn-His-Ile-Phe-Asn-Ser-Cys that resembles the metal-binding domain of general transcription factor TFIID. ORF I has a sequence with some homology to the DNA-binding viral *gag* polypeptides (group-specific antigen). The *I* elements are most common near the centromeric regions. Mutations induced by *I* are stable and do not revert (unlike to *P*). Many of the *I* elements are truncated and show internal deletions and rearrangement. The *R* factor is quite complex, and it is determined by both nuclear and cytoplasmic regulatory components. Its role is to release the *I* elements' expression. The *FB* family of transposable elements is complex ca. 6.5-kb, or smaller size transposons cause a variety of genetic effects. They seem widespread in *Drosophila* but are present in small copy number. They cause chromosomal rearrangement in 1/1,000 chromosomes. ▶transposable elements, ▶retroposons, ▶copia, ▶HEI; Engels WR 1996 Curr Top Microbiol Immunol 204:103; Simmons MJ et al 2002 Proc Natl Acad Sci USA 99:9306; Rio DC 2002 In Craig NL et al eds Mobile DNA II. Am. Soc. Microbiol. Press, Washington, DC, USA, p 484.

Hybrid Element Insertion: In meiotic recombination induced by a P element of *Drosophila* at the site of recombination, a hybrid P element is retained, most commonly with either a deletion or a duplication. The 5' and the 3' ends two elements join into a single transposon to form a hybrid element and may jointly transpose to other positions. Recombination then

generates deletions. Subsequent recombination events contribute to additional variability. ▶ [insertion elements](#), ▶ [hybrid dysgenesis](#); Gray YH et al 1996 Genetics 144:1601.

Hybrid Histocompatibility Phenomenon: ▶ [allogeneic inhibition](#)

Hybrid Hybridoma (quadroma): Fusion of two different hybridomas. ▶ [hybridoma](#), ▶ [heterohybridoma](#); Withoff S et al 2001 Br J Cancer 84:1115.

Hybrid Inviability: A post-mating or zygotic mechanism of sexual isolation. The hybrids die either before sexual maturity or the offspring is sterile. In a case of *Drosophila* species, hybrid inviability is based on epistatic interactions of the products of genes involved in the control of the nuclear pore complex (Presgraves DC et al 2003 Nature [Lond] 423:715). ▶ [hybrid lethality](#), ▶ [hybrid sterility](#), ▶ [zygotic lethal](#), ▶ [speciation](#), ▶ [Haldane's rule](#), ▶ [embryo culture](#); Burke JM, Arnold ML 2001 Annu Rev Genet 35:31.

Hybrid Lethality: The parental forms are normal yet hybrid embryos are aborted; this phenomenon is not uncommon when different species (with different chromosome numbers) are crossed. Functionally diverged genes in the parental species can be a contributing factor of lethality in the hybrids (Brideau NJ et al 2006 Science 314:1292). ▶ [hybrid inviability](#), ▶ [hybrid sterility](#), ▶ [zygotic lethal](#), ▶ [Haldane's rule](#)

Hybrid Nucleic Acid: Double-stranded structure from two strands of different origin. ▶ [DNA](#), ▶ [DNA hybridization](#), ▶ [heteroduplex](#)

Hybrid PCR Products: Hybrid PCR products can occur when the amplified sample is heterozygous or when related sequences are amplified with the same primer. ▶ [PCR](#)

Hybrid Released Translation (HRT): In HRT, cloned DNA is attached to a membrane filter and annealed with mRNAs. Then after melting the hybridized mRNA is eluted and then translated in an in vitro system (wheat germ or rabbit reticulocytes). The labeled polypeptides are then analyzed by electrophoresis. ▶ [hybrid arrested translation](#); Conlan RS et al 1995 Plant Mol Biol 28(3):369.

Hybrid Resistance: ▶ [allogeneic inhibition](#)

Hybrid Specific Amplification (HAS): A procedure for the isolation of common fractions of two DNA samples, avoiding the repeated sequence background. The principle of the procedure is basically the same as that of subtractive suppression hybridization. ▶ [subtractive suppression hybridization](#); Lecerf F et al 2001 Nucleic Acids Res 29:e87.

Hybrid Sterility: In hybrid sterility, the hybrid gonads or gametes are abnormal and incapable of normal sexual union. Usually, this phenomenon is based on malfunction of numerous genes. More commonly, the sterility affects the males or the male gametes and the females may be successfully backcrossed with normal males. ▶ [hybrid dysgenesis](#), ▶ [hybrid inviability](#), ▶ [hybrid lethality](#), ▶ [sterility](#), ▶ [zygotic lethal](#), ▶ [male sterility](#), ▶ [Haldane's rule](#); Orr HA, Turelli M 2001 Evolution Int J Org Evolution 55:1085; Barbash DA, Ashburner M 2003 Genetics 163:217.

Hybrid Swarms: Hybrid swarms arise when the habitats of two related species are adjacent and mass outcrossing takes place. In such cases, the parental and the hybrid forms may not be easily recognized in the zone.

Hybrid Vigor: The superior performance (growth, fitness) of hybrids has been observed for centuries before the birth of modern genetics. In its simplest case, hybrid vigor may be attributed to the presence of *complementary dominant* genes. If one parent is *AAbb* and the other is *aaBB*, their offspring is *AaBb*, which has now the favorable dominant alleles at both loci (*dominance theory of hybrid vigor*). Geneticists measure vigor by reproductive advantage, fitness. The fitness of a homozygous recessive (R) class may be $w_{aa} = 1 - s$, where s is the coefficient of selection. The frequency of the homozygous recessives in a population may be determined by the rate of mutation (μ) from allele *A* to allele *a*. The average proportion of the recessive class is expected to be: $\hat{p}^2 = \mu/s$ and the average frequency of recessive alleles is expected to be $\hat{q} = \sqrt{\mu/s}$. The average fitness of the population then becomes $\hat{w} = 1 - s\hat{q} = 1 - s\sqrt{\mu/s} = 1 - \sqrt{s^2\mu/s} = 1 - \sqrt{s\mu}$.

If each of the n alleles contributes equally to the performance of the individual (additive effect), the average reduction of fitness caused by homozygosity of the recessive alleles in the populations is $n\sqrt{s\mu}$. For example, assuming that an organism has 10,000 gene loci and an average mutation rate of 10^{-5} , the selection coefficient against the recessive alleles is 0.01. After substitution we obtain $n\sqrt{s\mu} = 10,000 \sqrt{0.01 \times 0.00001} \cong 3.16$. This indicates that inbreeding may reduce fitness of the population by a factor of about three compared to the situation when each locus has at least one dominant allele at all loci of a diploid organism.

On the average, this hypothetical example is in agreement with experimental observations on inbred and hybrid populations and lends support to the dominance theory of hybrid vigor (heterosis). If the mid-parent value, $m = 0.5(P_1 + P_2)$ and $0.5(P_1 - P_2) = d$ and $h = F_1 - m$, it is possible to predict—in case of

perfect additivity of all genes and the F_1 displays hybrid vigor—the best performance to be expected by accumulating all the favorable alleles in the inbreds. $P_{\text{mx}} = m + \frac{h}{\sqrt{H/D}}$ where H are the heterozygotes and D = the homozygous dominants.

Increased vigor of hybrids may be caused also by *overdominance* (superdominance), i.e., the heterozygote Aa surpasses both AA and aa . Let us assume that the selection coefficient of each of the two classes of homozygotes (AA and aa) is -0.05 . In such a case, the three genotypic classes (according to the Hardy-Weinberg theorem) would occur in one generation of reproduction: AA (95): Aa (200): aa (95). If the population is mating at random, the allelic frequencies are equal (0.5) and the fitness of both types of homozygotes is also equal. Since the size of the population (the three classes combined) is 390 rather than 400 as expected without selection, the proportion of the surviving zygotes is $390/400 = 0.975$, indicating 2.5% (10/400) reduction by a single cycle of reproduction. This reduction may not be significant for the majority of species that produce more offspring than the population that the habitat can maintain. The reduction in size may become, however, quite serious if overdominance occurs at not only one but also at several or many loci (see Table H5). The table indicates that for most populations even a 0.5% disadvantage of the homozygotes at larger number of loci may have very serious adverse consequences and would be hardly acceptable in herds of domesticated animals or in crop plants. The contribution of overdominance at single loci may be large enough to be of selective advantage in feral conditions or improve the performance of agricultural species. ▶inbreeding, ▶selection coefficient, ▶superdominance, ▶overdominance; Barton NH 2001 Mol Ecol 10:551.

Hybrid Zone: At the geographical boundary of two races natural hybrids occur and as a result speciation may ensue. ▶speciation; Perry WL et al 2001 Evolution 55:1153.

Table H5. Reduction in population size at three different percentages of disadvantages of the homozygotes

| Number of overdominant loci | 5% | 1% | 0.5% |
|-----------------------------|------------------------|---------|---------|
| 10 | 0.77633 | 0.95111 | 0.97528 |
| 100 | 0.07952 | 0.60577 | 0.77856 |
| 1000 | 1.01×10^{-11} | 0.00665 | 0.08183 |

Hybridization: Crossing (mating) of genetically different individuals. Also, annealing DNA single strands with RNA or a single-stranded DNA of different origin (probe). The two nucleic acid strands must bear some homology to anneal. ▶Mendelian laws, ▶ c_0t curve, ▶Southern hybridization, ▶Northern hybridization, ▶Western hybridization, ▶South-Western method, ▶in situ hybridization, ▶dot blot

Hybridization Arrest: Antisense oligonucleotides selectively interfere with the function of a particular part of the genetic material by virtue of Watson—Crick or Hoogsteen base pairing. ▶antisense technologies, ▶Watson and Crick model, ▶Hoogsteen pairing

Hybridization Probe: A radioactively or by fluorochrome (e.g., biotin) labeled nucleotide sequence that hybridizes with the complementary nucleotide sequences and identifies the homologous tract(s), either on an extracted DNA or in situ in a chromosome. ▶probe, ▶radioactive label, ▶biotinylation

Hybridogenetic: A species hybrid containing, say, the A and B genomes and that normally mates with one of the parental species (say B), but its gametes transmit only one of its genomes (say A), thus the A genome is reproduced clonally while the B genome is added newly by each mating. ▶hemiclonal, Marescalchi O, Scali V 2001 Mol Reprod Dev 60(2):270.

Hybridoma: A myeloma (cancer) cell fused with a spleen B lymphocyte, producing monoclonal (identical by origin) antibodies. The cancer cell assures rapid proliferation and indefinite growth, while the other component determines the specificity. Hybridomas have many applications in basic research and are very useful for the production of monoclonal antibodies and for the generation of lymphokines. An alternative to hybridomas—which may be unstable—may be splenocytes derived from mice transgenic for temperature-sensitive SV40 large tumor antigens, driven by a mouse major histocompatibility promoter. Such a system produces monoclonal antibodies under permissive conditions (Pasqualini R, Arap W 2004 Proc Natl Acad Sci USA 101:257). ▶senescence, ▶immortalization, ▶monoclonal antibody, ▶lymphokines, ▶magic bullet, ▶lymphocytes, ▶heterohybridoma, ▶hybrid hybridoma; Springer TA ed 1985 Hybridoma Technology in the Biosciences and Medicine, Plenum, New York; European database: http://www.cabri.org/CABRI/srs-doc/ecacc_hybrid.info.html.

Hybridoma Growth Factor (HGF): ▶interferon β -2

Hydatidiform Mole (19q13.3-q13.4, 6q24): A human hyperplasia resulting from an abnormal fertilization when the epithelial layer of the ovum is induced to proliferate into a tuft of cysts resembling a bunch of

grapes. No embryo is formed. The karyotype of such a structure is 46 (XX) and all the chromosomes are derived from a diploidized sperm of 23 (X) constitution. In the familial biparental hydatidiform mole (gene NALP7, 19q13.4), the maternal complement lacks the imprinting factor but otherwise resembles the androgenetic form of the disease. In several families exon 3, exon 5, or exon 7 splice junction base substitution mutations were found. NALP7 is a maternal effect negative regulator of IL-1 β and it is involved in inflammatory responses, apoptosis, spontaneous abortion, and stillbirth (Murdoch S et al 2006 Nature Genet 38:300). ►[androgenesis](#), ►[demethylation](#), ►[imprinting](#), ►[mole](#), ►[Muckle-Wells syndrome](#); <http://orca.gen.kyushu-u.ac.jp>.

Hydra: An about 25–30 mm freshwater animal of about 100,000 cells. The freshwater hydra (*Hydra vulgaris attenuata*) (see Fig. H81) is $2n = 32$. It propagates mainly by budding; clonal offspring are produced every 1.5 to 2 days. Sexual reproduction plays a minor role; the production of a few eggs—predominantly by hermaphroditic means—takes a few weeks. It produces a variety of cell types (including a nerve system) and a differentiated body under the control of morphogens similar to those in more complex animals. Some hydras are green because of symbiosis with algae and thus in the past were mistaken as plants. They have excellent abilities for regeneration. The image shows the green fluorescent protein-labeled endodermal epithelial stem cells in transgenic *Hydra*. The procedure used permits the tracking of stem cells during morphogenesis. The photograph is the courtesy of Professor CG Bosch. ►[regeneration](#); Lohmann JU, Bosch TC 2000 Genes Dev 14:2771; Wittlieb J et al 2006 Proc Natl Acad Sci USA 103:6208; <http://www.ucihs.uci.edu/biochem/steele/default.html>; www.hydrabase.org.

Figure H81. *Hydra vulgaris*

Hydrocarbons: Organic compounds containing only hydrogen and carbon; can be aliphatic (alkanes

[paraffin], alkenes, alkynes, cyclic aliphatic) or aromatic. Although some of them are chemically rather inert (paraffin), the complex polynuclear hydrocarbons (benzo-a-pyrene, benzantracenes, methylcholantrenes) are highly toxic, carcinogenic, and mutagenic. They are present in combustion products. ►[environmental mutagens](#), ►[cigarette smoke](#)

Hydrocephalus (Xq28): A disease of cerebrospinal fluid accumulation in the brain as a result of defect in its secretion and absorption. It can be the symptom of physiological or mechanical lesions and may be due to several autosomal recessive (Dandy-Walker syndrome) occlusions of the openings of the fourth ventricle of the brain, the symptoms of Albers-Schönberg osteopetrosis [extreme bone density and bone proliferation]). Autosomal dominant (achondroplasia, osteogenesis imperfecta congenital Type II, defects in bone formation), X-linked recessive (narrowing of a brain fluid channel following inflammation or bleeding), and X-linked dominant (orofacial-digital syndrome I, involving oral, digital and mental abnormalities) genetic causes are involved. Its prevalence is 0.01 to 1×10^{-3} births. It may be entirely sporadic, or the recurrence risk when it is hereditary may vary from 15 to 50% within families, depending on the type of inheritance involved. Prenatal diagnosis may be feasible using ultrasound detection or brain tomography or magnetic resonance imaging. ►[prenatal diagnosis](#), ►[mental retardation](#), ►[Walker-Wagner syndrome](#), ►[Arnold-Chiari malformation](#), ►[orofacial-digital syndrome](#), ►[Dandy-Walker syndrome](#), ►[osteopetrosis](#), ►[sonography](#), ►[anencephaly](#)

Hydrocortisone: A glucocorticoid hormone, an anti-inflammatory drug. It can be biosynthesized in yeast with the cooperation of eight mammalian proteins. ►[cortisone](#); Szczebara FM et al 2003 Nature Biotechnol 21:143.

Hydrogel: Synthetic extracellular matrix for in situ genetic engineering. It may assist tissue morphogenesis and tissue remodeling and regeneration by cell adhesion, growth factors, and cell-associated proteases. (Pratt AB et al 2004 Biotechnol Bioeng 86:27).

Hydrogen Bond: A weak bond between one electronegative atom and a hydrogen atom that is covalently linked to another electronegative atom C or N. Hydrogen bonds tie together the polynucleotide chains of a DNA double helix ($A = T$ and $G \equiv C$), and also affect conformation of proteins. ►[hydrogen pairing](#), ►[base analogs](#), ►[Watson and Crick model](#), ►[protein structure](#); Pauling L 1960 The Nature of the Chemical Bond, Cornell Univ. Press, Ithaca, NY; Luscombe NM et al 2001 Nucleic Acids Res 29:2860.

Hydrogen Hypothesis: ►endosymbiont theory

Hydrogen Pairing: Hydrogen pairing secures the double-stranded form of DNA or RNA by establishing hydrogen bonds between the O atom attached to the C atom at position 4 (or position 6, depending upon whether the American or the Beilstein numbering system is used for the pyrimidine ring) of thymine (uracil) and the NH₂ group at the C of position 6 in

adenine. The second hydrogen bond is formed between the hydrogen attached to the N at position 3 (or according to the Beilstein system 1) of the pyrimidine ring of thymine. Cytosine pairs with three hydrogen bonds with guanine between positions 4-6, 3-1 and 2-2 as shown in the figure (see Fig. H82). Cytosine and adenine cannot form hydrogen bonds, unless a tautomeric shift occurs. Similarly, the pairing of thymine (or analogs) with guanine requires another

Figure H82. Keto–enol transformations. Hydrogen bonding between DNA bases. Normal bonds are dashed lines. After tautomeric shift, the hydrogen bonds are formed as represented by the heavy lines.

tautomeric shift. The tautomeric shift is an isomerization of the bases, changing the position of a hydrogen atom from position 3N to position O⁴ on the thymidine molecule, or moving one hydrogen from N⁶ position to 1N position in adenine. As the formula shows, the bases may undergo keto–enol transformations. Although hydrogen bonding assures the great specificity of DNA replication the deoxythymine and the deoxyadenine analogs difluorotoluene deoxynucleoside and 9-(*aza*-4-methyl-benzylimidazolyl)-1'-β-2'-deoxyribose, which are very similar in shape to the normal nucleosides are incapable of hydrogen pairing. Nevertheless these analogs are capable of directing the *in vivo* incorporation of thymine and adenine, respectively with high fidelity (Delaney JC et al 2003 Proc Natl Acad USA 100:4469). This fact indicates that the base shape alone may be sufficient to determine the fidelity during the transfer of the genetic information. ▶DNA, ▶base substitution, ▶point mutation, ▶base analogs, ▶tautomeric shift, ▶imino transformation, ▶steric-exclusion model, ▶metallo-base pairing; see Fig. H83; Kool ET 2001 Annu Rev Biophys Biomol Struct 30:1; chemically redesigned bonds: Brenner SA 2004 Science 306:625.

Figure H83. Enol keto interconversion

Hydrogen Peroxide (H₂O₂): H₂O₂ may act as an intracellular messenger in both plant and animal tissues. In plants, salicylic acid inactivates catalase and that may be a factor in the activation of plant defense mechanisms against pathogens. In animal tissues, it may be involved in the activation of NF-κB transcription factor, the regulation of the immune reaction, and immunosuppression. H₂O₂ may initiate apoptosis. When cells are stimulated by cytokines, phorbol esters and growth factors, H₂O₂ may be released into the extracellular space. ▶NF-κB, ▶host-pathogen relationship, ▶immunosuppression, ▶glucocorticoids, ▶granulomatous disease, ▶super-oxide dismutase, ▶ROS, ▶OH[•]

Hydrogen Pump: ▶proton pump

Hydrogenosomes: Mitochondria-like organelles in *Trichomonads* that seem to be evolutionarily precursors of mitochondria (Boxma, B. et al. Nature [Lond] 434:74). They are surrounded by double membrane and produce ATP from pyruvate and hydrogen or other molecules, but have no DNA. In the ciliate *Nyctotherus ovalis*, living in the intestinal tract of

cockroaches, hydrogenosomes were found that contain a minimal DNA genome, but the hydrogenase gene of the ciliate resides in the nucleus and the protein encoded by it is imported into this organelle. In the hydrogenosome of the parasite, *Trichomonas vaginalis*, DNA could not be found (Clemens DL, Johnson PJ 2000 Mol Biochem Parasitol 106:307). ▶mitochondria, ▶mitochondria cryptic, ▶mitosome, ▶endosymbiont theory; Dyall SD, Johnson PJ 2000 Curr Opin Microbiol 3(4):404; Sutak R et al 2004 Proc Natl Acad Sci USA 101:10368.

Hydrolases: Enzymes carrying out hydrolysis reactions. ▶hydrolysis

Hydrolethalus Syndrome: Recessive 11q23-q25 hydrocephalus, polydactyly, and other developmental defects, which have a prevalence ~2 ↔ 10⁻⁴ in Finland.

Hydrolysis: Splitting a molecule by inserting a molecule of water; one of the parts of the former will obtain OH, and the other H, from the H₂O.

Hydropathy Index: The hydropathy index indicates the relative hydrophilic and hydrophobic properties of chemicals.

Hydropathy Plot: The hydropathy plot is used to determine the hydrophobic amino acid tracts in (membrane) proteins on the basis of the energy requirement for transfer into water from a nonpolar solvent. ▶membrane proteins; Jayasinghe S et al 2001 J Mol Biol 312:927.

Hydrophilic: A hydrophilic substance is readily miscible with water; it has polar groups.

Hydrophobic: A hydrophobic substance is insoluble in water, or poorly (if at all) soluble in water; it lacks polar groups. Also, the (unjustified) fear of (drinking) water, such as occurs in the viral disease *rabies*, is called hydrophobia.

Hydrophobic Vacuum Cleaner: The mechanism of action of multidrug resistance transporters. ▶multiple drug resistance; Sharom FJ et al 2001 Semin Cell Dev Biol 12(3):257.

Hydrophobin: A hydrophobic membrane material on the surface of aerial hyphae and on dikaryons of fungi. ▶hypha, ▶dikaryon; Wosten HA 2001 Annu Rev Microbiol 55:625.

Hydroponic Culture: Growing plants in salt solutions, rather than in soil, under semi-axenic conditions. (See Hill WA et al 1992 Adv Space Res 12(5):125).

Hydrops: An edema (accumulation of fluids) may occur in kidney diseases or in erythroblastosis fetalis and in many other diseases. ▶erythroblastosis fetalis

Hydrops-Ectopic

Motheaten Skeletal Dysplasia (HEM, Greenberg dysplasia, 1q42.1): A short-limbed dwarfism with ectopic and unusual ossifications. Cholesterol synthetic enzyme or lamin B receptor defects may be involved. ▶ [laminopathies](#), ▶ [cholesterol](#); Chitayat D et al 1993 Am J Med Genet 47:2723.

Calcification–

Hydrops Fetalis: Prenatal anemia accompanied by fluid accumulation in the fetal body, caused by failure to synthesize the α chain of hemoglobin (an extreme form of thalassemia major), or by destruction of hemoglobin in other hemolytic anemias (rh). The idiopathic form is of spontaneous origin and others are caused by certain immunological conditions. ▶ [thalassemia](#), ▶ [hemoglobin](#), ▶ [Rh](#), ▶ [erythroblastosis fetalis](#), ▶ [adrenomedullin](#)

Hydroxyapatite: Calcium phosphate hydroxide (may contain also silica gel). The phosphate residues of nucleic acids bind to calcium and thus double-stranded DNA binds to it more strongly than it does to single-stranded molecules. On this basis, by adsorption chromatography, the two types of DNA can be separated from each other and DNA-RNA hybrids can be separated from RNA. The single-stranded molecules come off the columns by low molarity buffer, and at higher molarity the double-stranded molecules can be eluted. Hydroxyapatite also participates in calcification of the extracellular matrix and in bone formation. Calcification of the arteries may lead to aortic failure and death.

Hydroxyguanine: One of the products of oxidative damage to the DNA that is generally repaired by base excision. ▶ [DNA repair](#); Tuo J et al 2001 J Biol Chem 276:45772.

Hydroxyl Radical ($-\text{OH}^\cdot$): The hydroxyl radical is widespread in biological molecules; it can be formed from hydrogen peroxide in the presence of transition metals and may cause damage to macromolecules. A relational database, ORChID (OH Radical Cleavage Intensity Database), contains extensive hydroxyl radical cleavage data produced from two DNA libraries (Greenbaum JA et al 2007 Genome Res 17:947). ▶ [hydrogen peroxide](#), ▶ [transition state](#), ▶ [ROS](#), ▶ [SOD](#)

Hydroxylamine (NH_2OH): An antagonist of pyridoxal-phosphate (PLP)-requiring enzymes, cleaves Asp-Gly linkages at high pH, blocks oxidation of H_2O , but permits electron transfer through photosystems I and II from artificial donors. Its poisonous effect (α effect) may be based also on its high nucleophilic reactivity. For genetics, it is important that hydroxylamine react with carbonyl groups ($\text{C}=\text{O}$) of pyrimidines, target specifically cytosine residues in nucleic acids,

generate hydroxylaminocytosine (a thymine analog), and cause the transition of a $\text{G} \equiv \text{C}$ base pair into a $\text{T} = \text{A}$ pair, resulting in base-specific mutations. It is however, a weak mutagen, effective in prokaryotes, but without much effect in higher eukaryotes. ▶ [transition mutation](#), ▶ [base analog](#), ▶ [base substitution](#), ▶ [hydrogen pairing](#); Freese E 1971 In: Hollaender A (ed) Chemical Mutagens, Plenum, New York, p 1.

21-Hydroxylase Deficiency: ▶ [adrenal hyperplasia](#)

5-Hydroxymethyl Cytosine: The most common form of cytosine in T-even phage DNA. ▶ [DNA methylation](#), ▶ [5-azacytidine](#), ▶ [DNA base composition](#)

3-Hydroxy-3-Methylglutaryl CoA Lyase Deficiency: Leucine is degraded in six enzymatic steps into acetoacetic acid and in the process acetyl-CoA is generated. The last enzyme in this path is 3-hydroxy-3-methylglutaryl CoA lyase. Deficiency of this enzyme causes acidosis (accumulation of acids) and reduction of sugar in the blood (hypoglycemia). This potentially fatal disease is controlled by autosomal recessive mutation. ▶ [isoleucine-valine metabolic pathway](#), ▶ [isovalericacidemia](#), ▶ [methylcrotonylglycinemia](#), ▶ [methylglutaconicaciduria](#), ▶ [amino acid metabolism](#)

Hydroxytryptamine: ▶ [serotonin](#)

Hydroxyurea (NH_2CONHOH): An inhibitor of ribonucleoside reductases; thereby it prevents the formation of deoxyribonucleotides from ribonucleotides. Consequently, it blocks DNA synthesis in the S-phase of the cell cycle and thus, is also an antineoplastic agent and a strong poison. ▶ [neoplasia](#), ▶ [S phase](#), ▶ [DM \[doubleminute\] chromosome](#)

Hyena: *Crocuta crocuta*, $2n = 40$; *Hyena brunnea*, $2n = 40$. ▶ [behavior genetics](#)

Hygromycin B (Hyg, {5-deoxy-5-[[3-[4-[(6-deoxy- β -D-arabino-hexofuranos-5-ulos-1-yl)oxy]-3-hydroxyphenyl]-2-methyl-1-oxo-2-propenyl]amino]-1-2-O-methylene-D-neoinositol}): An antibiotic, commonly used for screening transformed plant and animal cells by the expression of hygromycin phosphotransferase gene (*hph*) as a selectable marker (confering resistance). Hyg inhibits ribosomal ATPase. It is also an antihelminthic drug. ▶ [antibiotics](#); Ganoza MC, Kiel MC 2001 Antimicrob Agents Chemother 45:2813.

Hylandra suecica (formerly *Arabidopsis suecica*): a putative amphidiploid ($2n = 26$) of *Arabidopsis thaliana* ($2n = 10$) and *Cardaminopsis arenosa* ($2n = 32$). The photograph (see Fig. H84) is of laboratory specimens of *Cardaminopsis* ($2n = 32$) and *Arabidopsis* ($2n = 20$) and the hybrid is an amphidiploid ($2n = 16 + 10$); (Rédei, unpublished). (See Löve Å 1961 Svensk Bot Tidskr 55:211).

Figure H84. Hylandra is a putative hybrid of *Cardaminopsis* and *Arabidopsis*

Hymenium: A fruitingbody-forming tissue in fungi.

Hyoscyamine: An anticholinergic alkaloid that blocks neurotransmission through the parasympathetic system (originating in the brain and controlling the heart, head, neck, chest, abdomen, and pelvic organs). It is an alkaloid of the solanaceous species of plants *Hyoscyamus*, *Datura*, and *Atropa*. ▶alkaloids

Hyoscyamus: ▶henbane

Hyperactivity: ▶attention deficit-hyperactivity

Hyperacute Reaction (HAR): In the hyperacute reaction, in xenotransplantation of organs to immunologically competent human tissues, the circulating natural antibodies immediately recognize the Gal α 1-3Gal antigens on the endothelial lining of the graft vascular tissues and this activates the recipient's complement. As a result, the transplant is destroyed within minutes to hours. ▶xenotransplantation, ▶xenograft, ▶complement, ▶antibody, ▶grafting in medicine; Dawson JR et al 2001 Immunol Res 22 (2–3):165.

Hyperammonemia: ▶carbamoylphosphate synthetase deficiency, ▶ornithine transcarbamylase deficiency, ▶ornithine aminotransferase deficiency, ▶urea cycle, ▶glutamate dehydrogenase, ▶acetylglutamate synthetase deficiency

Hyperargininemia: ▶argininemia

Hyperbetalipoproteinemia: ▶hyperlipoproteinemia

Hyperbilirubinemia: Excessive amounts of bilirubin in the blood causing jaundice, common symptom of several diseases involving destruction of red blood cells. It may be involved in indirect epistasis. ▶Dubin-Johnson syndrome, ▶Criggler-Najjar syndrome, ▶Gilbert syndrome, ▶bilirubin, ▶epistasis

Hyperbranched Strand Displacement Amplification: By hyperbranching, hundreds of DNA copies are generated within a few hours. The procedure permits

identification of gene losses or dosage imbalance in tumor cell lines. Comparative genomic hybridization is applicable to the samples. ▶comparative genomic hybridization; Lage JM et al 2003 Genome Res 13:294.

Hypercalciuric Hypercalcemia: There are two forms of hypercalciuric hypercalcemia: the homozygous dominant primary severe neonatal, the hyperparathyroidism (NSHPT) at chromosome 3q13.3-q21, and the heterozygous (recessive) hypocalciuric hypercalcemia (HHC1) at the same 3q13.3-q21 chromosomal location. The basic defect is attributed to G-protein receptors and the connected Ca²⁺ sensors that are involved in parathyroid hormone release from the cell. ▶hypercalcemia-hypercalciuria, ▶G-proteins, ▶parathormone

Hyperchimerization: Hyperchimerization indicates the production of humanized antibodies by transfer of the CDR. ▶humanized antibody, ▶CDR, ▶civilization

Hypercholanemia, Familial: Familial hypercholanemia involves elevated serum bile acid level, fat malabsorption, and itching. The basic defect is in the tight junction protein-2 (TJP2, 9q12-q13) that binds the cytoplasmic C termini of the proteins to the cytoskeletal actin. Defects in glycine *N*-choloyltransferase (BAAT, 9q22.3) also disrupt bile acid transport and circulation. Thus, a complex inheritance is displayed. (Carlton VEH et al 2003 Nature Genet 34:91).

Hypercholesterolemia: ▶familial hypercholesterolemia

Hyperchromicity: As per hyperchromicity, single-stranded nucleic acids have increased UV absorption relative to the double-stranded molecules. ▶DNA, ▶DNA denaturation, ▶DNA thermal stability

Hyperferritinemia with Cataracts: An iron storage disease encoded at 19q13.3-q13.4. ▶ferritin

Hypergeometric Distribution: In hypergeometric distribution, when a collection or population is sampled

(selected) without replacement, the probabilities will change, unlike in the binomial or multinomial distributions where the basic probabilities are assumed to remain constant. The distribution can be characterized by the formula shown. Where T = the finite number of elements, k = the exclusive and exhaustive classes of T , N = the number of observations = $n_1 + n_2 + \dots + n_k$, $T = T_1 + T_2 + \dots + T_k$. ▶distributions, ▶Fisher's exact test; McDonald JW et al 1999 Biometrics 55:620.

$$\frac{\begin{bmatrix} T_1 \\ n_1 \end{bmatrix} \begin{bmatrix} T_2 \\ n_2 \end{bmatrix} \dots \begin{bmatrix} T_k \\ n_k \end{bmatrix}}{\begin{bmatrix} T \\ N \end{bmatrix}}$$

H

Hyperglycemia: The increase in blood glucose level.

Hyperglycerolemia: ▶glycerol kinase deficiency

Hyperglycinemia (hyperglycinuria, 13q32): Hyperglycinemia may be the result of a deficiency of propionyl-CoA carboxylase I. It may cause protein intolerance, retarded development, swollen face, lethargy, frequent vomiting, low platelet counts, and other blood diseases. ▶thrombocytopenia, ▶glycinemia ketotic, ▶glycine biosynthesis, ▶iminoglycinuria

Hyperhaploid: Gametes with more than the full basic chromosome number. ▶disomic

Hyperhomocysteinemia (MTHFR, 1p36.3): MTHFR is caused by mutation in the 5,10-methylenetetrahydrofolate reductase (MTHFR) enzyme, and homozygotes for the condition have increased levels of homocysteine, an increased risk of cerebrovascular (brain), and peripheral (vein) and coronary heart disease. Mutations in methionine synthase (1p43) may be responsible for both hyperhomocysteinemia and hypermethioninemia (Watkins D et al 2002 Am J Hum Genet 71:143). Homocysteinemia may be caused also by other metabolic defects. ▶homocystinuria, ▶cobalamin, ▶vitamin B12 defects, ▶tetrahydrofolate; Chen Z et al 2001 Hum Mol Genet 10:433.

Hyper-IgE Syndrome (Job syndrome): An immunodeficiency with high IgE, recurrent skin abscesses, and pneumonia, located in the short arm of human chromosome 4.

Hyper-IgM Syndrome: ▶immunodeficiency

Hyper-IgM Syndrome (HIGM, HIM, X-linked immunodeficiency with hyper IgM): HIGM is located to chromosomal position Xq26. Although initially a defect in the B cells was suspected, recent evidence indicates a defect involving a ligand of CD40 in the helper T cells. Other symptoms (neutropenia, inflammations, etc.) have also been described. Usually, the

production of IgG, IgA, and IgE is reduced, but IgM and IgE are not affected. The clinical symptoms are respiratory infections, lymphoid hyperplasia, oral ulcers, autoimmunity, etc. ▶CD40, ▶CD-40 ligand, ▶immunoglobulins, ▶class switching, ▶ectodermal dysplasia; Weller S et al 2001 Proc Natl Acad Sci USA 98:1166.

Hyperimmunoglobulinemia D (HIDS): A human chromosome 12q24 disease with strong resemblance to mevalonic aciduria, periodic fever, rash, diarrhea, swollen lymphnodes (adenopathy), and arthralgia (pain in joints). HIDS seems to be involved with a deficiency of mevalonate kinase. ▶mevalonic aciduria

Hyperinsulinemia: ▶hypoglycemia

Hyperinsulinism: ▶hypoglycemia

Hyperkalemic Paralysis: A group of dominant periodic paralysis diseases induced by high level of potassium caused by human chromosome 17q23-q25 defects. ▶periodic paralysis

Hyperlexia: Precocious reading ability. The posterior superior temporal cortex of the brain is hyperactivated. The same area is hypoactivated in dyslexia. ▶dyslexia

Hyperlipidemia: The autosomal dominant condition has similarities to familial hypercholesterolemia, but in this case hypercholesterolemia is not found in the offspring. Familial combined hyperlipidemia (FCHL) has a prevalence of 0.01 to 0.02, and is responsible for 10–20% of the early onset coronary heart disease. One gene responsible for hyperlipidemia has been located to human chromosome 1q21-q23 in the area of the apolipoprotein A-II locus (APOA2). Generally, very low and low-density lipoproteins accumulate. Early onset is relatively rare and results in hypertriglyceridemia. Its incidence exceeds by five times that of hypercholesterolemia. ▶coronary heart disease, ▶cholesterol, ▶lipid, ▶apolipoprotein, ▶familial hypercholesterolemia, ▶familial triglyceridemia, ▶sterol, ▶HLP, ▶hypertension, ▶CD36; Allayee H et al 1998 Am J Hum Genet 63:577.

Hyperlipoproteinemia: Hyperlipoproteinemia is caused by a dominant gene in human chromosome 19q13.2, coding normally for apolipoprotein E-d, a 299-amino acid polypeptide. A defect in this protein involves the accumulation of chylomicron (a small lipoprotein which normally transports dietary cholesterol and triacylglycerides [triglycerides] from the intestines to the blood stream). As a consequence of the defect, the conditions for coronary heart disease may develop. Several forms of this disease are usually distinguished. Some types (IV) are induced by high carbohydrate diet, alcohol, uremia, glycogen storage

diseases, and steroid contraceptives. Recessive form of the Type I disease is associated with human chromosome 8p22. The latter type involves large amounts of chylomicron accumulation even on normal diet, but disappears on a fat-free diet. It may not lead to early atherosclerosis. Lipoprotein lipase activity is deficient in this recessive form. The lipase gene encodes a 475 amino acid protein, including a 27-residue leader peptide. ▶coronary heart disease, ▶lipoprotein, ▶triacylglyceride, ▶cholesterol, ▶sex hormones, ▶chylomicron, ▶atherosclerosis, ▶lipase, ▶apolipoprotein, ▶abetalipoproteinemia, ▶beta-lipoprotein

Hyperlysinemia (7q31.3): An autosomal recessive phenotype caused by a defect in the enzyme lysine- α -ketoglutarate reductase. This enzyme is a bifunctional complex also of saccharopine dehydrogenase, controlling a step subsequent to α -ketoglutarate reduction in lysine degradation. The complex is also called α -aminoacidipic semialdehyde synthase. The defect in this enzyme causes the accumulation of lysine in the blood, resulting in physical and mental retardation. Hyperlysinemia may also occur if the transport of lysine into the mitochondria fails. Dibasic aminoaciduria also involves excessive urinary excretion of lysine. ▶dibasicaminoaciduria, ▶lysine biosynthesis, ▶amino acid metabolism; Sacksteder KA et al 2000 *Am J Hum Genet* 66:1736.

Hypermethylation: In many types of cancers, dozens of genes (tumor suppressors) are silenced by hypermethylation in the promoter regions within CpG islands. The oncogenes—in contrast—are hypomethylated and thus expressed at a higher rate than in normal cell. ▶methylation of DNA, ▶hypomethylation, ▶tumor suppressor gene, ▶CpG island, ▶oncogene

Hypermorphic Mutant: A hypermorphic mutant over-expresses a particular trait. ▶hypomorphic, ▶gain-of-function mutation

Hypermutation (somatic hypermutation): A common phenomenon in the variable (V) region-coding sequences of immunoglobulin (Ig) genes. If a κ chain promoter is inserted upstream of the constant region (C), it may cause mutational events also in the C and V regions, indicating that transcription may be required for somatic hypermutation. Some other genes (e.g., BCL-6) may also undergo hypermutation if an Ig enhancer is introduced in B cells. The rate of mutation has been estimated to be six orders of magnitude higher than the average somatic rate of mutation in other genes. DNA polymerase ι (iota) seems responsible for somatic hypermutation of immunoglobulins, although the repair DNA polymerases (η , κ and rev1) are also error-prone (Faili A

et al 2002 *Nature (Lond)* 419:944). If the variable κ immunoglobulin gene segment was replaced by heterologous sequences (prokaryotic *neo*, *gpt*, or β -globin), the rate of hypermutations did not decrease. Although many of the hypermutational event appear to be point mutations, a substantial fraction of the mutations involve double-strand breaks in the B cells that have completed the cell cycle. ▶AIDS, ▶antibody, ▶affinity maturation, ▶immune response, ▶immunoglobulins, ▶junctional diversification, ▶somatic hypermutation, ▶transposon, ▶transposable elements, ▶antibody gene switching BCL, ▶enhancer, ▶neomycin, ▶DNA polymerases; Muramatsu M et al 2000 *Cell* 102:553; Kinoshita K, Honjo T 2001 *Nature Rev Mol Cell Biol* 2:493; Rattray AJ, Strathern JN 2003 *Annu Rev Genet* 37:31.

Hypermutation, Germinal: Germinal hypermutation may occur in the germinal centers under stress. This mechanism may generate random mutations, including adaptationally (evolutionarily) beneficial ones, at high frequencies. ▶directed mutation, ▶germinal center; Toellner KM et al 2002 *J Exp Med* 195:383.

Hypernephroma (adenocarcinoma of kidney): Hypernephroma, most commonly, involves rearrangement (translocations) of the short arm of human chromosome 3 or loss of 3p14.2. Trisomy or tetrasomy 7 may also be associated with kidney carcinomas. ▶renal cell carcinoma, ▶von Hippel-Lindau syndrome

Hyperornithinaemia: ▶urea cycle

Hyperoxauria: ▶oxalosis

Hyperparathyroidism (HRPT1, 1q25-q31, MEN1, 11q13): Dominant adenoma of the parathyroid gland. The condition is caused by a defect in the thyrotropin receptor A, G-protein receptor. Another dominant form is characterized by multiple bone tumors on the jaws. An autosomal recessive form affecting newborns is also known. Mutations in the calcium-sensing receptor (Casr) may upset parathyroid hormone production and may cause familial hypocalcemia or hypocalciuric hypercalcemia. The parathyroid hormone receptor is at 3p22-p21.1. ▶adenoma, ▶goiter, ▶G-protein, ▶parathormone, ▶hypocalcemia, ▶multiple endocrine neoplasia

Hyperphagia (overeating): An important cause of obesity, caused by mutation in the melanocortin receptor MC4R. ▶obesity, ▶melanocortin

Hyperphenylalaninemia: An autosomal recessive condition attributed to reduced phenylalanine hydroxylase activity or dihydropteridine reductase deficiency. Hyperphenylalaninemia is caused also by deficiency of pterin-4- α -carbinolamine dehydratase (10q22).

►phenylketonuria, ►phenylalanine, ►pteridines, ►GTP cyclohydrolase I deficiency

Hyperplasia: Abnormal increase of normal cells in a normal tissue. ►neoplasia

Hyperploid: A hyperploid contains extra chromosome(s) beyond the normal number.

Hyperpolarization: A negative shift in the electric potential in a cell membrane. ► I_h

Hyperprolinemia: Type II (1p36) is caused by autosomal deficiency of the enzyme Δ^2 -pyrroline carboxylate dehydrogenase and consequently by accumulation of proline and also glycine in the blood (the mechanism is unclear). The patients generally show some degree of mental retardation and convulsions. In Type I (22q11.2) disease, proline oxidase is deficient and renal problems occur with or without mental defects. ►proline biosynthesis, ►amino acid metabolism, ►iminoglycinuria

Hypersensitive Reaction (HR): In a hypersensitive reaction, at the place of infection by fungi, bacteria, and viruses, plant cells may suddenly die in a limited area and thus stop the spread of the infection and convey resistance to the host (see Fig. H85). This is considered to be an autophagy, an innate plant immune system. Several genes play a role in this programmed cell death (Liu Y et al 2005 Cell 121:567). The hypersensitivity reaction in case of fungi is elicited by hyphal cell membrane and in particular by the fatty acids eicosapentaenoic (EPA) and arachidonic (AA) acids, and it is inhibited by β -1,3 and β -1,6-glucans. The availability of EPA and AA is determined by lipoxygenase activity. Peroxides or other reactive oxygen intermediates (ROI) may also have a role in the development of HR and may be signal transducers. Bursts of ROI can be generated by NADPH oxidases. Mutation in the oxidase eliminates ROI but not significantly, cell death; however, in the presence of salicylic acid cell death occurs (Torres MA et al 2005 Nature genet 37:1130). In mammalian macrophages, ROI is usually aided by nitric oxide (NO) to attack invading bacteria. In plants, the HR seems to be activated by an oxidative burst and

increase in NO. In addition, NO may initiate a signaling pathway through phenylalanine ammonia lyase and salicylic acid leading to the activation of different disease resistance genes. The development of the HR may also be the cause or consequence of the alteration of ion channel functions. In bacteria, *hrp* (hypersensitivity and pathogenesis) genes and mutants were identified and these interact with various plant products, e.g., the plant flavonoids (acetosyringone) initiates the activation of the virulence cascade of *Agrobacterium*, although these bacteria do not produce a typical HR and an early report could not be generally confirmed. The hairpin 44-kDa regulatory protein has been implicated in the HR expression. The bacterial avirulence (*avr*) genes may suppress the HR, depending on particular host species. In animals, the hypersensitivity is usually called allergy. In the *immediate response*, the allergens bind to the surface of IgE and the following degranulation causes the release of histamines and interleukins resulting in inflammation. In the late-phase (4–24 h) inflammation response, leukotrienes and platelet-activating factors are secreted. The hypersensitive reaction is functionally comparable to apoptosis in animals, although it programs cell death by somewhat different mechanisms, by a vacuolar protease rather than by caspases, which do not occur in plants (Hatsugai N et al 2004 Science 305:855). Similar to animal apoptosis, the mitochondria of plants also control cell death. The pro-apoptotic Bax protein promotes plant cell death. BAX-inhibitor like proteins has also been found in plants. Plants also have caspase-like enzymes but their role in HR is not clear compared to the critical role of caspases in animals. The inner mitochondrial membrane enzyme called alternative oxidase (AOX) is absent from animal mitochondria, but present in plants. Its suppression by antimycin results in hypersensitivity and cell death. In contrast, activation of AOX may reduce the size of the necrotic spots. Some plastid proteins may also mediate HR. In plants, the MAPK pathway is activated during the hypersensitive reaction with the concomitant generation of hydrogen peroxide. ►host-pathogen relation, ►hydrogen peroxide, ►MAPK, ►allergy, ►phenylalanine ammonia lyase, ►nitric oxide, ►salicylic acid, ►histamine, ►interleukins, ►leukotrienes, ►platelet activating factor, ►apoptosis, ►porin, ►ROS; Lam E et al 2001 Nature [Lond] 411:848; Ren D et al 2002 J Biol Chem 277:559.

Figure H85. Hypersensitive reaction

Hypersensitive Site: A hypersensitive site includes nucleotide sequences, which are readily cut by endonuclease because these tracts are (relatively) free of chromosomal proteins. These sites are generally found in front of transcribed genes and it

is supposed that these facilitate the attachment of the transcriptase enzyme. ►[regulation of gene activity](#)

Hypersensitivity: A term used in mutagen (carcinogen) testing, indicating the percentage of compounds classified as carcinogens (mutagens) among all compounds tested by a system. Also, it designates atopic (hereditary) allergy manifested within minutes after exposure to an allergen. ►[allergy](#), ►[DTH](#); Kleinjan DA et al 2001 Hum Mol Genet 10:2049.

Hypertelorism: Abnormally long distance between two organs or organ parts in the body (see Fig. [H86](#)).

Figure H86. Hypertelorism

Hypertension: Hypertension is probably under the control of a few or several (~50) genes. In humans, the heritability of essential hypertension is about 30–35%. In rats, genetic analysis identified at least two genes with major effects BP/SP-1 and BP/SP-2 (blood pressure/sodium pump) in rat chromosome 10 (human chromosome 17q23). BP/SP-1 is probably linked closely to gene ACE1 (angiotensin converting enzyme). Hypertension has also an important physiological component associated with the lithium-sodium countertransport and thus depends on environmental (dietary) factors. A RHO-associated, Ca^{2+} -sensitive protein kinase seems to have a regulatory role. Hypertension occurs in about of a third of the human populations and is frequently evoked by kidney diseases. Hypertension is the most common cause of heart disease, especially among US blacks (33% vs. whites 25%). ►[coronary heart disease](#), ►[cardiovascular disease](#). Various familial disorders are frequently associated with hypertension: coarctation of the aorta, polycystic kidney disease, Alport syndrome, pheochromocytoma, neurofibromatosis, aldosteronism, hypoadosteronism, hyperthyroidism, homocystinuria, Wilms tumor, familial hypertriglyceridemia, hyperlipidemia, and hydroxysteroid dehydrogenase deficiency (11 β HSD). Blood pressure may vary from 80 mm (Hg) or less at the diastole (expansion of the heart ventricles) to the very high 200 mm at systole (contraction of the ventricles). The average normal blood pressure in adults is 80 at diastole and 120 at systole. In children it is lower, in older people it is usually higher. Elevated salt diet is normally

conducive to hypertension as the heart releases an atrial natriuretic peptide. The formation of this peptide is regulated by a guanyl cyclase A receptor (GC-A). Disruption of the GC-A gene in mice results in high blood pressure irrespective of the amount of salt in the diet. Mutations in the 11- β -hydroxysteroid dehydrogenase (16q22) may lead to hypertension. A mice mutation for Emilin1, a cysteine-rich secreted glycoprotein increases blood pressure and reduces blood vessel size. Emilin binds specifically to pro-TGF- β and inhibits its maturation by furin convertase. Inactivation of a single TGF- β allele restores blood pressure to normal level (Zacchigna L et al 2006 Cell 124:929). In patients with *essential hypertension* who typically lack sufficient RAS activation, ACE inhibitors (angiotensin converting enzyme) and angiotensin receptor blockers (ARBs) effectively reduce blood pressure and ameliorate cardiovascular complications suggesting that dysregulation of the RAS contributes to their elevated blood pressure. AT1 angiotensin receptors expressed in the kidney are the primary determinants of hypertension and end-organ damage in Angiotensin II-dependent hypertension (Crowley SD et al 2006 Proc Natl Acad Sci USA 103:17985).

A possible and promising gene therapy approach uses in an adenoviral helper vector system the gene of the atrial natriuretic peptide under the control of the mifepristone promoter. The level of the expression can be regulated according to the dosage of mifepristone. Such a system in a rodent model increased urinary cGMP output, significantly reduced systolic blood pressure and heart weight. The major advantage of this gene therapy system is its regulatable nature compared with the external supply of the peptide (Schillinger KJ et al 2005 Proc Natl Acad Sci USA 102:23789). ►[aldosteronism](#), ►[mineral corticoid syndrome](#), ►[Liddle syndrome](#), ►[Gitelman syndrome](#), ►[Gordon syndrome](#), ►[pseudohypoadosteronism](#), ►[brachydactyly](#), ►[hypotension](#), ►[angiotensin](#), ►[LDL](#), ►[nitric oxide](#), ►[stroke](#), ►[debrisoquine](#), ►[RHO](#), ►[hyperlipidemia](#), ►[hypercholesterolemia](#), ►[PPAR](#), ►[pulmonary hypertension](#), ►[DC36](#), ►[gene therapy](#), ►[adenovirus](#), ►[cGMP](#), ►[mifepristone](#), ►[TGF](#), ►[furin](#); Garbers DL, Dubois SK 1999 Annu Rev Biochem 68:127; Lifton RP et al 2001 Cell 104:545; genetic bases: Cowley AW Jr 2006 Nature Rev Genet 7:829.

Hyperthermia (malignant hyperthermia, MHS): MHS may involve only an increase of the skin temperature, or a general elevation of the body temperature (hyperpyrexia) may occur after anesthesia. The susceptibility is under dominant control in humans but it is recessive in the light-skinned pigs. Gene MHS1 is in human chromosome 19q13.1, encoding also a ryanodine receptor (RYR1), MHS2 is at

17q11.2-q24, MHS3 encodes a subunit of a voltage-dependent Ca^{+} channel at 7q21-q22, MHS4 is at 3q13.1, MHS5 at 1q32, and MHS6 is in 5p. Several other genes also play various roles in hyperthermia. ▶temperature-sensitive mutation, ▶cold hypersensitivity, ▶halothane gene, ▶ion channels, ▶ryanodine; Robinson RL et al 2000 Ann Hum Genet 64:307.

Hyperthyroidism: An autosomal dominant defect may be caused by inadequate response of the thyrotropin secreting cells to the pituitary thyroid-stimulating hormone (TSH). As a consequence, high levels thyroid hormones appear and goiter, increased pulse rate, fatigue, nervousness, sweating, heat intolerance, and other symptoms develop. In a recessive form (human chromosome 14), a deficiency of the TSH receptor is caused by an insert of a 8-amino acid sequence near the NH_2 end of the protein. A human chromosomal site (22q11-q13) codes for a thyroid autoantigen but that is not the receptor as once assumed. ▶thyroid hormone response element, ▶TRE, ▶hormones, ▶cardiovascular disease, ▶goiter

Hypertonia: Excessive tension of the muscles, hard to stretch. It seems that hypertonia in the central nervous system of the mouse is due to mutation to reduced γ -aminobutyric acid type A receptor. ▶GABA; Gilbert SL et al 2006 Nature Genet 38:245.

Hypertonic: The salt concentration of this type of solutes is high enough to draw out water from a cell. ▶isotonic, ▶hypotonic

Hypertranscription: A mechanism of dosage compensation in the male *Drosophila* by upregulation of transcription of the genes in the single X chromosome, thus making the phenotypes in males (XY) akin to females (XX). It is mediated by the MSL proteins, which seem to be required for the accumulation of histone H4, acetylated at lysine 16 in the X of the male. Apparently, MLE and MSE proteins direct an acetyltransferase to the X-chromosomal histone. ▶dosage compensation; Gorman M, Baker BS 1994 Trends Genet 10:376; Ruiz MF et al 2000 Genetics 156:1853.

Hypertrichosis: Excessive hairiness. In the autosomal dominant hypertrichosis universalis, hair covers abundantly the entire body until the end of infancy, in another form gum disease was also present. In an autosomal recessive form, the excessive hairiness was accompanied by nerve disease (neuropathy). An Xq24-q27.1-linked hypertrichosis affects the males more than the females where lyonization causes patchy appearance of hair. The condition is very rare; only about 50 cases have been so far described. Excessive hairiness does occur, however, as part of several syndromes such as the Hurler

syndrome, de Lange syndrome, Coffin-Sirius syndrome, Lawrence-Seip syndrome, Schinzel-Geidion syndrome, Gorlin-Chaudhary-Moss syndrome. ▶hair, ▶hirsute, ▶atavism, ▶lyonization; and the syndromes listed above.

Hypertriglyceridemia: An increase in the hepatic very-low density lipoprotein secretion. Carnitin appears to regulate hypertriglyceridemia. ▶hyperlipidemia, ▶carnitin

Hypertrophic Cardiomyopathy: Autosomal dominant heart defect in the β -myosin heavy chain or the myosin light chain, or troponin. ▶heart diseases, ▶myosin, ▶troponin, ▶cardiomyopathy dilated, ▶cardiomyopathy hypertrophic familial

Hypertrophy: An overgrowth generally with larger than normal cells.

Hyperuricemia: Abnormal amount of uric acid in the blood and may cause gout. ▶gout, ▶uric acid, ▶allopurinol

Hypervalinemia (valinemia): Accumulation of valine in the urine and blood plasma because of a defect in the enzyme valine transaminase, caused by an autosomal recessive factor. Symptoms include drowsiness and vomiting. Prenatal diagnosis is feasible. ▶isoleucine-valine biosynthetic pathway

Hypervariable Loci: Hypervariable loci are involved in cell surface proteins of pathogenic organisms and facilitate the evasion of the host defense system. Huntington's chorea and the fragile X syndrome in humans involve hypervariable chromosomal sites. ▶phase variation, ▶mutator genes, ▶Huntington's chorea, ▶fragile X, ▶trinucleotide repeat; Verstrepen KJ et al 2005 Nature Genet 37:986.

Hypervariable Sites: In the light and heavy chains of antibody molecules, hypervariable sites are responsible for their high specificity in recognizing different antigens. They are short polypeptide loops and called also the complementarity determining regions (CDRs). ▶antibody

Hyperzincemia: Hyperzincemia causes dwarfism, anemia, hypogonadism, etc. due to abnormally high level of Zn in the blood. ▶acrodermatitis enteropathica

Hypha (plural hyphae): Fungal filaments, cylindrical structural units of the mycelia. They are surrounded by a wall and filled with cytoplasm unless they are vacuolated. They elongate by growing at the tips (apex). When branching hyphae aggregate, they may form an erect mycelium, called *coremium*, or horizontal strands may form *rhizomorphs*. The spherical or irregular aggregates functioning as enduring (dormant) bodies are *sclerotia*. Hyphae aggregating in

pseudoparenchyma tissue are the *stroma*. Hyphae may be involved in plasmogamy and activity in some sort of sexual function (*somatogamy*), although they may not be sexually specialized. ▶ [fungal life cycles](#), ▶ [heterokaryon incompatibility](#); Xiang Q et al 2002 Genetics 160:169.

Hypoaldosteronism (adrenal hyperplasia): The two genes responsible for the recessive 11-β-hydroxylase deficiency have been located to human chromosome 8q21, and a defect of these is responsible for the accumulation of 11-deoxycorticosterone and consequently for hypertension, and other hormonal defects. The same enzymes are involved also in the hydroxylation of 18-hydroxysteroids and 17-hydroxysteroids. These genes are members of the P450 (cytochrome) enzyme coding family. Affected females show masculinization and the males show precocious puberty because of the accumulation of steroids. Some of the aldosterone deficiency mutations are allelic to the aldosterone-overproducing defect (aldosteronism) indicating the presence of a multifunctional protein. The *pseudohypoaldosteronism*, which is caused not by aldosterone deficiency but by the recessive deficiency of the mineral corticoid receptor, encoded at human chromosome 4q31.1 or q31.2. This condition is characterized by salt wasting in the urine, and responds favorably to salt administration. The hypoaldosteronism defects appear quite common among oriental (Persian) Jews. Pseudohypoaldosteronism type I may be due either to a defect in an epithelial sodium channel (ENaC) resulting in hyperkalaemic (high in potassium) acidosis and salt wasting. The α subunit of the channel is encoded in human chromosome 12p13.1-ter, whereas the β and γ subunits are coded by chromosome 16p12.2-p13.11. The most common basis of pseudohypoaldosteronism is, however, mutation in the mineral corticoid receptor gene (MRL). ▶ [aldosteronism](#), ▶ [P-450](#), ▶ [Jews and disease](#), ▶ [Liddle syndrome](#), ▶ [Bartter syndrome](#), ▶ [Gitelman syndrome](#), ▶ [mineral corticoid syndrome](#), ▶ [cardiovascular diseases](#), ▶ [ion channels](#), ▶ [pseudohypoaldosteronism](#)

Hypo-α-Lipoproteinemia (11q23.3, 9q22-q31): One of the several lipid metabolism disorders contributing to coronary heart disease. ▶ [Tangier disease](#), ▶ [lipoproteins](#), ▶ [cardiovascular diseases](#); Kort EN et al 2000 Am J Hum Genet 66:1845.

Hypoascorbemia: ▶ [ascorbic acid](#)

Hypobetalipoproteinemia (hypo-β-lipoproteinemia, 2p23, 3p21-p22): Hypobetalipoproteinemia involves dominant, reduced levels of apolipoprotein B that may result in increased levels of blood cholesterol and atherosclerosis, yet individuals with this anomaly may

have prolonged lifespan. ▶ [apolipoproteins](#), ▶ [atherosclerosis](#), ▶ [hyperlipoproteinemia](#), ▶ [abetalipoproteinemia](#), ▶ [cardiovascular diseases](#), ▶ [beta-lipoprotein](#)

Hypoblast: The precursor of the mesoderm and endoderm. ▶ [mesoderm](#), ▶ [endoderm](#)

Hypocalcemia: Reduced amount of calcium in the blood in several diseases involving defects in ion channels. Autosomal dominant hypocalcemia (CASR, 3q13.3-q21) is mutation in the calcium-sensing receptor of the parathyroid gene (PTH, 11p15.3-p15.1) or in PTH itself. ▶ [ion channels](#), ▶ [parathormone](#), ▶ [hypocalciuric hypercalcemia](#)

Hypocalciuric Hypercalcemia (HHC2, 19p13.3): The calcium level in the blood and urine is elevated. In some cases, it involves bone and blood vessel disorders. The basic defect seems to be in a G-protein receptor. The phenotype is very similar to that of hypercalciuric/hypocalciuric hypercalcemia at 3q13.3. ▶ [G-proteins](#), ▶ [hypercalciuric hypercalcemia](#)

Hypochlorate (Ca[ClO]₂): Calcium and sodium hypochlorites (hypo) are among the oldest and most effective oxidative sterilizing agents. The former does not leave alkalic residues after washing and it is more useful as an antiseptic for live tissues. ▶ [sterilization](#)

Hypochlorous Acid (HOCl): HOCl is generated in neutrophils and catalyzed by myeloperoxidase (MPO) as a highly reactive defense mechanism:

Hypochondriasis: A type of affective disorder when illness is imagined on the basis of irrelevant signs. ▶ [affective disorders](#)

Hypochondrogenesis: A connective tissue disorder caused by mutation in collagen.

Hypochondroplasia: This autosomal phenotype is reminiscent of achondroplasia, but the tibia (shin-bone) and the head are rather normal. The fingers are short but the hand is not three-pronged. This gene appears to be allelic to that responsible for achondroplasia. It may be caused by a defect in the function of fibroblast growth factor receptor 3, FGFR3 at human chromosome 4p16.3. ▶ [stature in humans](#), ▶ [achondroplasia](#), ▶ [achondrogenesis](#), ▶ [dwarfism](#), ▶ [fibroblast growth factor](#), ▶ [dwarfism](#), ▶ [receptor tyrosine kinase](#)

Hypochromicity of Nucleic Acids: In double-stranded molecules, the free rotation of the bases is hindered, resulting in reduced optical density in UV light compared to single-stranded molecules (hyperchromicity). ▶ [DNA](#), ▶ [hyperchromicity](#)

Hypocotyl: The section of a plant embryo or plant situated between the cotyledon attachment point and the radical or root, respectively.

Hypocretin: ►orexin

Hypodontia (adontia): Autosomal dominant condition of lack or underdevelopment of up to six teeth (see Fig. H87). PAX9 gene (14q21) encoding 342 amino acids is defective. ►teeth, ►dental non-eruption, ►dentinogenesis imperfecta, ►dental ankylosis, ►tooth agenesis, ►olygodentia, ►PAX

Figure H87. Hypodontia. (Form Bergsma D ed 1973 Birth Defects. Atlas and Compendium. By permission of the March of Dimes Foundation)

Hypogammaglobulinemia/

Common Variable Immunodeficiency (CVID): Complex immunodeficiency with uncertain familial determination. Defects in tumor necrosis factor-like receptor TNFRSF138 gene product, TAC1 (transmembrane activator), are involved with the condition, resulting in IgA deficiency in a complex manner (Salzer E et al 2005 Nature Genet 37:820; Castigli E et al 2005 Nature Genet 37:829). ►gammaglobulinemia, ►immunodeficiency, ►Epstein-Barr virus, ►Hirschsprung disease

Hypoglossia/Aglossia (Hanhart syndrome): Small tongue and very small mandibles, generally with short fingers. It is sporadic or autosomal recessive.

Hypoglycemia: Hypoglycemia involves lower than normal blood sugar content and may result in shaking, cold sweat, low body temperature, headache, irritability, and eventually even coma. An autosomal recessive gene may cause it by a deficiency of glycogen synthetase in the liver. Another recessive gene in human chromosome 1p31 may cause acyl-coenzyme A-dehydrogenase deficiency and hypoglycemia. Mutations in the sulfonylurea receptor gene may cause hyper-insulinemia (human chromosome 11p14-p15.1) and consequently hypoglycemia. Hypoglycemia may result indirectly from a large number of different ailments. ►epilepsy, ►ion channels, ►sulfonylurea

Hypogonadism: less than normal function of the gonads (ovary and testes); it is frequently associated with retardation in growth and mental abilities. Mutation in the DAX-1 human gene may result in adrenal defects such as adrenal hypoplasia and hypogonadotropic hypogonadism (deficiency in the hormone gonadotropin and gonadal hypofunction). Mutation in the gonadotropin-releasing hormone receptor (4q13.1-q21.1) may also be responsible. It may involve obesity. ►adrenal hypoplasia, ►Kallmann syndrome; Pitteloud N et al 2006 Proc Natl Acad Sci USA 103:6281.

Hypogonadotropic Hypogonadism (19p13.3, 9q34.3): A genetically heterogeneous defect in pubertal maturation caused mainly by deficiency of the gonadotropin-releasing hormone (GNRH1) and G-protein-coupled receptor (GPR54), receptor of the KiSS-1 peptide regulating the onset of puberty (Kaiser UB, Kuohung W 2005 Endocrine 26:277). ►Kallmann syndrome, ►luteinizing hormone-releasing, ►Marinesco-Sjögren syndrome

Hypohidrosis: Reduced ability to sweat caused by autosomal recessive defect of the sweat glands.

Hypokalemia: Autosomal recessive (16q13) low potassium and magnesium level in the body causing neuromuscular abnormalities. ►periodic paralysis, ►hypoadosteronism, ►pseudoaldosteronism, ►Gitelman syndrome, ►Bartter syndrome

Hypolactasia: ►disaccharide intolerance, ►lactose intolerance

Hypomagnesemia (11q23): A dominant renal defect involving wasting of Mg^{2+} and frequently involving Ca^{2+} excretion, due to mutation in the Na^+ , K^+ -ATPase γ subunit.

Hypomelanosis of ITO: Pale skin spots in whorls or patches of tan associated with other, diverse anomalies, indicating that this syndrome is a mixed bag, often associated with breakage of different chromosomes. ►incontinentia pigmenti, ►pigmentation defects, ►skin diseases

Hypomethylation of DNA: Hypomethylation of DNA may cause chromosomal instability and cancer. ►methylation of DNA; Eden A et al 2003 Science 300:455; Gaudet F et al 2003 Science 300:489.

Hypomorphic: The product of the gene is below the level of that of the wild type. ►leaky mutant

Hypomyelination: ►hypomyelinopathies

Hypomyelinopathies: Hypomyelinopathies involve defects in the myelin coat of the nerves, such as congenital hypomyelinating neuropathy. ►Charcot-Marie-Tooth type 1 disease, ►neuropathy, ►sensory neuropathy, ►Egr, ►Dejerine-Sottas syndrome, ►HMSN, ►HNPP

Hyponasty: ►epinasty

Hypoparathyroidism: The activity of the parathyroid gland is reduced, resulting in hypocalcemia and hyperphosphatemia. The patients suffer from neuromuscular problems including even seizures. Vitamin D may alleviate the problems. The anomaly is controlled at several autosomal locations with dominant or recessive alleles. One rare form is linked to Xq26-q27.

Hypophosphatasia: Either a *dominant* mutation expressed in adults as a deficiency of the liver (general) alkaline phosphatase gene in human chromosome 1p36.1-p34, or the *recessive* mutation in the same locus appears as the infantile hypophosphatasia. The adult phenotype involves early loss of teeth and bowed legs, like in rickets. The level of intestinal alkaline phosphatase is normal. In some forms the stature is somewhat shorter. The infantile type is manifested already before birth, and involves severe skeletal anomalies, increased levels of phosphoethanolamine, inorganic pyrophosphate in the urine, and in the serum higher levels of pyridoxal phosphate. Death may occur within a year. In some instances, infusion of normal blood plasma resulted in prolonged normalization. It was suggested that a cofactor of the enzyme is missing. ►stature in humans, ►dwarfism, ►hypophosphatemia, ►rickets

Hypophosphatemia: A dominant bone disease coded in human chromosome Xp22 region resulting in low level of phosphate in the blood, and no or minimal response to vitamin D. The defect may involve abnormal phosphate absorption too. Its prevalence is 2×10^{-4} . *Autosomal dominant hypophosphatemic rickets* (ADHR, 12p13.3) is due to mutation in gene FGF23; it is resistant to vitamin D. The *autosomal recessive gene* ARHP has been mapped to 4q21 where it encodes dentin matrix protein 1, which appears to be a regulator of FGF23, an osteomalacia (insufficient mineralization of the spongy bone, rickets) inducing protein (Lorenz-Depiereux B et al Nature Genet 2006 38:1246). The X-linked PHEX gene encodes a neutral endopeptidase and is responsible for the *hypophosphatemic rickets* (XLH, Xp22.2-p22.1). The heterogeneous *autosomal hypophosphatemic bone disease* (HBD) and the autosomal recessive *hereditary hypophosphatemic rickets with hypercalciuria* (HHRH) both respond to vitamin D. ►hypophosphatasia, ►exostosis, ►spermine, ►FGF, ►rickets; Sabbagh Y et al 2001 Hum Mol Genet 10:1539; Sabbagh Y et al 2005 Proc Natl Acad Sci USA 102:9637.

Hypoplasia: Underdevelopment of an organ. ►aplasia

Hypoploid: A hypoploid contains less than the full set of chromosomes. ►autopolyploid, ►nullisomic

Hypoproconvertinemia: A recessive bleeding disease caused by deficiency of blood clotting factor VII encoded in human chromosome 13q34-qter. The afflicted individuals may be deficient also in antihemophilic factor X. ►antihemophilic factors, ►proconvertin

Hypospadias: The urethra opens at the lower part of the penis; it has autosomal dominant and recessive transmission. Prevalence is close to 0.3%, with a heritability of about 0.57 and may accompany several syndromes, e.g., hypertelorism (22q11.2), steroid α -reductase 2 type pseudohermaphroditism (2p23), androgen receptor defects (Xq11-q12), Wilms tumor (11p13), mutation in the HOXA13 gene (7p15-p14.2), McKusick-Kaufman syndrome (20p12), etc. Hypospadias were attributed to mutation in CXorf6 (human chromosome Xq28) in Japanese populations (Fukami M et al 2006 Nature Genet 38:1369). ►penis, ►steroid dehydrogenase, ►named individual entries

Hypostasis: A condition when another gene, the epistatic one, masks the expression of a gene. ►epistasis

Hypotension: Hypotension, in contrast to hypertension, involves low blood pressure. Some of the cases may be determined only by different alleles of identical loci. The autosomal dominant orthostatic form (*Shy-Drager syndrome*) is characterized by incontinence, anhidrosis (absence of sweating), ataxia, tremor, and low norepinephrine level in the plasma. The *pseudo-hypoaldosteronism* (*PHA-I*) is autosomal dominant and involves serious dehydration, salt wasting, high level of potassium, and a form of hyperaldosteronism. The mutation seems to affect the genes controlling the same ion channel as in the Liddle syndrome. The *Gitelman syndrome* is a human chromosome 16 recessive that involves a defect in the Na-Cl cotransporter and consequently, salt wasting. ►hypertension, ►adrenergic receptors, ►Liddle syndrome, ►aldosteronism, ►mineral cortical syndrome; Zuscik MJ et al 2001 J Biol Chem 276:13738.

Hypothalamus (forebrain): The part of the brain where the vision, visceral activities, water balance, temperature, sleep, etc. control centers are located. ►brain human

Hypothesis: A supposition or multiple alternative suppositions (hypotheses) are used to explain certain experimental data and generally statistical approaches are used to decide which of the alternatives have the greatest probability to be true. One must keep in mind that the statistical methods do not prove cause-effect relationships or mechanisms, only the degree of chance or likelihood is indicated. Karl Popper, the philosopher, stated, "Our belief in some hypotheses can have no stronger basis than our repeated

unsuccessful critical attempts to refute it” (The Logic of Scientific Discovery). The refutability, of course, depends also on the precision of the factual basis of the hypothesis. The trust in the validity of a hypothesis is increased greatly if it is supported by replication under somewhat different circumstances or by different procedures, rather than under exactly identical conditions, which may be loaded by the same bias each time. The *working hypothesis* is used as guidance to design experimental procedures to test the most likely mechanism involved. In experimental science, such as genetics, only the testable hypotheses have any value. ▶ [null hypothesis](#), ▶ [probability](#), ▶ [likelihood](#), ▶ [maximum likelihood](#), ▶ [chi square](#), ▶ [genetic risk](#); Page GP et al 2003 Am J Hum Genet 73:711; Lipton P 2005 Science 307:219.

H

Hypothyroidism: ▶ [goiter](#)

Hypotonia: Weak muscle tension. It is a typical feature of the Down syndrome, Prader-Willi syndrome, cri-du-chat syndrome, and various other chromosomal anomalies and trisomies.

Hypotonic: The concentration of salts in this type of media is lower than the osmolality of the cell, therefore water from the cells may be drawn out into the medium. ▶ [hypertonic](#), ▶ [hypotonic](#), ▶ [osmolality](#), ▶ [osmotic pressure](#)

Hypotrichosis: Rare autosomal recessive reduction of hair on the face and absence of pubic hairs even after puberty. Baby hair is shed shortly before or after birth. Congenital atrichia (baldness) or hypotrichosis of Marie Unna was mapped to 8p22-p21, but the latter does not seem identical with congenital atrichia. Hypotrichosis simplex (HSS), a rare dominant baldness affecting both sexes early on, was mapped to 6p21.3. The gene encodes corneodesmosin, a glycoprotein expressed in the epidermis and the inner root sheath of the hair follicles (Levy-Nissenbaum E et al 2003 Nature Genet 34:151). The recessive hypotrichosis associated with juvenile macular dystrophy encodes P-cadherin at 16q22.1. ▶ [hair](#), ▶ [hypertrichosis](#), ▶ [alopecia](#), ▶ [cadherin](#), ▶ [macular corneal dystrophy](#), ▶ [lymphedema](#); Sprecher E et al 2001 Nature Genet 29:134.

Hypotrophy: Less than normal growth of a tissue or organ caused by inadequate nourishment.

Hypouricemia: A type of nephrolithiasis. In the Dalmation coachhund type, the kidneys do not reabsorb urate. In other cases, the decrease of urate in the urine is accompanied by excessive excretion of calcium. ▶ [nephrolithiasis](#), ▶ [kidney diseases](#)

Hypoventilation: Hypoventilation may be controlled at several human loci (20q13.2, 11p13, 5p131 and 4p12. The congenital central hypoventilation syndrome (CCHS) is an abnormal respiration without

lung disease, neuromuscular, or brain defects. Its most important cause appears to be a defective PHOX2B homeobox gene at 4p12 (Amiel J et al 2003 Nature Genet 33:459). Some of the factors involved in Hirschsprung disease are also responsible for hypoventilation. ▶ [Hirschsprung disease](#)

Hypoviruses: Hypoviruses are persistent and hard to transmit infectious agents in fungi and cause no symptoms. However, the synthetic transcripts of such viruses when introduced into the chestnut blight fungus (*Cryphonectria parasitica*) by electroporation can reduce the virulence of the fungus and thus indicates a means of biological control. ▶ [symbionts hereditary](#)

Hypoxanthine: A purine base very similar to guanine, except that from the C2 position in hypoxanthine, NH₂ is removed (see Fig. H88). It can be formed also by deamination at the 6 position of adenine. Its nucleoside is (confusingly) inosine and its nucleotide is called inosinic acid. It may occur in some anticodons of tRNA. Insine (I) is a “universal base” because it can pair with various bases in this order with decreasing thermal stability I•C > I•A > I•T ≈ I•G > I•I. Therefore, it can be used in degenerate PCR primers

Figure H88. Hypoxanthine (left), Guanine (right)

and for degenerate microarray probes (Watkins NE et al 2005 Nucleic Acids Res 33:6258). When guanine is deaminated into hypoxanthine through chemical mutagens (nitrous acid), lethal mutation occurs because hypoxanthine cannot support nucleic acid replication. The enzyme hypoxanthine-guanine phosphoribosyl transferase (deficient in the Lesch-Nyhan syndrome) can phosphorylate both of these purines in the salvage pathway of nucleic acid. ▶ [HPRT](#), ▶ [salvage pathway](#), ▶ [HAT medium](#), ▶ [nitrous acid mutagenesis](#), ▶ [inosine](#), ▶ [wobble](#), ▶ [ADA](#)

Hypoxanthine-Guanine Phosphoribosyl Transferase (HGPRT): The enzyme that donates the ribose phosphate moiety to the purine bases hypoxanthine and guanine from 5'-phosphoribosyl-1-pyrophosphate and thus forms the corresponding nucleotides. Another enzyme, adenosine phosphoribosyl transferase, synthesizes adenylic acid from adenine. HGPRT is the key enzyme in the salvage pathway of nucleic acid synthesis. ▶ [salvage pathway](#), ▶ [HAT medium](#), ▶ [Lesch-Nyhan syndrome](#)

Hypoxia: Low oxygen concentration in the environment of cells or tissues. The effectiveness of ionizing radiation in induction of mutation or chromosome breakage is reduced under low oxygen concentration. Hypoxia may trigger the formation of double minutes and chromosomal instability. Hypoxia promotes the binding of hypoxia-inducible factors (HIF) to the hypoxia-response element in the vascular endothelial growth factor promoter and it so stimulates angiogenesis. Deletion of the hypoxia-response element may cause motor neuron degeneration that resembles the anomaly of amyotrophic lateral sclerosis. Hypoxia is a factor in tumorigenesis. Hypoxia inhibits the translation of mRNA by suppressing key regulators such as eIF-2A, eEF-2, and TOR among other factors resulting in energy conservation under low oxygen level (Liu L et al 2006 Mol Cell 21:521). *Normoxia* is normal oxygen tension in the environment. ►oxygen effect, ►HIF, ►eIF, ►eEF, ►TOR, ►animation, ►double minutes, ►fragile sites, ►angiogeneses, ►VEGF; von Hippel-Lindau syndrome; Jiang H et al 2001 Proc Natl Acad Sci USA 98:7916; Harris AL 2002 Nature Rev Cancer 2:38.

Hypoxic Genes: Hypoxic genes are expressed primarily under anoxia. ►anoxia, ►amyotrophic lateral sclerosis

Hysterectomy: The surgical removal of the uterus. ►uterus

Hysteresis: A time lag between two processes. Also, hysteresis refers to the lowering of the point of freezing without lowering the temperature required for melting; antifreeze proteins may regulate it. Hysteresis is a common mechanism of regulation of gene expression networks. Networks of positive feedback may control hysteretic or bistable switches. Bistable expression system can throw OFF and ON the threshold-dependent toggles. Hysteretic systems require bigger signals for OFF and ON switching by interfacing historical and current input signals. Epigenetic toggle switches may involve two rather stable expression states. The response may be based on a graded dose input. Synthetic hysteretic system may have great potentials for gene therapy in as much as the transgene expression may reflect the needs of the metabolic system of the recipient rather than responding to a single, fixed dose. A tetracycline responsive positive feedback loop may communicate with a constitutive macrolide-dependent transrepressor expression unit and impinges on transcription modulation of the transgene. At macrolide concentrations around the switching dose, the network shows hysteresis and represents “artificial memory” imprinted on the expression of the transgene (Kramer BP, Fussenegger M 2005 Proc Natl Acad Sci USA 102:9517). ►antifreeze proteins, ►temperature-sensitive mutation, ►epigenesis, ►macrolide, ►tetracycline, ►gene therapy, ►genetic networks

Historical vignettes

On May 8 1900 William Bateson wrote in the J Roy. Hort. Soc. (Lond) 25:54

“An exact determination of the laws of heredity will probably work more changes in man’s outlook on the world, and in his power over nature, than any other advance in natural knowledge that can be foreseen.

There is no doubt whatever that these laws can be determined. In comparison with the labour that has been needed for other great discoveries it is even likely that the necessary effort will be small.”

Boyce Rensberger (science journalist) in Science 289:61 (2000)

“Without a grasp of scientific ways of thinking, the average person cannot tell the difference between science based on real data and something that resembles science—at least in their eyes—but is based on uncontrolled experiments, anecdotal evidence, and passionate assertions.”

I Blood Group (Ii system): I and i are universal erythrocyte antigens that exhibit alteration during development but minimal polymorphism. The synthesis of I/i antigens results from the cooperation of glycosyltransferases on common substrates and there is not a single diagnostic immunodeterminant sugar specific for the blood type. It may be associated with autoimmune hemolytic anemias. ▶blood types, ▶ABO blood type, ▶hemolytic disease, ▶hemolytic anemia

I Element: ▶non-viral retrotransposable elements, ▶retroposon, ▶retrotransposon

I.U: International unit is a quantity of various vitamins, hormones, enzymes, etc. that bring about a standard response as determined by the International Conference for Unification of Formulas.

IAA: Denotes indole acetic acid. ▶plant hormones. (see Fig. I1).

Figure I1. Indole-3-acetic acid

IAM: ▶infinite allele mutation model, ▶microsatellite, ▶minisatellite, ▶SMM model

IAP: ▶chloroplast import

IAP (intracisternal [within closed compartments] A particles): These are retroviral elements in the mouse genome capable of transposition. They are normally not active but demethylation of their long terminal repeats increases their transcription 50–100 fold. Male germ cells are demethylated shortly before the formation of the spermatogonia. Female germs are demethylated slightly later but only during the period between the primordial germ cells and growing oocytes. The spermatogonia and the oocytes are heavily methylated. The IAP elements are not found in humans. ▶Prader-Willi syndrome, ▶dyskeratosis; Vogler C et al 2001 *Pediatr Res* 49(3):342.

IAP (inhibitor of apoptosis): Controls apoptosis by binding or in other ways interfering with caspase or pro-caspase activation. At its N-terminus it contains one or more BIR motifs and its C-terminus has a RING finger domain for recruiting caspase. The

IAPs are involved in ubiquitin ligase activity and may autoregulate their degradation by proteasomes. The expression of a construct containing the RING domain of X-linked IAP causes its ubiquitylation and degradation by the proteasome. This results in apoptosis and markedly reduced melanoma proliferation following the administration of cisplatin (Silke J et al 2005 *Proc Natl Acad Sci USA* 102:16182). The Smac/DIABLO protein binds to the IAP and promotes caspase activity. Binding proteins REAPER, HID and/or GRIM promote caspase activity presumably by neutralizing the IAP. ▶apoptosis, ▶BIR, ▶caspase, ▶RING finger, ▶ubiquitin, ▶proteasome, ▶Smac, ▶DIABLO, ▶melanoma, ▶cisplatin; Verhagen AM et al 2001 *Genome Biol* 2: reviews 3009; Sharief MK, Semra YK 2001 *J Neuroimmunol* 119:350.

IARC: The International Agency for Research on Cancer, Lyon, France, publishes reviews on carcinogens as scientific publications of the IARC. ▶cancer, ▶environmental mutagens, ▶databases; <http://www.iarc.fr/>.

Iatrogenic: (adjective) Refers to the adverse effect(s) resulting from or concomitant to medical treatment, hospital-acquired infections. ▶nosocomial

IBD: Identical by descent refers to an allele inherited from an ancestor that is exactly the same as that of the particular ancestor and not the result of a new mutation identical by state (IBS). IBD-APM means identical by descent for affected-pedigree-member. More information can be obtained by combining conventional linkage tests with high-resolution single nucleotide polymorphism scans (Burdick JT et al 2006 *Nature Genet* 38:1002). ▶inbreeding coefficient, ▶SNIP

ibid: An abbreviated form of the Latin adverb *ibidem* means the same place; it is sometimes used in citations when another paper appears at the same place, i.e., in the same journal.

IBIDS: ▶ichthyosis

IbpA, IbpB (Inclusion Body Proteins): These are small heatshock protein chaperones of prokaryotes. ▶sHSP; Kitagawa M et al 2000 *FEMS Microbiol Lett* 184(2):165.

IBS: ▶IBD, ▶identity of state

IC₅₀: Refers to median inhibitory concentration (of a drug or other chemical compound).

ICAD (inhibitor of CAD): ▶CAD, ▶caspase, ▶AIF; Sakahira H et al 1999 *J Biol Chem* 274:15740.

ICAM (CD54, intercellular adhesion molecule, 19p13.3-p13.2): These proteins bind together

(epithelial) cells through integrins. The concentration of ICAM-2 in uropod projections, rather than being evenly distributed, is a special target for cytotoxic lymphocytes (CTL). The targeting is assisted by the cytoskeletal - membrane linker protein ezrin. ICAM-1 protects against allograft rejection. ►N-CAM, ►cadherin, ►integrin, ►DC-SIGN, ►CD proteins, ►dengue fever, ►LFA, ►uropod, ►T cell; Springer TA 1990 Nature [Lond] 346:425; Sultan P et al 1997 Nature Biotechnol 15:759; crystal structure: Song G et al 2005 Proc Natl Acad Sci USA 102:3366.

ICAT (isotope-coded affinity tag): This is a protein analytical procedure that may be substituted for the two-dimensional gel electrophoresis. The cells are grown under two different conditions and a biotin-linked isotope is used to label the cysteine residues of the proteins. The extracted protein is digested and the labeled peptides are subjected to affinity chromatography and the peptides are further analyzed by high-performance liquid chromatography/mass spectrometry. Differences in the expression of genes are demonstrated by differences at the level of the isotope. ►gel electrophoresis, ►two-dimensional gel electrophoresis, ►MALDI/TOF/MS, ►proteomics; Smolka MB et al 2001 Anal Biochem 297:25; Han DK et al 2001 Nature Biotechnol 19:946; Turecek F 2002 J Mass Spectrom 37:1.

Iccosomes: Dendritic cells package antigen: antibody complexes into budding structures that shed from their surface. ►dendritic cell; Terashima K et al 1992 Semin Immunol 4(4):267.

ICE (interleukin-1 β converting enzyme, caspase 1 in human chromosome 11q22): A cysteine protease which is activated during Fas-mediated apoptosis. Its family includes CPP32 and Ich-1 proteases. The ICE is a mammalian homolog of *ced-3*. ►Fas, ►apoptosis, ►interleukins, ►CPP32, ►granzyme B, ►RNKP-1, ►IL-1, ►caspase; Druilhe A et al 2001 Cell Death Differ 8(6):649.

Ice Man (Ötzi): A frozen mummy was discovered in 1991 in the Tyrolean Alps, its age was estimated to be 5,100 to 5,300 years. Some claims have been made that it may be a scientific hoax but detailed analysis has negated this possibility. Also, 10-genome equivalent quantity of DNA per gram of its tissue, comprising only redundant sequences, has been recovered. One DNA sequence of the hypervariable region of the mitochondrial DNA indicated close similarities to central and north European populations. The cause of his death as revealed by an X-ray was an arrow flint. DNA analysis revealed four different types of blood on his clothing leading to the conclusion that he was involved in bloody fighting with others. ►mtDNA, ►ancient DNA, ►mummies;

Williams AC et al 1995 Biochim Biophys Acta 1246:98; Bortenschlager S, Oegg K eds. 2000 The Iceman and His Natural Environment. Springer, Wien, Austria.

Iceland: The Icelandic population has been considered one of the genetically most homogeneous populations in the world in terms of blood group, allozyme data and mitochondrial DNA (Helgason A et al 2000 Am J Hum Genet 66:999). However, a re-examination of the mitochondrial DNA diversity does not confirm the validity of this view (Árnason E 2003 Ann Hum Genet. 67:5). The latter view has been questioned, as it is thought to be based on inappropriate comparisons (Helgason A, Stefánsson K 2003 Am J Hum Genet 73:947).

I-Cell Disease: ►mucopolysaccharidosis

ICER (inhibitor of CRE): A basic leucine zipper domain protein of the CREB family lacking the C-terminal transactivation domain. It is inducible by FSH. ►CRE, ►CREB, ►FSH, ►leucine zipper; Trocme C et al 2001 J Neurosci Res 65(2):91.

ICF: ►immunodeficiency, ►methylation of DNA

ICH1: This is a protease implicated in apoptosis. Its N-terminus is homologous to caspase 2. ►apoptosis, ►caspase; Zeng Q et al 2000 J Comp Neurol 2000 424:640.

Ichthyosis: This non-inflammatory keratosis of the skin appearing in different forms under different genetic controls is often associated with various syndromes (see Fig. 12). In the *autosomal dominant* (with poor penetrance) ichthyosis vulgaris (1q21), the scaling of palms and soles appears during the first three months after birth and it may be caused by keratohyalin deficiency, a precursor of filaggrin, an element of keratin fibers (Smith FJD et al 2006 Nature Rev Genet 38:337). Sequencing of this large, highly repetitive gene has revealed 15 variants, including seven that are prevalent. All the variants are either nonsense or frameshift mutations that, in representative cases, result in loss of filaggrin production in the epidermis and manifest childhood eczema (Sandilands A et al 2007 Nature Genet 39:650). There are a number of variations of the dominant types. Its incidence among schoolchildren in England was ~1/250. The *autosomal recessive* lamellar (14q11.2, keratinocyte transglutaminase, TGM1) form has many variations involving redness of the skin, brittle hair, blisters, liver disease, physical and mental retardation, etc. There are other recessive lamellar ichthyosis genes in human chromosome 2 (LI2, 2q33-35) and LI3 is located at 19p12-q12. The recessive forms are generally more serious than the dominant ones. The harlequin type (2q34; so named

because the diamond-shaped 4–5 cm diameter scaly, horny spots resemble the diamond-patterned costume of a harlequin) may cause death within the first week after birth. The defect is in the ABC transporter A12. Some recessive forms involve hair loss, progressive neural defects, enlarged liver and kidney defects. In the Sjögren-Larsson syndrome (17p11.2) the frequency of the recessive gene responsible for the disease in a county of Sweden was 0.01 and that of carriers was 0.02 while the prevalence was 8.3×10^{-5} . Fatty aldehyde dehydrogenase deficiency, neurological disorders and keratosis characterize this latter form of ichthyosis. Another form of recessive ichthyosis is related to triglyceride storage anomalies. In the autosomal recessive ichthyosis (14q11) the activity of keratinocyte transglutaminase activity is considerably reduced. X-linked ichthyosis (Xp22.32) based steroid sulfatase deficiency may produce asymmetric malformations of the lung, thyroid, several nerves, etc. and hypoplasia on the same side as the ichthyosis. Another X-linked (distal part of Xp) group reveals deficiency of placental steroid sulfatase. This is also called IBIDS. ▶keratosis, ▶skin disease, ▶collagen, ▶lyonization, ▶trichothiodystrophy, ▶collodion fetus, ▶filaggrin, ▶Chanarin-Dorfman disease, ▶erythroderma, ▶eczema

Figure 12. Ichthyosis

ICOS (inducible co-stimulator, a human homolog of CD28): This is a homodimeric protein (M_r 55–60K) which enhances T cell proliferation, lymphokine secretion, upregulates cell-to-cell interaction, antibody production by B cells and the production of IL-10 (but not IL-2) in response to foreign antigens. The B7 related protein (B7RP) expressed on B cells and ICOS without interacting with the B7—CD28 system, stimulates adaptive immune response. ICOS^{-/-} mice are deficient in immunoglobulin class switching and germinal center formation. CD40 and its ligand may compensate for the ICOS defects. The ICOS may influence T_H-1 and T_H-2 lymphocytes and may be partly responsible for graft rejection and autoimmune disease. ▶CD28, ▶B7 protein, ▶CTLA, ▶IL-10, ▶IL-2, ▶T cell receptor, ▶immunoglobulin, ▶germinal center, ▶CD40, ▶autoimmune disease; McAdam AJ et al 2001 Nature 409:102; Özkaynak E et al 2001 Nature Immunol 2:591 and following articles.

Icosahedral: This is a body with 20 facets like the capsids of some viruses. ▶isometric phage

ICR: Compounds synthesized by the International Cancer Research Institute, Philadelphia, are acridines with alkylating side chains and cause frameshift mutations. ▶mutagens

ICR: Refers to the internal control regions through the zona pellucida. ▶A box

ICR (insulator control region): ▶enhancer competition, ▶insulator

ICSI (intracytoplasmic sperm injection): Spermatozoa in some humans and animals are unable to penetrate the egg. In such cases the spermatozoon may be injected mechanically into the ooplasm. This technology can also be used for genetic transformation. However, there are some risks of mechanical or chemical (in the delivery fluid) injury to the egg. The genetic risk is that the spermatozoon injected is not competing and a less viable or defective one may fertilize. This method enables men with a very low sperm count to father children. Unfortunately, the genetically determined low sperm count is transmitted to the offspring. Mouse and human spermatozoa have small acrosomes compared to bulls, boars and hamster and the inclusion of the acrosome during ICSI can be very harmful to the oocytes in as much as lysis and deformation can occur (Morozumi K, Yanagimachi R 2005 Proc Natl Acad Sci USA 102:14209). The removal of both the plasma membrane and acrosome from the mouse spermatozoa before the ICSI not only accelerates the onset of oocyte activation, but also results in improved embryonic development (Morozumi K et al 2006 Proc Natl Acad Sci USA 103:17661). ▶ART, ▶in vitro fertilization, ▶acrosome; Ma S et al 2001 Fertility & Sterility 75:1095; Faddy MJ et al 2001 Nature Genet 29:131; Cox GF et al 2002 Am J Hum Genet 71:162.

Icterus: A technical term for jaundice. ▶kernicterus, ▶hyperbilirubinemia

ID: ▶idant

ID (integrating database): This is formed in the GenBank containing information on accession number, ASN.1, gi, Bioseq. ▶GenBank, ▶accession number, ▶ASN.1, ▶gi, ▶Bioseq

ID₅₀: Refers to the dose of an infectious agent that infects 50% of the cells exposed to it.

ID Proteins: These interfere with differentiation by blocking the access of basic helix-loop-helix transcription factors to the E box in the DNA. In mice there are four *Id* genes and knocking out all of them is

lethal, but when at least one allele is functional premature withdrawal of the neuroblasts from the cell cycle and failure of the normal angiogenesis and vascularization occur. Overexpression of Id2 is due to the activation of the transcription of the Myc family of oncoproteins. For the progression of the cell cycle induced by Myc requires the inactivation of Rb (retinoblastoma) protein by the dominant-negative Id2. Id1 opposes the effect of p16^{INK4a} in senescence. The degradation of Id2 by the anaphase-promoting complex (APC-CDH1) and D box motifs promotes axonal growth (Lasorella A et al 2006 Nature [Lond] 442:471). ▶E box, ▶D box, ▶anaphase promoting complex, ▶Cdh1, ▶angiogenesis, ▶helix-loop-helix, ▶retinoblastoma, ▶Myc, ▶p16^{INK4a}, ▶senescence; Alani RM et al 2001 Proc Natl Acad Sci USA 98:7812.

Idant: A higher hierarchical genetic structure as conceived during the early/middle nineteenth century. Biophores (~alleles) aggregated into ids (~loci) and ids formed idants (~chromosomes).

Idaxozan: ▶clonidine

IDC (Idiopathic Dilated Cardiomyopathy): ▶cardiomyopathy dilated

IDDM: Denotes insulin-dependent diabetes mellitus. ▶diabetes mellitus

Identical By Descent: ▶IBD

Identical By State: ▶IBD

Identical Twins: ▶twinning

Identifier: Sequences within introns or non-coding 3' regions are involved in genetic regulation. The identifier sequences are transcribed by RNA polymerase III and may define chromatin regions and facilitate the transcription by RNA polymerase II as promoters are made more accessible to soluble transacting molecules. ▶introns, ▶regulation of gene activity, ▶RNA polymerase, ▶transacting element; Mellon SH et al 1988 Nucleic Acids Res 16:3963.

Identifier Syntax: In the BLAST search program this indicates the source of the information, e.g., GenBank, EMBL and Swiss-Prot. ▶gi

Identity By Descent (IBD): The shared gene(s) in a pedigree is derived from a common ancestor and is not due to an identical mutation (identity by state).

Identity Gene: This controls developmental specifications for an organ. (Science 2002 296:297–316)

Identity Index: ▶evolutionary distance

Identity of State: When the coefficient of inbreeding is determined, the identity of an allele must be specified as *identity by descent* (i.e., passed on by a common

ancestor) not by coincidentally occurring mutation. Mutation may generate only *identity by state*. ▶coefficient of inbreeding, ▶consanguinity

Idiogram: This is a diagram of the chromosome set, including all essential morphological features of chromosomes, such as arm ratio, satellites and banding pattern (see Fig. I3).

Figure I3. Idiogram

Idiomorphs: Refer to the opposite mating type-determining gene loci in fungi. Typically, they occupy the same location in various haplotypes but have a different sequence (Arie T et al 2000 Mol Plant Microbe Interact 13:1330).

Idiopathic: This means spontaneous, i.e., the cause or origin is unknown.

Idiopathic Hypogonadotropic Hypogonadism: ▶hypogonadotropic hypogonadism

Idiopathic Torsion Dystonia (ITD, DYT1, Torsin A): This is a dominant (human chromosome 9q34) neurological disorder (~30% penetrance) with onset before the late 20s, it first affects the limb muscles and the effects may later spread. Its incidence ($1.6-5 \times 10^{-4}$) is higher among Ashkenazy Jews compared to other populations. Torsin A is a protein of the ATPase family. ▶dystonia; Clarimon J et al 2005 Ann Neurol 57:765.

Idiopathic Ventricular Fibrillation (IVF): This is a common cause of fatal heart disease involving arrhythmia. Missense or splice-donor mutations in cardiac sodium channel gene SCN5A may increase the risk of developing this condition.

Idioplasm: A nineteenth century hypothetical concept about the physical basis of heredity.

Idiotope: Refers to the determinant of antigenic specificity. ▶antigen, ▶antibody

Idiotype: The term was originally coined in 1884 for identifying the entire complex of genetic determinants in a cell but it is no longer used in that sense. In modern immunogenetics it refers to idiotopes that distinguish one group of antibody producing cells

from other groups of immunoglobulin producing cells. Thus, the idiotype represents the specificity of all the idiotopes because the antigens bind within or at the idiotopes to the variable region of the antibody. The recurrent (also called public, major or cross-reactive) idiotypes regularly appear during the immune response but the private (or minor) idiotypes may or may not appear even in genetically identical individuals. ▶epitope, ▶paratope, ▶allotype, ▶isotype, ▶antibody, ▶immunoglobulins, ▶HLA, ▶anti-idiotypic, ▶internal image immunoglobulin; Jerne NK 1985 Science 229:1057.

Idiotypic Exclusion: In a family of genes only one gene product is expressed. ▶allelic exclusion, ▶locus exclusion

Idling Reaction: In amino acid starved cells synthetic activity is reduced ▶stringent control., and the ribosomes are uncharged with aminoacylated tRNAs. Under such conditions uncharged tRNAs may be attached to the ribosomes and block any residual protein synthetic activity as the idling reaction. ▶protein synthesis; Bilgin N et al 1992 J Mol Biol 224:1911.

iDNA (initiator DNA): At the onset of DNA replication the polymerase α /primase synthesizes it before polymerase δ takes over the chain elongation. ▶replication fork, ▶DNA replication; Law A et al 1998 Nucleic Acids Res 26:919.

Iduronic Acid: This is an epimer (a diastereomer [stereoisomers without being mirror images]) of glucuronic acid and dermatan sulfate, heparan sulfate and heparin. ▶mucopolysaccharidosis, ▶Hurler's syndrome, ▶glucuronic acid, ▶heparin

IES: ▶internally eliminated sequences

IEX (immediate early expressed protein): This may block apoptosis induced by FAS and TNF. Its function is mediated by NF- κ B. ▶apoptosis, ▶NF- κ B, ▶TNF, ▶FAS; Segev DL et al 2001 J Biol Chem 276:26799.

IF-1, IF-2, IF-3: These are protein synthesis initiation factors in prokaryotes and eukaryotic organelles. IF-1 is a ribosome dissociation factor and it cooperates with IF-2 and IF-3. IF2-1 and IF2-2 facilitate the binding of the tRNA^{fMet} to the AUG translation initiation codon on the 30S ribosomal subunit. In *E. coli* IF2-1 is a 97.3-kDa single polypeptide with a GTP binding domain in its center. IF2-2 is 79.7 kDa? IF-3 (20.7 kDa) is a ribosome subunit anti-association factor and a facilitator of tRNA^{fMet} and initiator codon interaction. In the eukaryote *Saccharomyces* there is a (*FUN1* gene product yIF2) homolog to the IF2. The eukaryotic eIF2 is a three

subunit functionally similar but structurally different protein. The yIF2 is present in an evolutionarily similar form from *Archaeobacteria* to eukaryotes. ▶protein synthesis, ▶eIF, ▶alarmone, ▶Shine-Dalgarno sequence; Carter AP et al 2001 Science 291:498.

IGT (irradiation and fusion gene transfer): Human chromosomes are fragmented by irradiation (~3 Krad) and then allowed to hybridize somatically with rodent chromosomes. From such a cell culture the majority of human chromosomes and fragments are eliminated but those fragments that recombine with the chromosome are retained. The co-retention of human markers sheds light on their physical proximity within the human chromosomes. ▶somatic cell hybrids, ▶chromosome assignment, ▶radiation hybrid; Walter MA, Goodfellow PN 1995 Mol Biotechnol 3(2):117.

IFN: ▶interferons, ▶IFR

IFN-Gamma: This is the same as MAF, a lymphokine.

IFR (interferon regulatory factor): This is a negative regulator of interferon and when it binds to CCE it activates histone 4 transcription, involved in the progression from the G1 to the S phase of the cell cycle. ▶histones, ▶interferons, ▶HiNF, ▶CCE, ▶cell cycle; Nakaya T et al 2001 Biochem Biophys Res Commun 283:1150.

Ig: This means immunoglobulin (with additional letters to identify various types). ▶antibody, ▶immunoglobulins, ▶immune system

Ig and Ig β : These are immunoglobulin-associated proteins that form disulfide linked heterodimers (Ig α —Ig β). They belong to a large family of antigen receptor-associated signal transducers and include a tyrosine-containing cytoplasmic motif. B cell activation requires this dimer for triggering the Src and Sky family kinases for receptor phosphorylation. These proteins play an additional regulatory role. The heterodimer is essential for the differentiation of B cells. ▶lymphocytes, ▶immunoglobulins, ▶Src, ▶Sky, ▶CD40; Rudolph AK et al 1981 Eur J Immunol 11(6):527.

IGCs: ▶speckles intranuclear

IGF: ▶insulin-like growth factor

IGI (integrated gene index): This is a list of all genes revealed in a genome. ▶IPI

IGM (inheritable genetic modification [of humans]): ▶GMO

IgNAR: This is an atypical immunoglobulin heavy chain (in cartilaginous fishes) which does not associate with

a light chain. Each heavy chain has one variable and five constant domains. ►immunoglobulins, ►antibody; Stanfield RL et al 2004 Science 305:1770.

Ignorant DNA: This molecular by-product of coincidental amplification may be slightly harmful but may also be beneficial under certain circumstances, e.g., rRNA and satellite sequences. ►selfish DNA, ►junk DNA, ►satellite; Epplen JT 1988 J Hered 79(6):409.

IGS: ►intergenic spacer

IgSF (immunoglobulin superfamily): The cell adhesion molecules (CAM) commonly contain immunoglobulin domains. These domains have a core with two face-to-face arranged β -sheets and highly variable other regions. ►immunoglobulins, ►CAM, ►protein structure

IGTC: International Gene Trap Consortium: <http://www.genetrap.org/>; ►trapping promoters

I_h (I_f): Refers to hyperpolarization-activated cation channels (HAC) in the cell membrane activated by cAMP and cGMP controlled Na⁺/K⁺ ion. Such a process determines the pacemaker activity of active neurons and heart cells. The three cloned HACs contain 863, 910 and 779 amino acids, respectively. ►hyperpolarization, ►ion channels

IHF (integration host factor): A heterodimeric host protein that is required for site-specific recombination. It may also have some function in transcription and replication. It is a member of the high mobility group proteins and its function may bear some similarity to that of histones in eukaryotes. ►high mobility group proteins, ►site-specific recombination, ►recombination, ►intasome; Holbrook JA et al 2001 J Mol Biol 310:379.

iHOP (information hyperlinked over proteins): This contains 12 million sentences over 80,000 genes for more than 1,500 organisms, including humans, mice, *Drosophila*, *Caenorhabditis*, zebrafish, *Arabidopsis* yeast, *E. coli* and others. <http://www.pdg.cnb.uam.es/UniPub/iHOP>

Ii Genes: ►ABO blood group

Ii: This is an invariant chain of the major histocompatibility complex involved in the assembly of class II molecules in the endoplasmic reticulum. This chain is subsequently degraded by lysosomal proteinases and amino acids 81–104 are retained as CLIP (class II-associated Ii peptide) before the foreign antigen is loaded on to the T lymphocytes and it is removed by chaperone H-2M. ►major histocompatibility complex, ►HLA; Frauwirth K, Shastri N 2001 Cell Immunol 209(2):97.

iIF-3P: Refers to the translation elongation factor stimulating the preinitiation complex on the 40S ribosomal subunit. ►protein synthesis, ►eIF, ►PIC

IIH: This is shorthand for TFIIH. ►transcription factors

I_{KAch}: Inwardly rectifying acetylcholine regulated K⁺ channel, activated by G_i protein, inhibits the opening of the voltage-gated Ca²⁺ channels and thus regulates nerve and muscle functions. ►ion channels, ►G_i protein

Ikaros: A transcriptional regulator of lymphocytes which is associated with pericentromeric heterochromatin. The gene is alternately spliced to generate multiple zinc finger proteins involved in gene regulation and chromatin remodeling. ►heterochromatin, ►lymphocytes; Trinh LA 2001 Genes Dev 15:1817; Lopez R A et al 2002 Proc Natl Acad Sci USA 99:602.

I κ B (inhibitor of NF- κ B): This regulatory protein binding to transcription factor NF- κ B retains it in the cytoplasm until it is degraded by proteolysis after being phosphorylated, and then it releases the transcriptional activator NF- κ B to migrate into the nucleus. The inactivation of I κ B usually requires stress signals or a pathogenic attack. Ankyrin repeats characterize the various types of I κ B and are also present in several morphogenetic factors of *Drosophila* (e.g., *cactus*). The Epstein-Barr virus nuclear antigen contains glycine-alanine (GA) repeats, which are inhibitory to cis MHC class I restricted antigen presentation. Thus, it prevents the activation of cytotoxic T cells (CTL) and the virus may evade immune recognition. The insertion of GA repeats into the I κ B α chain protects it from ubiquitination and thereby the activation of the NF- κ B transcription factor (see Fig. 14). Phosphorylation and proteolytic cleavage are key instruments in the separation of I κ B from the NF- κ B complex and it gives the two NF- κ B subunits a chance to migrate into the nucleus and serve as transcription factors. The phosphorylation of I κ B is carried out by the morphogenesis factor and cytokine-activated kinases IKK- α and - β isozymes (M_r 70–90 K), respectively. IKK is part of a large complex which also includes an associated scaffold protein (IKAP, 150 K M_r). I κ B is modified by the ubiquitin-carrier protein SUMO-1 and it is therefore not ubiquitinated and protected from degradation by proteasomes. While ubiquitination is favored by phosphorylation, SUMO-1 is inhibited by phosphorylation. I κ B ζ is an inducible protein which regulates the expression of the Toll/IL-1 receptor and associated genes (Yamamoto M et al 2004 Nature [Lond] 430:218).

I κ B-Ras1 and 2 proteins degrade the I κ B β subunit at a lower rate than the α subunit.

Figure 14. The action path of IκB (Modified after T. Mariatis 1997 Science 278:818)

►signal transduction, ►regulation of gene activity, ►NF-κB, ►FADD, ►RIP, ►TRADD, ►MAPKKK, ►PEST, ►TNF, ►glucocorticoid, ►immunosuppression, ►ankyrin, ►morphogenesis in *Drosophila*, ►ubiquitin, ►antigen presenting cell, ►PIC, ►IKK, ►NIK, ►RAS; Imbert V et al 1996 Cell 86:787; Pahl HL 1999 Oncogene 18:6853; Bottero V et al 2001 J Biol Chem 276:21317; Ruefli-Basse AA et al 2003 Science 302:1581.

IKK: Denotes IκB protein serine kinases. IKKα (IKK1) responds to morphogenetic signals in the activation of NF-κB whereas IKKβ responds to proinflammatory cytokines and controls NF-κB, which in turn regulates inflammation and apoptosis. IKKα phosphorylates histone H3 and thus mediates cytokine-induced gene expression of NF-κB-dependent genes (Yamamoto Y et al 2003 Nature [Lond] 423:655). IKKγ (NEMO) is a modulatory subunit of NF-κB. Aspirin inhibits IKKβ. ►IκB, ►NAK, ►NF-κB, ►NEMO, ►aspirin, ►cyclooxygenase, ►Akt, ►ectodermal dysplasia, ►prostate cancer; Senftleben U et al 2001 Science 293:1495.

IL: Refers to interleukin. (See O'Neill LAJ, Bowie A eds. 2001 Interleukin Protocols, Humana Press, Totowa, NJ, USA).

IL-1: This is a lymphocyte-activating factor. The IL-1α (17-kDa) and β (also about 17-kDa) chains are encoded in human chromosome 2q13 at very close linkage. IL-1ra is a cytokine receptor antagonist of IL-1. The IL-1 receptors (IL-1R) are encoded close by in human chromosome 2. IL-1 mediates Ser/Thr phosphorylation of various proteins (cytoskeleton) and Hsp27. The IL-1 activated Ser/Thr kinase is IRAK and the specific transduced molecule is TRAF6. These molecules are elements of the NF-κB cascade. The IL-1 system is involved with the hematopoietic cells, the neuroendocrine and the central nervous systems. It generally cooperates with TNF. IL-1 has clinical implications for inflammations, blood coagulation, osteoporosis, metastasis, neurodegenerative

and autoimmune diseases. ►interleukins, ►IL-17, ►prostaglandin, ►Toll, ►mental retardation, ►dendritic cell, ►ICE, ►NF-κB, ►IRAK, ►TNF, ►hepcidin; Bomford R, Henderson B eds. 1990 Interleukin-1, Elsevier, New York.

IL-2: Refers to the T-cell growth factor, TCGF, a ~15.5-kDa glycoprotein, encoded at 4q26-q27. It promotes the proliferation and differentiation of lymphocytes. The discovery of IL-2 has made possible the long time culture of T cells. The IL-2Rβ and the IL-2Rγ chain subunits are members of the cytokine receptor superfamily. The IL-2Rβ (human chromosome 22q11.2-12) and γ (Xq13) chains are shared by the other IL receptors. The human IL2Rα (chromosome 10p14-p15) has only 13 amino acids in its cytoplasmic domain and it may not have a significant role in signal transduction. The IL-R receptor complex has a prominent role in various signal transduction pathways. Mice with the IL-2 receptor chain β (IL-Rβ) show excessive differentiation of B cells into plasma cells and excessive amounts of immunoglobulins G1 and E and the production of autoantibodies resulting in hemolytic anemia. Defects in the widely shared IL-2Rγ cause severe combined immunodeficiency (SCID) in humans. It is synthesized primarily by CD4⁺-T_H lymphocytes. The IL-2 gene is activated by a Jun kinase at the 5'-untranslated region and also modulated at the 3'-untranslated sequences. IL-2 may serve as an adjuvant in genetic immunization. ►interleukins, ►B cells, ►T cells, ►immunoglobulins, ►autoantibody, ►anemia, ►SCID, ►cytokines, ►NF-AT, ►AP-1, ►Oct-1, ►NF-κB, ►RAP1, ►JUN, ►ICOS, ►cytokines, ►memory immunological, ►immunization genetic; Lotzova E, Herberman RB eds. 1990 Interleukin-2 and Killer Cells in Cancer, CRC Press, Boca Raton, FL; structure of IL-2 and its α receptor: Rickert M et al 2005 Science 308:1477.

IL-3: This haematopoietic growth factor is a 28-kDa glycoprotein secreted by CD4⁺ lymphocytes, encoded in human chromosome 5q31. IL-3 is within a

gene cluster IL-3—CSF2—IL-13—IL-4—IL-5→ centromere. IL-3 plays an important role in the development of immunity to parasites by stimulating the formation of hematopoietic effector cells. Together with IL-13 they inhibit inflammation and boost humoral immunity and IgE responses. ►interleukins, ►hematopoiesis, ►IL-13, ►CIS, ►allergy; Craddock BL et al 2001 J Biol Chem 276:24274.

IL-4: B-cell growth factor, ~18-kDa glycoprotein, encoded at human chromosome 5q31.1. It stimulates the formation of immunoglobulins G and IgE. Its receptor is encoded at 16p12.1-p11.2. The activation of gene expression by IL-4 requires phosphorylation of tyrosine, homodimerization and nuclear translocation of STAT6. IFN- β and - γ inhibit IL-4 induced activation of STAT6 and STAT6 induced genes partly by inducing SOCS-1. IL-4 and IL-13 are implicated in asthma and allergic reactions. ►interleukins, ►immunoglobulins, ►IL-13, ►IL-3, ►STAT, ►IFN, ►SOCS, ►asthma; Spitz H 1992 IL-4: Structure and Function, CRC Press, Boca Raton, FL; Kelly-Welch AE et al 2003 Science 300:1527; IL-4 antagonist structure: LaPorte SL et al 2005 Proc Natl Acad Sci USA 102:1889.

IL-5 (eosinophil differentiation factor): This is encoded at human chromosome 5q31. IL-5R α is expressed on B lymphocytes, eosinophilic and basophilic granulocytes. It is involved in the differentiation of B cells by being associated with the syntenin protein that binds transcription factor Sox4. ►IL-3, ►lymphocytes, ►syntenin, ►allergy, ►Sox; Geijsen N et al 2001 Science 293:1136.

IL-6 (IFN- β 2/BSF-2): An interleukin group of proteins (21–28-kDa), encoded in human chromosome 7p21, it binds to upstream DNA sequences in some genes. Its receptor, IL-6R, is a transmembrane protein. IL-6 formation is induced by infection and primarily mediates humoral immune reactions. The IL-6 promoter contains GRE, AP-1, SRE and other transcription factor-binding sites. The IL-6 receptor (IL-6R) is trimeric and includes gp130 (918 amino acids, encoded at 5q21), IL-6R α chain (80-kDa, encoded at 1q21) and IL-6. Its level is correlated with total body fat; IL-6 and IL-1 deficiency together causes hyperphagia and obesity in mice (Chida D et al 2006 Diabetes 55:971). ►interleukins, ►GRE, ►AP-1, ►SRE, ►CRE, ►gp130, ►hepcidin; Marsch J et al eds. 1992 Polyfunctional Cytokines: IL-6 and Lf, Wiley, New York; MacKiewicz A et al eds. 1995 Interleukin-6-Type Cytokines, Annals of the New York Academy of Science vol. 762.

IL-7 (lymphopoietin, ~25-kDa): Stimulates lymphocyte precursors in the bone marrow. It is indispensable for normal proliferation of T cells. If the α -chain

of the IL-7 receptor is defective in mice, D-J joining is normal in immature B cells but recombination of the distantly situated heavy chain V gene segments is progressively impaired in proportion to their distance from D-J. The IL-7 receptor ligands seem to signal for the recombination by regulating the access of the recombinase to the DNA. IL-7 promotes embryonic neurons. It regulates antiviral CD4⁺ T cell memory (Lenz DC et al 2004 Proc Natl Acad Sci USA 101:9357). ►immunoglobulins, ►B cell, ►T cell, ►TNF, ►osteoporosis; Tan JT et al 2001 Proc Natl Acad Sci USA 98:8732.

IL-8: This activates neutrophils, cell migration, adhesion, inflammation. ►SDF, ►melanoma growth-stimulatory factor; Xie K 2001 Cytokine Growth Factor Rev 12(4):375.

IL-9 (32–39-kDa glycoprotein): An erythroid colony stimulating factor that promotes (mast) cell proliferation and differentiation. The IL-9 receptor (522 amino acids) is encoded in the pseudoautosomal region of Xq28. But pseudogenes are found at 9p34, 10p15, 16p13.3 and 18p11.3 as well in the X and Y chromosomes. IL-9R appears to be constitutively expressed in Hodgkin's disease and seems to be involved in asthma. IL-9 appears to stimulate myeloid leukemia. ►pseudoautosomal, ►Hodgkin's disease, ►pseudogene, ►mast cells, ►asthma, ►T cell regulatory, ►leukemia; Demoulin JB et al 2001 Cell Growth Diff 12(3):169.

IL-10 (CSIF): This 18.5-kDa protein encoded at 1q31-q32 is produced primarily by T_H cells and acts as a cytokine synthesis inhibitor, yet it may stimulate the growth of mast cells and CD8⁺ T cells. IL-10 is involved in autoimmune diseases, protozoan, fungal and bacterial infections and various carcinomas. Its receptor (hIL-10R, 90–110-kDa) is similar to the interferon receptors and is encoded at 11q23.3. A second receptor gene is in human chromosome 21. IL-10 signals through the Jak-STAT and Tyk2 pathways. Gene therapy used for the alleviation of inflammation seems promising. ►mast cell, ►T cell, ►ICOS, ►signal transduction, ►osteopontin, ►Tyk2; Moore KW et al 2001 Annu Rev Immunol 19:683; Xing Z, Wang J 2000 Curr Pharm Des 6:599.

IL-11 (23-kDa, encoded at 19q13.3): This controls hematopoiesis in the bone marrow. Many of its functions overlap with those of IL-6. The ~43 kDa IL-11 receptor, IL-11R α 1 chain is encoded at 9p13 close to IL-11R α 2. They recruit gp130 and gp190 glycoproteins and activate the Jak/Tyk cytoplasmic tyrosine kinases. ►hematopoiesis, ►gp130, ►gp190; Kaye JA 1996 Stem Cells 14 Suppl 1:274.

IL-12 (interleukin-12): A heterodimeric cytokine that is, one of the most potent stimulators of T helper cells (T_H), natural killer cells (NK) and B lymphocytes, it increases the production of interferon γ (IFN- γ). It is produced by macrophages, neutrophils, dendritic cells and B lymphocytes. The light chain (p35) is encoded at human chromosome 3p12-q132 and the heavy chain (p40) is at 5q31-q33.1. IL-12 receptor (IL12R) deficiency causes susceptibility to infections. Microbial lipoproteins stimulate IL-12 production by macrophages and the process is mediated by Toll-like receptors. Nitric oxide synthase (NOS2) is important in mediating signaling to IL-12. IL-12 is a very promising tool in controlling HIV, Leishmaniasis, malaria, tuberculosis, schistosomiasis and other infectious diseases although some of its side effects (toxic shock syndrome, atherosclerosis) may limit its application. separate entries, ►osteopontine; Lotze MT et al eds. 1996 Interleukin 12, Annals of the New York Academy Science Volume 795; Picard C et al 2002 Am J Hum Genet 70:336.

IL-13: The 131 or 132 amino acid protein is encoded at human chromosome 5q31. It is a monocyte and B lymphocyte regulator, synergistic with IL-2. It is functionally related to IL-4 although the homology between the two is about ~20%. Unlike IL-4, IL-13 is not a T cell proliferation factor. IL-13 receptor $\alpha 1$ subunit is encoded at Xq13. ►IL-3, ►IL-4, ►asthma; Chiaramonte MG et al 1999 J Immunol 162:920.

IL-14: This is produced by activated T cells and B cell lymphoma. ►T cell, ►lymphoma; Ford R et al 1995 Blood 86:283.

IL-15: A ~114 amino acid T- cell growth factor, encoded at human chromosome 4q13, is produced by monocytes and epithelial cells. IL-15 induces the proliferation of activated T cells and B cells. Along with IL-2 it boosts the production of IFN γ and TNF α . ►T cell, ►monocyte, ►IFN, ►TNF, ►memory immunological, ►chymase; Perera LP 2000 Arch Immunol Ther Exp 48(6):457.

IL-16 (LCF, lymphocyte chemoattractant): This 130 amino acid lymphokine (M_r 13,500) is secreted by activated CD8 $^+$ cells, it binds to T cells by the CD4 receptor and suppresses HIV and SIV. ►HIV, ►SIV, ►T cell; Cruikshank WW et al 2000 J Leukoc Biol 67(6):757.

IL-17 (CTLA-8): An interleukin with homology to ORF13 of Herpes Virus Samiri (HVS). The human IL-17 is a 20 to 30-kDa homodimeric protein. It regulates cytokine and (leukemia) oncogene mRNA stability. Along with IL-1, it is involved in the activation of T cells and thus plays a role in autoimmune arthritis (Nakae S et al 2003 Proc Natl

Acad Sci USA 100:5986). IL-17 producing CD4 T cells form a separate lineage from the T_H1 and T_H2 helper cells and play a central role in inflammatory responses (Harrington LE et al 2005 Nature Immunol 6:11213; Park H et al 2005 Nature Immunol 6:1133). ROR γ t orphan receptor directs the differentiation of proinflammatory IL-17 $^+$ TH cells (Ivanov II et al 2006 Cell 126:1121). ►CTLA, ►IL-1, ►IL-25, ►arthritis, ►inflammation, ►T cells, ►T H , ►ROR; Shi Y et al 2000 J Biol Chem 275:19167.

IL-18 (IGIF, interferon γ inducing factor): This is produced by peripheral blood mononuclear cells, dendritic cells, intestinal epithelial cells, osteoblastic stroma cells and upon stimulation by monocytes, macrophages (Kupffer cells). It has two different immunoglobulin receptors. IL-18 enhances inflammatory responses but in cooperation with IL-12 it is antiallergic. IL-18 activates natural killer lymphocytes, T_H cells and the production of interferon γ . It is a defense molecule against bacteria, viruses, some fungal pathogens and protozoa. Along with IL-12 and INF γ it may cause tumor regression. Its therapeutic use, however, is hampered because of the toxicity of cytokines and also because it leads to inflammatory and autoimmune reactions. ►monocytes, ►killer cell, ►T H , ►interferons, ►cytokines, ►Kupffer cell, ►autoimmune disease; Nakanishi K et al 2001 Annu Rev Immunol 19:423.

IL-20: A 176 amino acid homolog of IL-10, its overexpression in transgenic mice is lethal. IL-20 binding activates STAT3 in keratinocytes. It is upregulated in psoriasis. ►psoriasis, ►STAT, ►keratin; Rich BE, Kupper TS 2001 Curr Biol 11:R531; Blumberg H et al 2001 Cell 104:9.

IL-21: Along with its receptor (IL21R) IL-21 regulates the clonal expansion of natural killer lymphocytes and the production of immunoglobulins. ►autoimmune disease; Parrish-Novak J et al 2000 Nature [Lond] 408:57; Ozaki K et al 2002 Science 298:1630.

IL-22 (12q15): A cytokine of epithelial tissues which mediates epithelial innate immunity when activated by CD4 $^+$ T cells and T_H cells.

IL-23 (human chromosome 12): This is a heterodimeric cytokine which shares a p40 subunit with IL-12. It stimulates IL-17 and is critical for the inflammation response of the brain and other tissues. IL-23 is increased in tumors and upregulates matrix metalloprotease MMP9, it increases angiogenesis and reduces infiltration (tumor surveillance) by CD8 T cells. In contrast IL-12 promotes tumor surveillance as well as the cytotoxic effect of T cells (Langowski JL et al 2006 Nature 442:461). ►IL-12, ►IL-17, ►immunological surveillance, ►T cell, ►acanthosis,

►**metalloproteinases**; Aggarwal SW et al 2003 J Biol Chem 278:1910; Cua DJ et al 2003 Nature [Lond] 421:744.

IL-24: ►**mda-7**

IL-25: This is a suppressor of inflammatory responses (Kleinschek MA et al 2007 J Exp Med 204:161).
►**IL-17**

IL-32: An inducer of tumor necrosis factor α , IL-1, IL-6 and IL-8, it appears to be involved in the inflammatory pathway, including rheumatoid arthritis. ►**TNF**, ►**IL-1**, ►**IL-6**, ►**IL-8**, ►**rheumatoid fever**; Kim S-H et al 2005 Immunity 22:131; Joosten LAB et al 2006 Proc Natl Acad Sci USA 103:3298.

IL-33: This is an IL-1 like interleukin; its receptor is ST2 and it activates NF- κ B and MAP kinases. In vivo, it induces the expression of IL-4, IL-5 and IL-13 (Schmitz J et al 2005 Immunity 23:479). ►**IL-1**, ►**IL-4**, ►**IL-5**, ►**IL-13**, ►**NF- κ B**, ►**MAP kinases**

ILK (integrin-linked protein kinase): It phosphorylates protein kinaseB, Akt and cyclins. ►**protein kinases**, ►**Akt**, ►**integrin**, ►**cyclins**; Yamaji S et al 2001 J Cell Biol 153:1251.

Illegitimate Child: Such a child is sired by a male other than the legal father. This status can be ascertained by DNA fingerprinting. The mother is always certain. Illegitimacy, contrary to some myths, does not endow the “love baby” with better abilities, despite some famous examples (Leonardo da Vinci, Francis Bacon, etc.). The out-of-wedlock children generally suffer physical and emotional stress. Illegitimate offspring in old pedigrees may confound recombination frequencies, especially at tight linkage, it may cause problems in prenatal diagnosis of some disorders, and may frustrate genetic counseling. ►**DNA fingerprinting**, ►**prenatal diagnosis**, ►**genetic counseling**

Illegitimate Insertion: Insertion elements may be incorporated into the genome by a process that does not require complete or even substantial homology unlike general recombination events that usually have the requisite of homology between the sites of recombination. Restriction enzymes may facilitate integration when it is non-homologous but do not promote homologous insertion. ►**illegitimate recombination**; Manivasakam P et al 2001 Nucleic Acids Res 29:4826.

Illegitimate Pairing: Refers to the synapsis between not entirely identical strands, which may lead to aberrant crossover products. ►**oblique crossing over**, ►**unequal crossing over**

Illegitimate Recombination: Refers to recombination when the synaptic strands are not or not entirely

homologous (microhomology). Insertion and transposable elements are integrated by non-homologous recombination and their target site shows minimal homology. ►**homologous combination**, ►**non-homologous recombination**, ►**non-homologous end-joining**, ►**recombination**, ►**ectopic recombination**, ►**Ku**, ►**DNA ligases**, ►**synapsis**, ►**RecA-independent recombination**, ►**insertion element**, ►**transposable elements**; Ehrlich SD et al 1993 Gene 135:161; Hanada K et al 2001 J Bacteriol 183:4964.

Illumination: Various types of units of measurement are in use. The most common unit is Lux = 1 standard new candela from 1 m distance per 1 m^{-2} or it is measured in watt or joule units. ►**joule**, ►**watt**, ►**candela**

ILTs (LIR, MIR, CD85, human chromosome 19q): These are surface receptors on monocytes, macrophages, dendritic cells and B lymphocytes containing immunoglobulin-like domains and most of them carry ITIM sequences in the cytoplasmic side. ILT1 and ILT7 lack ITIM and are associated with ITAM containing Fc ϵ RI γ membrane adaptor protein. ►**ITAM**, ►**ITIM**, ►**Fc ϵ RI γ** ; Volz A et al 2001 Immunol Rev 181:39.

Image Analyzer (image processor): This technique uses video cameras with high light sensitivity, attached to the microscope. The camera is connected to a computer that can further enhance the image recorded by the camera. Thus it can electronically enhance (by digitalization) and process the image and can detect details that cannot be perceived by directly viewing through the microscope. The electronic system may show the picture in “false colors”, i.e., selected by the operator rather than the natural color of the object. The use of such devices can rid the image of background “noise” and greatly enhance its clarity. In addition, the operator’s eyes are not stressed. The tissue-specific distribution and expression of the bacterial luciferase transgene can be monitored by the microchannel plate enhanced photon counting analyzers. This set-up consists of a microscope, an image processor, a TV monitor and a computer. The heart of the equipment can be outlined as:

MICROSCOPE → photocathode
→ microchannel plates
→ phosphor screen → DISCRIMINATING
VIDICON

This system can resolve a single photon. By comparison a single native bacterial cell releases about 10,000 photons. Image analyzer (e.g., VAX Station II/GP4) is also used for scanning DNA fingerprint autoradiograms. ►**microscopy**, ►**luciferase**

Image Clones: These are gridded sequences verified (Research Genetics: <http://www.resgen.com/>) or not sequence verified human and other gene clones, gene clusters, suitable for microarray hybridization. ▶ **Uni-Gene**, ▶ **microarray hybridization**

Image Processing: ▶ **image analyzer**

Imaginal Disks: After fertilization of the *Drosophila* egg, the zygote nucleus begins to divide within a common cytoplasm and forms a syncytium (a multinucleate protoplasm) without actual separation by cell membranes. After about 2 h and almost 13 divisions the cellular blastoderm stage is reached (around 6,000 cells). Then the cells move to the periphery of the embryo and the yolk occupies the central space. Within less than 24 h the larva is hatched and this developmental stage (3 instar steps) lasts for about 4 days. Inside the larva some groups of cells, distinguishable by location, shape and size, the *imaginal disks* (50,000 cells) are set aside for serving as initials for the various organs and structures of the adult organism. The larva does not use the imaginal disks and removal of these disks does not kill the organism. As the larva is metamorphosed into pupa most of the larval tissues disintegrate to support the development of the differentiation from the disks. During pupation, from these “prefabricated elements”, the imago is assembled by cell and tissue fusions. From the anterior (front) part the head, from the middle region the thorax and from the posterior (hind) part the abdomen develop. If the imaginal disks are removed from their original position after the 3rd instar stage (about 5 days) and grafted into a new location of another larva, these disks develop into an extra eye, a wing, a leg or other structures, depending on which imaginal disk has been chosen for the surgery and not on the host tissue. Thus, in the imaginal disks developmental determination is completed much before the onset of morphological and functional differentiation. For correct differentiation it is necessary that the transplant is done in a larva and not in an adult. In the abdomen of an adult the disks only proliferate. After a series of transfers through adults, the original determination of the disks may change, and when the proliferated disk tissue is transplanted into a larva, an antennal disk may lead to the development of a leg instead. This altered course of differentiation is called *transdetermination*. The path of transdetermination is not accidental or random. For example, a genital disk may develop into a proboscis (mouthpart) or may pass through some indirect steps in a certain order such as genitalia → proboscis → antenna → leg. A wing from the genital disk cannot be formed directly but may develop through an antenna or a leg. The process of transdetermination is only a change in competence for

differentiation without a mutational change whereas in homeotic mutants one structure is replaced or altered after a change in the DNA. ▶ *Drosophila*, ▶ **morphogenesis**, ▶ **homeotic genes**, ▶ **development**, ▶ **fate maps**, ▶ **determination**, ▶ **proboscis**, ▶ **antenna**, ▶ **blastoderm**, ▶ **homeotic mutants**; Ramirez-Weber F-A, Kornberg TB 2000 Cell 103:189.

Imaging: New technologies (fMRI, tomography, endoscopic confocal microscopy) permit scanning of the whole body to monitor the turning on of genes and follow metabolic processes (including activities in the brain), stages of cancer and its metastasis, without sacrificing the animals or invasive examination of humans. The use of [^{18}F] fluorodeoxyglucose is selectively done by cells of high glucose metabolism (cancer) and facilitates the identification of malignancy when used with tomography (FDG-PET). Vascular cell adhesion molecule (VCAM) can be used to reveal increased angiogenesis in cancer. Radio-labelled Annexin V and TRAIL can reveal apoptosis. The anti-tumor efficacy of epothilones (spindle-fiber poisons) can be detected. ▶ **nuclear magnetic resonance spectroscopy**, ▶ **microscopy**, ▶ **image analyzer**, ▶ **tomography**, ▶ **angiogenesis**, ▶ **annexin**, ▶ **TRAIL**, ▶ **VCAM**, ▶ **epothilone**; Swedlow JR et al 2003 Science 300:100; Weissleder R 2006 Science 312:1168.

Imago: Refers to the adult form of an insect either male or female (see Fig. 15). ▶ *Drosophila*, ▶ **imaginal disk**

Figure 15. Imago

Imatinib: ▶ **Gleevec**, ▶ **Desatinib**

Imbibition: Refers to the absorption of water or other liquids.

IMC: Denotes intramolecular chaperone. ▶ **chaperone**

Imerslund–Grasbeck Syndrome: This refers to megaloblastic anemia (MGA1).

Imidazole: This is present in many organic molecules and may mediate tautomerism. ▶ **Src**, ▶ **tautomeric shift** (see Fig. 16).

Figure I6. Imidazole

Imino Form: Refers to a type of an amino acid that arises from an amino form according to the following reaction:

Similar transformation can take place in nucleotides and can facilitate unusual hydrogen pairing between bromouracil and guanine or cytosine and adenine. ▶[hydrogen pairing](#)

Iminoaciduria: Proline and hydroxyproline use the semi-recessive renal glycine reabsorption mechanism and when it fails these amino acids accumulate in the urine. ▶[aminoacidurias](#)

Iminoglycinuria: In this condition excessive proline and hydroxyproline are present in the urine. This is probably due to heterozygosity of hyperglycinuria. ▶[hyperglycinemia](#)

Imitatory Epigenotype: This theory assumes that the functional units of the phenotype are genetically modular and integrated within the group and relatively independent of the rest of the phenotype. It can be studied by the statistical methods used for QTL. ▶[QTL](#); Mezey JG et al 2000 Genetics 156:305.

Immediate Early Genes: These early genes of a virus are first turned on after infection without any requirement for synthesizing virally encoded proteins. ▶[delayed early genes](#), ▶[late genes](#)

Immobiline: Precast gel strips for first-dimensional run in two-dimensional gel-electrophoresis.

Immortalization: Denotes that a cell in a culture will not senesce but will proliferate indefinitely. Normally, cultured cells die but cancerous transformation or by fusing normal cells with a cancer cell makes them “immortal”. Immortalization and tumorous growth are, however, under separate genetic control. Cells of the germ line are also practically immortal because of their transmission from generation to generation until the extinction of the strain. ▶[hybridoma](#), ▶[cancer](#), ▶[telomeres](#), ▶[p16^{INK}](#); Tevethia MJ, Ozer HL 2001 Methods Mol Biol 165:185.

Immune Clearance: Refers to the destruction of infecting foreign cells by the phagocytotic activity of various special lymphocytes. Its major sites are in the liver, and to a lesser degree in the spleen but other

tissues with phagocytotic activity may also perform this function. The C3 complement and its receptors, C5b-9 and IgG, are important factors. ▶[complement](#), ▶[immunoglobulins](#)

Immune Deviation: In non-atopics postnatal exposure to inhalant allergens may redirect the fetal immune response toward the T_H1-like cytokine pattern. ▶[atopy](#), ▶[allergen](#), ▶[allergy](#), ▶[asthma](#)

Immune Evasion (immune escape): Some viruses may inactivate the MHC class I antigen presentation system and thus escape the attention of the cytotoxic T lymphocytes (CTL). Nevertheless, the killer cells (NK) may destroy the invader. Herpes simplex viruses may inactivate or interfere with the TAP transporters and various subunits of the proteasomes. In HIV-infected human cells the peptide epitopes of the virus may mutate and rather than being a ligand they may serve as T cell receptor antagonists resulting in the inactivation of the HIV-specific T cells. Some adenoviral glycoproteins immobilize the MHC class I molecules to the endoplasmic reticulum. Some cytomegaloviruses (CMVs) make proteins that bind to the MHC class I molecules and “dislocate” the heavy chains into the cytosol (from the endoplasmic reticulum) and thus the proteasomes destroy them. Another trick of some viruses to mediate the internalization and thus inactivation of the MHC I proteins. CMVs may produce their own MHC class I homolog proteins (UL18, m144) that help evade natural killer cell attacks on the virus. These protein homologs may regulate the immune system in various other ways as well. CMV may also down regulate the synthesis of the MHC II type molecules involved in the B lymphocyte defense system. An IL-10 homolog encoded by the Epstein-Barr Virus (EBV) may interfere with T cell function. The inhibition of the mRNA translation of the virus-encoded antigen limits antigen presentation on the MHC class I molecules to CTL (Yin Y et al 2003 Science 301:1371). Viral IL-10 homologs may subvert the IL-12-regulated interferon, cytokine and TAP production. Some viruses may interfere with the process of apoptosis, used by the organ to pathogen infected cells before the maturing infective viral particles could be released. *Staphylococcus* bacteria secrete poly- γ -DL-glutamic acid (PGA) to facilitate growth and survival in human hosts. PGA shelters *S. epidermidis* – an opportunistic hospital-acquired pathogen—against host antimicrobial peptides and neutrophil phagocytosis (Kocianova S et al 2005 J Clin Invest 115:688). Some bacteria and viruses modulate the surface structures (inhibit the complement of the host or display antigenic variations) in order to avoid recognition. The pathogens may activate or interfere with the Toll-like receptor

(TLC) signaling pathway. Host receptors may be degraded, antigen presentation may be inhibited, cell surface molecules may be modulated, etc. ▶ [immune system](#), ▶ [antigen presenting cell](#), ▶ [epitope](#), ▶ [anti-microbial peptides](#), ▶ [neutrophil](#), ▶ [MHC](#); T cell; MICA; Kavanagh DG et al 2001 J Exp Med 194:967; Groh V et al 2002 Nature [Lond] 419:734; common and specific principles of immune evasion by viruses and bacteria: Finlay BB, McFadden G 2006 Cell 124:767.

Immune Homeostasis: After an immune reaction the immune system is reset to the pre-immunization state and can then respond to a new antigen. ▶ [immune system](#)

Immune Privilege: Grafts to certain sites (eyes, testes, brain) may be protected from rejection caused by the constitutive expression of the Fas ligand (FasL). Other factors may be blood tissue barriers, direct secretion of the tissue fluid into the blood, absence of efferent lymphatics, potent immunosuppressive environment (TGF β), reduced expression or induction of MHC, neuropeptides, α -melanocyte-stimulating hormone, vasoactive intestinal peptide, calcitonin gene-related peptide [CGRP], and membrane-bound inhibitors of the complement activation and fixation. Immune privilege may be necessary for pregnancy, for avoiding certain diseases and graft rejection, etc. ▶ [TGF](#), ▶ [Fas](#), ▶ [MHC](#), ▶ [calcitonin](#), ▶ [complement](#); Rall GF et al 1995 J Exp Med 182:1201; O'Connell J et al 2001 Nature Med 7:321.

Immune Response: The response is mounted by the body against foreign invaders. It may be triggered by sensing some surface architectural elements of the invader (*stranger hypothesis*) or by stress signals emanating from the cells/tissues in the stressed body (*danger hypothesis*). Such signals may be conveyed by uric acid crystals, which are degradation products of nucleic acids. The dendritic cells then present the foreign antigen to the CD8⁺ T lymphocytes. The dendritic cells can also recognize the infectious agents by their Toll-like receptors and migrate to the lymphoid organs and secrete interleukin-12 (IL-12). Here they encounter CD4 T cells which can develop into either Th₁ or Th₂ helper T cells. The Th₁ lymphocytes secrete interferon- γ and mediate immunity against viruses or bacteria. The Th₂ effector cells use interleukin-4 (IL-4) to protect against multicellular pathogens or allergens. Correct recognition is important because inappropriate reaction may result not only in lack of protection, but also in autoimmune disease or allergy. In the activation of the Th₁ cells the four Notch receptors and their five ligands play a key role under the influence of the RBPJ κ transcription factor (a mammalian homolog of the *Drosophila*

Suppressor of Hairless [*Su(H)*]). If RBPJ κ is reduced or absent (in mouse cells) Th₂ development is favored. ▶ [MHC](#), ▶ [immune system](#), ▶ [glycans](#); Heath WR, Carbone FR 2003 Nature [Lond] 425:

460; Shi Y et al 2003 Nature [Lond] 425:516; Amsen D et al 2004 Cell 117:515; Tanigaki K et al 2004 Immunity 20:611.

Immune Selection: Refers to the process by which pathogens are capable of evading or resisting the host immune system.

Immune Suppression: Refers to the removal or inactivation of the antigen. This can be achieved by destroying the target cells by CTL, B cells, macrophages or killer cells or by cytokines and other immunosuppressive agents. An immunosuppressive drug reduces the body's ability to mount an immune response and defend against foreign antigens. Contradiction prevents suppression and allows for the development of immunity. ▶ [immune tolerance](#), ▶ [CTL](#), ▶ [killer cell](#), ▶ [veto cell](#); Takemoto SK 2000 Clin Transpl 481.

Immune Surveillance: ▶ [immunological surveillance](#)

Immune Synapse: On the surface of natural killer T cells (NK) inhibitory immunoglobulin-like receptors (KIR1, KIR2) occur that cause clustering of HLA-C molecules at the surface of the target cells. At the target and the NK cells HLA—KIR forms rings around the intercellular cell adhesion molecules and lymphocyte-associated antigen-1 for about 20 minutes. Multiple such synapses may occur as the T cells invade the selected target. Synapse formation requires the reorganization of the cytoskeleton of the T cells and the antigen-presenting cells. ▶ [killer cell](#), ▶ [KIR](#), ▶ [HLA](#), ▶ [antigen](#), ▶ [agrin](#), ▶ [cytoskeleton](#), ▶ [antigen-presenting cell](#); Khan AA et al 2001 Science 292:1681; Dustin ML, Coper JA 2000 Nature Immunol 1:23; van der Merwe PA, Davis SJ 2002 Science 295:1479.

Immune System: Refers to a complex defense organization of vertebrate animals. The main cellular components of the immune system are the lymphocytes and macrophages. B lymphocytes synthesize the antibodies that react and destroy the foreign antigens. T lymphocytes generate the antigen receptor-MHC protein complex that specifically recognizes individual antibodies and is involved in the destruction of foreign antigens (see Fig. 17). Lower animals may use phagocytosis as defense. Plants do not have an immune system like animals yet they also have pathogen-associated molecular mechanisms for recognition by the so-called elicitors. Some of the elicitors are peptides. A 23-amino acid peptide of *Arabidopsis* (*AtPep1*) activates the transcription of the defending

Figure 17. Development of the immune system and major components

gene (*PDF1.2*) and the synthesis of H_2O_2 . The precursor of the peptide (92 amino acids) can be induced by wounding, methyl jasmonate and ethylene. There are 6 paralogs of *PDF1.2* in *Arabidopsis* and orthologs occur in other plant species (Huffaker A et al 2006 Proc Natl Acad Sci USA 103:10098). The *AtPep1* receptor also functions in transgenic tobacco plants (Yamaguchi Y et al 2006 Proc Natl Acad Sci USA 103:10104).

The immune system protects the body from microbial infections and also from non-infectious foreign macromolecules such as proteins, polysaccharides and tissue grafts.

Smaller foreign molecules (*haptens*) may also trigger the immune system primarily when associated with proteins. The molecules that elicit the immune response are called antigens. Antigens stimulate the formation of antibodies which are the actual defense molecules. The immune reaction is extremely specific and minute differences between antigens, such as single amino acid substitutions or isomers may be particularly recognized. The immune system distinguishes the body's own antigens from those of extraneous origin. The absence of an immune response to the body's self antigens is known as *acquired immunological tolerance*. The tolerance, i.e., distinguishing self from foreign molecules develops in the thymocytes by negative selection of self-reacting T cells. The T cell antigen receptor controls the activation and subcellular localization of Ras and MAPK signaling intermediates and by a subtle margin and thus develops self-tolerance (Daniels MA et al 2006 Nature [Lond] 444:724).

The immature immune system may learn to ignore even a foreign antigen if exposed to it at a very early stage. Immunological tolerance may be produced in the later stages of development with immunosuppressive drugs, by very high or repeated exposure to extremely low amounts of the foreign antigen. Also, altering the so-called *antigen-presenting cells* may affect tolerance. These antigen-presenting cells bind, process and combine foreign antigens with Class I and II proteins of the HLA complex (MHC). T lymphocytes can be made tolerant to foreign antigens more readily than the B cells. In some rare *autoimmune diseases* even self-discrimination may break down with very serious consequences for the individual because the defense system of the body may destroy its own tissue. The key players in mounting an immune response are approximately two

trillion lymphocytes (white blood cells) of the human body. *B lymphocytes* are involved in the *humoral* (circulating in the blood) immune response. B cells produce antibodies. These are called B cells because they are produced in the bursa of Fabricius (intestinal pouches) in birds. In humans, B cells originate from the stem cells of the fetal yolk sac, then in the liver and finally in the bone marrow (humans do not have a bursa). The pre-B cells appear in the fetal liver by the 8th week of gestation and contain μ immunoglobulin chains in their cytoplasm but not on their surface. About 2 weeks later B cells appear. By the 13th week B cells have μ immunoglobulin on their surface. By the 12th week B cell production shifts to the bone marrow. IgD (immunoglobulin δ) appears by the 14th week in the spleen, lymph nodes and blood. After the 14th week HLA antigens begin to appear. As the antibody gene rearrangements proceed all other immunoglobulin genes may be expressed (see Fig. 18). The proliferation and differentiation of B cells requires the presence of antigens on their surface and some soluble factors obtained from the T cells. The T_H (helper) and T_S (suppressor) cells regulate the development of B cells. The activation of helper T cells requires the presence of APC cells (*antigen-presenting cells*), HLA Class I and II proteins and interleukin-1. The T_H cells secrete some mediators (e. g., lymphokines).

The activated lymphocytes and mediators then induce the formation of receptors that is followed by the proliferation and differentiation of both T and B lymphocytes. The suppressor lymphocytes may prevent the induction of the immune response by exposure to a wide variety of molecules. Important representatives of the immune system are *T lymphocytes* (shaped in the thymus), their primordia develop by the 5th-6th week of human gestation and the first mature T cells appear by the 9th-10th week (see Fig. 19). T cells are involved in the *cell-mediated* immune response, i.e., they react with antigens bound to their surface. As the maturation of the T cell precedes the CD antigens (CD1, Cd2, CD4, etc.) appear on their surface and identify T cell subsets. By the 16th-20th week the spectrum of subsets reaches that of adults. T cells usually respond to antigens in association of the HLA complex (MHC, major histocompatibility complex). T cells with CD8 antigens respond to Class I proteins of the HLA complex whereas CD4 T cells are limited to HLA Class II proteins (DP, DQ, DR). This phenomenon is called

Figure 18. Development of the immune system and its major components. The B and T lymphocytes in mature individuals are generated by the hematopoietic cells in the bone marrow. The virgin B cells become either plasma cells or memory cells upon the encounter of a foreign antigen and lymphokines. As a response the plasma cells manufacture antibodies that are first embedded in the plasma membrane of the B cells, and when the membrane is “saturated”, they are released as circulating antibodies. Antibody IgM polymerizes into a pentamer and joins A J peptide chain. The IgA antibody forms a dimer and A J polypeptide chain also braces it. The memory cells do not become active until follow-up exposure to the particular antigen. Each of the antibody-producing cells makes one single type of antibody and its clonal progeny also makes the same antibody. Different antibodies are made by different B cell clones. The immature T cells differentiate into T cells within the thymus. The thymus is a bilobate organ that develops in the embryo and it reaches its maximal function during puberty and then begins a gradual, slow decline, accompanied by a decrease of T lymphocyte production and a weakened immune response. The mature T cells are of three main types: *killer cells* (cytotoxic T lymphocytes, CTL), *helper T cells* (T_H) and *suppressor T cells* (T_S). The specificity of the T cell function depends on the surface antigens carried by the antigen-presenting cells. The TCR (T cell receptor) has substantial structural and functional homology with the immunoglobulin proteins. The TCR complex is formed by the participation of the MHC protein, encoded by the HLA complex and a series of cell membrane proteins. The killer cells destroy the membranes of the invading cells, followed by lysis of their content

MHC restriction. Maternal IgG may cross the placenta after the 16th week and provides early immune protection for the fetus. Fetuses and newborns may not respond much to foreign cells because lymphocyte development may be arrested when contacted by antigens and anti-idiotypic antibodies. IgM and IgA are normally (in the absence of infection) not present in substantial amounts in newborns. Although after birth the maternal IgG tends to be eliminated, it is gradually replaced by the infant’s own antibodies. By the age of 3, IgG levels become sufficient. Before the end of the first year IgM levels reach those of adults but IgA levels rise very slowly, reaching adult levels only by 9–12 years of age. The appearance of the immune reaction is the result of a developmental process. The *virgin T cells* (that have never been exposed earlier to a specific antigen) become *effector cells*, i.e., they begin to proliferate and

produce either the cell-mediated (T cell) or the humoral (B cell) response. Some other lymphocytes are also induced to proliferation and differentiation. This time they do not participate in the immune response but become *memory cells* that will “remember” the same antigen by virtue of their differentiation, and assume the effector cell role later on similar exposure (*clonal mechanism of secondary immune response*).

The immune response is mounted relatively slowly (in days or weeks) when exposed to a particular antigen for the first time (*primary immune response*) but on subsequent exposures the response is faster because of the availability of memory cells. This phenomenon forms the basis of immunization (vaccination) as it is used in medicine. In order to generate an immune response the lymphocyte receptors must be exposed to an antigen. This is

Figure 19. Some types of communication in the immune system

usually followed by the signals of cytokines and other co-stimulator molecules (CD40, CD80, CD86 on the antigen-presenting cells) resulting in the clonal proliferation of specific lymphocytes and memory cells. Contact of CD28 and CD80, CD86 initiates the immune response and the CTLA-4 receptor with CD80, CD86 terminates the T cell immune reactions. CD28 also stimulates the synthesis of the Bcl anti-apoptosis proteins or B cells. The C3d component of the complement in association with the CD21 complement receptor is the co-stimulator. In case the antigen cannot reach the lymphocytes or the co-stimulatory response is defective there will be no immune response. The immune system is largely associated with lymph nodes and the spleen and as such represents systemic responses. Some of the immune reactions are, however, localized to specific tissues such as the gut epithelia or intraepithelial lymphocytes.

In insects, different types of peptides such as cecropin (35–39 amino acids), defensin, attacin, diptericin (82 amino acids), drosopcin, metnikowin, drosomycin, andropin and lysozyme mediate the humoral defense system. In addition, cellular response (phagocytosis) may also be available. A genome-wide survey of the *Drosophila* genome (13,197 genes tested) using microarray analysis revealed that microbial infection induced 230 genes and repressed 170. A different defense system occurs in plants. The molecules (virulence factors) of the invading pathogens act as elicitors for the production of host proteins. These proteins may cause basic changes in the plant metabolism. In extreme cases the hypersensitive reaction kills the infected plant cells to prevent the spread of the disease throughout the entire plant body (Nimchuk Z et al 2003 Annu Rev Genet 37:579). ▶antibody, ▶immune response,

Immune Tolerance: Refers to the failure of the immune system to respond to antigen(s) by supposedly suppressing the alloreactive T cells. The earlier belief was that neonates were supposed to exhibit immune tolerance, however, recent research has indicated that their immune response may be different. Immune tolerance is regulated either by anergy or by suppression. Suppression may be mediated by low oral doses of antigens or by clonal anergy when high doses of the antigen are provided. Oral tolerance may extend to tolerance of the gut immune system and may thus exhibit a systemic immune reaction to ingested proteins. The brain-blood barrier prevents lymphocytes from entering the central nervous system. The peripheral immune tolerance may include T cell-activated repression by the secretion of TGF- β . Both CD4 and CD8 regulatory T cells control and can transfer donor-specific tolerance for allografts (Sho M et al 2005 Proc Natl Acad Sci USAS 102:13230). It is somewhat baffling why allogeneic fetuses are not rejected by the maternal immune system. The mother's body may reject organ transplants from the child because of the paternal genes of the offspring. Notwithstanding, the same mother can carry to term the child. It has been hypothesized that either physical separation or antigenic immaturity of the fetus or some sort of immunological inertness of the mother toward the conceptus may be responsible. It appears that the maternal T cells specific for paternal MHC class I alloantigens are reduced during pregnancy. The

observation that the concentration of tryptophan is lower in the maternal-fetal interface tissues led to the experimentally supported assumption that tryptophan may be required for T cell proliferation. The level of tryptophan is reduced by indoleamine 2,3-dioxygenase (IDO). The inhibition of IDO by higher doses of tryptophan analog 1-methyltryptophan reduced the maintenance of allogeneic concepti in mice apparently by curtailing the chances for T cell mediated rejection. The loss of autoimmunity may occur after infection by pathogens due to molecular mimicry, epitope spreading or bystander activation. B cell tolerance may be lost after removal of the self-antigen or when T cell help is provided at the initial exposure but not if the T cell is available after the exposure to the self-antigen. In tissue or organ transplantation generally immunosuppressive drugs are used. However, these drugs themselves present health risks. Research is underway to find ways of minimizing the immune reaction to foreign proteins (Waldmann H, Cobbold S 2004 Science 305:209). Some tumors avoid destruction by induction of T cell tolerance (Willimsky G, Blankenstein T 2005 Nature [Lond] 437:141). ►antigen, ►anergy, ►mast cell, ►immunoediting, ►TGF, ►mucosal vaccines, ►T cell, ►T cell receptor, ►T cell regulatory, ►thymus, ►immune system, ►self-tolerance, ►immunosuppression, ►alloreactive, ►immunity, ►Rh blood group, ►incompatibility, ►conceptus, ►bystander activation, ►epitope, ►molecular mimics, ►transplantation in utero; Krensky AM 2001 Pediatr Nephrol 16:675; Godnow CC 2001 Lancet 357:2115; Robertson SA, Sharkey DJ 2001 Semin Immunol 13(4):243; Moffett-King A 2002 Nature Rev Immunol 2:656.

Immunity: Refers to a protected state against biological (microbial) or other agents. *Natural immunity* is the readily emerging incompatibility between donor and recipient tissues. The xenoreactive natural (human) antibodies (XNA) react with the Gala1–3Gal terminal antigens present on the endothelial lining of blood vessels of the xenografts of the majority of mammals (except humans and some primates). This binding then activates the human complement system. The graft *complement decay accelerating factor* (DAF), *membrane cofactor proteins* (MCP) and CD59 cannot neutralize the host natural immunity reaction and thus rejection may be initiated. Further injury to the graft is inflicted by the natural killer cells of the host. Although NK cells normally carry *inhibitory receptors* that usually prevent an attack on MHC class I molecules but this system may also fail with the MHC system of the graft. *Acquired immunity* develops as a reaction of the immune system of the organism. The transfer of antibodies or activated

lymphocytes from another body conveys *passive immunity*. *Natural immunity* means that the cells are not susceptible to a particular organism, e.g., humans are not infected by wheat rust. *Genetic or familial immunity* indicates that a group of individuals is resistant to or free of a particular type of infection. In *maternal or intrauterine immunity* humoral antibodies pass through the placenta into the fetus. *Cell mediated immunity* is the result of T lymphocyte activation by adoptive transfer (adoptive immunization) of an immune donor to syngeneic recipients. *Humoral immunity* is provided by the antibodies secreted by B lymphocytes. In *neonate immunity* IgG immunoglobulins are secreted by the mother's milk with the assistance of the FcRn receptor. At the newborn stage monocytes and macrophages have limited activity resulting in the reduction of the MHC class II proteins, co-stimulatory molecules, antigen processing and cytokines. Natural killer cells are present but not very active. *Phage immunity* describes the condition where a lysogenic bacterium cannot be superinfected by another bacteriophage. ▶immune response, ▶antibody, ▶humoral antibody, ▶MHC, ▶FcRn, ▶lymphocyte, ▶superinfection, ▶mucosal immunity, ▶syngeneic, ▶xenotransplantation, ▶complement, ▶killer cells, ▶immune tolerance, ▶MHC, ▶cytokines, ▶antigen-presenting cell, ▶killer cells

Immunization: Refers to the induction of immunity. It can be *active immunization* by introducing specific antigens into the body to promote the formation of a specific antibody or *passive immunization* by introducing antibodies into the body that may provide temporary immunity. Vaccination involves the introduction of live (attenuated) or killed microbes into the body either through the bloodstream or by oral means. The bonding subunit of *E. coli* heat-labile enterotoxin (LT-B) is a very effective immunogen. Bacterial polysaccharide vaccines are not effective in infants before 18–24 months of age although protein conjugates may be effective in few weeks old neonates. At this stage attenuated live viral or bacterial vaccines are usually not advisable. The results of DNA immunization at the early stages of life are still debated.

Transgenic plants encoding LT-B, express the foreign peptides, and are able to bind the natural ligand after oligomerization. Mice fed by antigens produced by transgenic plants can be orally immunized. Also, tobacco plants transgenic for murine antibody κ chain, hybrid immunoglobulin A - G heavy chain, an immunoglobulin J chain and a rabbit secretory component, respectively, after intercrossing produced segregating progeny that simultaneously expressed all four polypeptides. The polypeptide

chains were successfully assembled within the transgenic hybrid into a functional high molecular weight secretory immunoglobulin that could recognize streptococcal surface adhesion molecules. Interestingly, in plants this process can take place in a single cell whereas in animals it requires two cell types. The results indicate the possibility of using immunoglobulins manufactured by plants for oral vaccination. In "reactive immunization" the antigen is so highly reactive that a chemical reaction takes place at the site of the combining antibody. This mechanism may enhance catalytic antibody chemistry. The common type of immunization does not result in covalent interaction between the antigen and the antibody. Although sharks can synthesize a variety of immunoglobulins (somewhat different from higher mammals) they cannot be immunized. ▶antibody, ▶immunoglobulins, ▶immunization genetic, ▶vaccines, ▶transformation genetic [transformation of plants], ▶intercellular immunization, ▶intracellular immunization, ▶immunization in vitro, ▶memory immunological

Immunization, Genetic (DNA vaccination): Involves introducing into an animal (or into a specific animal tissue) a gene or expression gene library encoding a particular antigenic protein(s) by biolistic transformation or plasmid vectors resulting in antibody production. The transgene is introduced into muscle tissue or into the skin. The latter, especially when associated with lymphoid tissues, is more suitable because it harbors a greater number of antigen-presenting cells. This method does not involve the risk of live or attenuated pathogen vaccines. Targeting antigen-ligand (L-selectin or CTLA-4) constructs to the lymph nodes or to antigen-presenting cells (dendritic cells, macrophages and lymphocytes) enhances the effectiveness of DNA immunization 100 to 1000 fold. They may elicit Th1 or CD4⁺ and CD8⁺ T cell responses. The presence of special DNA sequences (IL-2) may serve as *adjuvants* and substantially magnify the reaction. Poly G:C or poly I:C or palindromic (5'-GACGTC, 5'-ADCGCT, 5'-AACGTT) sequences may effectively induce the production of interferons and interleukins, potent stimulants of the killer effects of lymphocytes. Co-injection of vectors containing mutant caspases stimulates T and B lymphocyte responses. DNA vaccination appears to be effective for infectious diseases, malaria, autoimmune diseases, cancer and also for proteomic research. DNA-based vaccines, encoding syngeneic or allogenic, lectin-like natural killer cell ligands (NKG2D) along with survivin or carcinoembryonic antigen activate both innate and adaptive antitumor responses (Zhou H et al 2005 Proc Natl Acad Sci USA 102:10846). The goal of this

procedure in the case of cancer is not prevention but the cure of tumors already present in the body. A potential advantage of DNA vaccination versus protein vaccines is the continuous expression of the antigen. DNA vaccines are expected to be processed for immune recognition by the cell's special protein degradation system, have high temperature-stability, and the cost may be low. A possible slight risk is that the transgenic products may have adverse side effects such as inducing autoimmune reaction or immune tolerance. DNA immunization appears to be substantially less effective as aging progresses. In a rat model, using orally administered adeno-associated virus vaccine containing the NR1 subunit of the NMDA receptor generated strong anti-epileptic and neuroprotective effects. ▶ **immunization**, ▶ **antibody**, ▶ **biolistic transformation**, ▶ **viral vectors**, ▶ **library**, ▶ **selectins**, ▶ **CTLA-4**, ▶ **T cell**, ▶ **gene therapy**, ▶ **IL-2**, ▶ **monoclonal antibody**, ▶ **malaria**, ▶ **auto-immune diseases**, ▶ **cancer**, ▶ **IFN**, ▶ **IL**, ▶ **immune tolerance**, ▶ **polynucleotide vaccination**, ▶ **NMDA receptor**, ▶ **adeno-associated virus**, ▶ **epilepsy**, ▶ **vaccine**, ▶ **surviving**, ▶ **carcinoembryonic antigen**; Xu M et al 2000 Trends Biotechnol 18:167; Maloy KJ et al 2001 Proc Natl Acad Sci USA 98:3299; Schadendorf D 2002 Semin Oncol 29:503; Chambers RS, Johnston SA 2003 Nature Biotechnol 21:1088, <http://www.natx.com/DNAVaccines.html>; DNA vaccine design server: <http://miracle.igib.res.in/dynavac/>.

Immunization, Intracellular: This is the same as immunization genetic.

Immunization In Vitro: B lymphocytes are cultured in vitro in the presence of cytokines and growth factor complexes in order to produce antibodies. It has somewhat limited significance; nevertheless, it may be particularly useful when antibody production is elicited against hazardous antigens. ▶ **immunization**

Immunoadsorption: Describes the process of binding a cognate antibody to an antigen in order to facilitate the separation of a specific type of antigen or antibody from a mixture. In *extracorporeal immunoadsorption* the blood is pumped out of the body and allowed to react with an affinity column and then may be pumped back into the body after this clearance, e.g., removal of radioactively labeled antibody. ▶ **immunofiltration**

Immunoassay: This is based on the recognition of an antigen by an antibody. ▶ **radioimmunoassay**, ▶ **Western blot**, ▶ **immunoblot**, ▶ **conformation-dependent immunoassay**

Immunoblotting: Refers to the separation of proteins by gel electrophoresis and identification of an appropriate component by the specific monoclonal antibody

labeled by fluorochrome or radioactivity. ▶ **Western blotting**, ▶ **electrophoresis**

Immunocontraceptive: The vaccination of animals with zonula pellucida proteins and adjuvants prevents fertilization to a substantial extent. Immunization with eppin is a reversible contraceptive measure used in male primates. ▶ **contraceptives**; eppin; O'Rand MG et al 2004 Science 306:1189.

Immunocytochemistry: Locates antigens in the cell with the aid of labeled antibodies through microscopic examination. ▶ **immunolabeling**

Immunodeficiency: This condition may be due to several different (~80) causes. Some of them have milder effects whereas others are lethal. Immunodeficiency is frequently caused by defects in the lymphocyte differentiation system (thymus). Some of the immunodeficiencies are parts of other syndromes such as Down's syndrome, sickle-cell anemia, ataxia telangiectasia, glycoprotein deficiency, glucose-6-phosphate dehydrogenase deficiency, immunoglobulin imbalance [deficiency of IgA and IgG but increased IgM], defects of the HLA histocompatibility system and some are caused by non-genetic events, such as infection [HIV] or drugs and various allergies that may have a genetic component. Xq13.1-linked immunodeficiency with hyperimmunoglobulin M (IgM) but absence of IgG, IGA and IgE is caused by a defect in the interleukin receptor IL-2R γ c chain and interaction between CD40 and CD 40L and accounts for nearly half of all the cases. As a consequence T cells and B cells do not differentiate normally. The ICF syndrome (human chromosome 20q11.2, immunodeficiency, centromere instability [centromere areas 1, 9 and 16]) and facial anomalies involve a defect in DNA methyltransferase 3B. Methylation at specific sites in the heterochromatin is essential for the maintenance of chromosome integrity (Hansen RS et al 2000 Hum Mol Genet 9:2575). Several immunodeficiencies are the consequence of medical treatment, e.g., cancer therapy or the use of immunosuppressive drugs in tissue transplantation. Jak-3 deficiency causes lymphocyte problems. ADA (adenosine deaminase) recessive defects are responsible for about 15–25% cases of severe immunodeficiency. RAG1/RAG2 (recombination activating genes) interfere with the generation of immunoglobulins and lead to impaired lymphocyte receptors. Recessive mutation in ZAP 70 gene (2q12) is detrimental to the development of T cell receptors. Recessive mutations at 11q23 (CD3 ϵ /CD3 γ) also cause immunodeficiency due to problems with immunoglobulins. Mutations in the MHC class I (6p21.3) and class II peptides adversely affect T and B lymphocytes. ▶ **agammaglobulinemia**, ▶ **hypoglobulinemia**, ▶ **hypogammaglobulinemia**, ▶ **severe**

Immunodominance: Of the many possible epitopes of the antigen, cytotoxic lymphocytes (CTL) recognize only one or a few. ▶epitope; CTL; Brehm MA et al 2002 Nature Immunol 3:627.

Immunoediting: This proposes that tumors that evoke strong immune response by T cells develop a survival mechanism by down regulating or eliminating the molecules to which the immune system reacted. ▶immune tolerance, ▶immunological surveillance

Immuno-Electronmicroscopy: Fluorescent antibodies label cell constituents and thus the location of proteins can be identified with electronmicroscopic resolution. ▶histochemistry, ▶microscopy; Yamazaki K, Eyden BP 1998 J Submicroscopic Cytol Pathol 30:217.

Immuno-electrophoresis: This can be carried out by different procedures. In *diffusion*, over the electrophoretically separated proteins, antisera (antibody or antibodies) are placed in a trough. The protein bands are permitted to diffuse in a radial manner from their original position in the gel while the antibody diffuses vertically and at their position of reaction with each other an elliptical arc of precipitation is formed. In *rocket electrophoresis* the antigen is placed in the wells of the gel that contain the antibody. After switching on the electric current the antigen moves and forms a rocket-shaped trail of precipitation as it reacts with the antibody. The length of the rocket indicates the amount of antigen applied to a well. ▶ELISA, ▶rocket electrophoresis

Immunofluorescence: Refers to the identification of a protein (antigen) by *direct* adsorption to a specific antibody that has an attached fluorochrome. Alternatively, to the first (unlabeled) antibody a second cognate, fluorochrome-labeled antibody is added for the sake of immunostaining (*indirect* method). ▶fluorochromes, ▶antigen, ▶antibody

Immunogen: This is a substance which elicits an immune response. ▶immune system

Immunogenetics: This is concerned with the hereditary and molecular aspects of antigen and antibody systems and the immune response. <http://imgt.cines.fr:8104/home.html>.

Immunoglobulins: These are the structural units of antibody molecules. Each antibody is a heterotetramer consisting of two identical light immunoglobulin chains (either of two λ κ) and two identical heavy chains (see Fig. 110). The five heavy chains of humans and mice exhibit considerable variations but the light chains are fairly constant. There are five classes (*isotypes*) of immunoglobulins IgM, IgG, IgA, IgD and IgE, identified according to the heavy chain subunits: μ , γ , α , δ and ϵ . The Ig heavy chains are glycoproteins containing about 15, 4, 10, 18, 18% sugars in a molecular mass of 70, 50, 55, 62 and 70 (kDa) for μ , γ , α , δ , and ϵ , respectively. IgM is a pentamer containing five μ heavy chains and five light chains and one J chain; its molecular mass is around 900 kDa.

Figure 110. The pentameric structure of immunoglobulin M (IgM), joined by J chain in the center. Note the absence of hinges. ▶antibody

The J polypeptide (ca. 20-kDa), synthesized within IgM secreting cells, is covalently attached between two Fc domains antibody, and it is supposed to initiate oligomerization. (The J polypeptide is not the product of the J genes located between the variable and constant gene clusters). The IgA antibody is a monomer or a dimer or a trimer with molecular weights 153, 325 and 580, respectively, and may have a J chain. Besides the J polypeptide IgA may also have a secretory component (SC) of 558 amino acids. The SC is picked up by the secretory IgA dimers from the surface of epithelial cells and it braces the IgA dimers and protects them from proteolysis.

The SC is part of the transport receptor and mediates the translocation of Ig and IgM into glandular secretions. The IgG, IgD and IgE antibody

monomers are of 150, 180 and 190-kDa, respectively. IgD and IgE are of minor significance although the latter mediates allergic reactions and its level is elevated hundreds of fold in chronic infections. Each of the five major types of heavy chains can be associated with either one of the light chains.

The five classes of antibodies play somewhat specialized roles. IgG is the humoral, circulating antibody and it is the major class. It can cross the placenta and enter extravascular areas. IgE manages the allergic reactions and IgA has a major role in defense against microbial infections. IgM and IgA have two subclasses, IgG and the λ chains have four, designated as e.g., IgM1 and IgM2. Some of the IgG subclasses can cross the placenta. IgM is secreted in low amounts by B lymphocytes but this is the first immunoglobulin produced by newborns which readily activates the complement cascade, and thus represents one of the first lines of defense. IgA is produced mainly in the gastrointestinal system and plays a major role in mucosal immunity. Within these subclasses *allotypes* are distinguished, 25 for human IgG, 2 for IgA and 3 for the kappa (κ) chain. These allotypes represent antigenic markers on the immunoglobulin chains and are designated as e.g., Gm1, Gm2... Am1... Km1... for IgG, IgA and κ chain markers, respectively. The allotype variants represent amino acid substitutions at one or more sites. The characteristic series of allotype markers are inherited as gene blocs and are called *haplotypes*.

The genes encoding immunoglobulins are clustered in three supergene families. The heavy chain genes are clustered at human chromosomal location 14q32.33. The κ genes are in human chromosome 2p12, whereas the λ gene family is in human chromosome 22q11.12.

Within the approximately 7,000-kb heavy chain region in the long arm of chromosome 14 the genes L encode the signal that leads the polypeptide to the endoplasmic reticulum. V_H (variable heavy), D (diversity), J (juncture) and the various constant heavy chain genes C_μ to C_α , are arranged in groups. The groups are separated by long base sequences (~~) and spacers (ζ) with switch signals (S) in front of the constant heavy chain genes. The general organization of immunoglobulin genes is very similar in all mammals although they are located in different chromosomes:

(ψ indicates pseudogenes). Up front of this sequence, the basal promoter of the Ig heavy chains contains non-translated regulatory transcriptional elements, such as the dispensable *heptamer* consensus: (5'-CTCATGA-3') and 10 to 40 bp downstream the indispensable *octamer* consensus: (5'-ATGCAAAT-3'). The latter is 30 to 60 bp upstream from the TATA box, that is

followed within about 20 to 30 bp the transcriptional initiation site for the LVDJ and the constant heavy chain sequences, μ to α_2 . (The orientation of the octamer is opposite to the direction of transcription). Between the LVDJ region and the constant heavy chain genes, there are enhancer elements of the 5'-CAGGTGGC-3' motif and three core repeats of multiple GC sequences.

The κ cluster is similarly organized in human chromosome 2:

The λ genes are in human chromosome 22. The variable genes occur in six groups. Here the J genes are not clustered separately but situated in front of the six constant λ gene groups. Some of the λ genes are outside the clusters and may not be functional. The individual λ segments are quite variable in size. The V_S , one of the switching sequences, is explained here.

The base promoter of the κ light chain contains at about 100 bp upstream from the transcription initiation site a pentanucleotide consensus, and within -90 to -60 bp the octamer consensus (oriented in the direction of the transcription) follows. This does not have the heptamer shown at the heavy genes. The TATA box is at about the same distance from the transcription initiation site as in the heavy chains. There are enhancer elements, designated as κB (5'-GGAAAGTCCCC-3') and Ek1 to Ek3 (variants of the enhancer motif shown at the heavy chains), between the LVJ genes and the constant κ gene group. The strongest enhancer is the κB . Both the heavy and light gene enhancers act preferentially in B lymphocytes. The heavy chain enhancers seem to be constitutive whereas the light gene enhancers become active after the rearrangement of the genes. Besides the enhancers, the immunoglobulin genes appear to have silencers of expression for non-lymphocyte chromosomes. Turning on the promoters requires transcription factors, one of them is 60-kDa OTF-2 which has specificity for the immunoglobulin enhancer consensus 5'-CAGGTGGC-3'. The 90-kDa OTF-1a general mammalian transcription factor is also present in the lymphocytes. The DNA-binding domains of these two factors are very similar but their other domains are different. These enhancers also bind other types of proteins and the only lymphocyte-specific enhancer appears to be the octamer. The light chain specific transcription factor is protein NF- κB that binds to the 5'-GGGPu(C/T)TPyPy(C/T)C-3' motif. After the immunoglobulin light chain has undergone rearrangement, preparatory to transcription, the pattern of the *nuclease-sensitive sites* in the promoter region is altered.

heptamers (7mers) at the ends of the two coding units and this leads to the elimination of the interjacent segment with the *signal ends*. The ends of the coding sequences are the *coding ends*. The signal ends may be joined to form a circular DNA structure and this circularization, followed by elimination, is apparently a major source of rearrangements. In some instances there is an inversion of the V gene relative to the J gene. In such a case the intervening material may not be deleted although the V gene may be inactivated. Some of the rearrangements are *non-productive* because they occur at random and are in the wrong register. Since codons are triplets, two-thirds of the rearrangements may result in garbled sequences. Some nucleotides may be lost at the coding ends and some may be added (*N nucleotides*) by the enzyme deoxynucleotidyl transferase. At the coding ends, the 5' terminus of one of the DNA strands may covalently fuse with the 3' terminus of its complementary strand. When the resulting hairpin structure breaks, a protruding end of nucleotides may be formed that can serve as a template to generate an inverted terminal repeat of a few nucleotides (*P nucleotides*). The 96th codon at the end of the V_H gene is actually generated by a fusion between the V and J genes. This is a critical point because the 96th amino acid is part of the antigen-binding region as well as the connection of the light and heavy chains. Both deletions and additions increase the variability of the antibody genes. The V_H regions can combine with any of the five constant heavy chains (μ, δ, γ, ε, α and their subclasses, *isotypes*) and this is a source of another variation.

The expression of the immunoglobulin genes requires that the promoter be transposed to the vicinity of an enhancer base promoter structure. The enhancer becomes normally active only in the B lymphocytes. Before any antigen is encountered, IgM and IgD class antibody production starts. In such virgin B cells, both immunoglobulins have identical variable regions but they may differ in the constant regions of the μ and the δ chains. Since B cells are diploid, genes in only one of the two homologous chromosomes can be expressed at a time and only one type of rearrangement can function in a cell, this is known as *allelic exclusion*.

The virgin B cells can then differentiate either into *plasma cells* or into *memory cells* upon exposure to an antigen. The former become an immediate producer

of an antibody, the latter would be activated into plasma cells only upon subsequent exposure to the same antigen. The differentiation is aided by *lymphokines* (a variety of growth regulating proteins), and various T lymphocytes (T_H, T_S) and macrophages. The association of the virgin lymphocytes with an antigen triggers the mechanism of *isotype switching*. Isotype switching brings about the selection of the proper heavy chain constant region by a process of transcription although DNA deletions may also be involved. In the undifferentiated B lymphocyte transcription begins at the heavy chain gene leader sequence upstream and continues through the variable and diversity regions to the end of the δ gene, passing through exons and introns. Polyadenylation signal follows the last exon of the transcribed constant region of the μ and δ genes:

Two types of μ chains exist at the early stage of the B lymphocyte. The μ_m chain (with a hydrophobic C terminus and an alternative processing event) and μΣ. The former is included in the lymphocyte membrane as a monomeric IgM antibody (2 light-2 μ chains) whereas the secreted IgM becomes pentameric and also adopts a ca. 20 kDa J peptide with the composition of (μ₂λ₂)₅J (the J is synthesized in the B lymphocyte but not coded in the constant heavy chain cluster). After recombination and deletion occur at one of the S switch points, in the non-coding ca. 2-kb upstream tracts, at the (GAGCT)_nGGGGT motifs, of the constant heavy chain genes, the rearranged gene are transcribed. The introns are eliminated and the transcript is processed into polyadenylated mRNA. The mRNA is translated into the individual heavy chain monomers:

switching at γ

V₂---D₅-J₅-----γ PRIMARY TRANSCRIPT
↓
IgG 50 kDa polypeptide

switching at α

V₂---D₅-J₅-----α PRIMARY TRANSCRIPT
↓
IgA 55 kDa polypeptide

In the examples given here the same VD and J genes are shown, actually any of the VDJ genes can be selected before switching. Additional variation is

generated by somatic mutation during the proliferation of the lymphocyte clones. The frequency of these mutational events (about 10^{-3} per base) appears to be higher than the usual mutation rate of other types of genes. After the heavy chain is completed it may combine with any of the two light chain polypeptides. IgG and IgA are further polymerized to form the final antibody. The activity of B cells is terminated partly by binding the antigen to the secreted antibody. This prevents the binding of the antigens to the B lymphocyte receptors and thus the stimulation of immunoglobulin synthesis ceases. Some birds (ducks, geese, swans) produce immunoglobulin Y (IgY), which does not occur in mammals or in some other avian species but it bears similarities to IgG and IgE. IgY is produced in larger and smaller forms; the latter is deficient in the crystalline fragment.

The completed polypeptide chains are modified glycosylation (using covalently D-galactose, N-acetyl-D-galactosamine, N-acetyl-D-glucosamine, L-fucose, D-mannose and acetylneuraminic acid) that affects their structure and function. IgG has only 3% carbohydrates whereas other chains may have 3–4 times as much. The glycans are mainly at the constant regions of the heavy chains although the number and location of the glycosylation sites vary. Glycosylation affects the activation of the complement, their stability in relation to proteolysis, the number of antigen binding sites available (avidity), etc. In certain diseases (rheumatoid arthritis, tuberculosis, Crohn's disease, Sjögren syndrome, scleroderma and some autoimmune conditions) the IgG molecules lose their galactose. The agalactosyl IgG molecules decrease during pregnancy and their level is lower during the first 25 years of life thereafter it increases again.

In humans and pigs the proportion of κ : λ chains is about 6:4 whereas in rodents κ chains are about 19 times more common than the λ chains. Chickens have only λ light chains, and in many other animals (bovines, horses) the λ chain is preponderant. All vertebrates synthesize immunoglobulins yet the antibodies of the lower animals (fishes, amphibians, reptiles, birds) are somewhat different from those of higher forms. In mammals usually five types of immunoglobulins are produced. There are exceptions, however. Rabbits lack IgD while mice and rats have all five types. In cattle, sheep, pigs and horses IgM, IgG, IgA and IgE occur. In cats IgG, IgM, IgA and IgE and several subclasses are found while dogs have all five types. In camels and llamas the IgG molecules are built of heavy and light chains whereas other immunoglobulins have only heavy chains and the variable domain of the light chain is missing. Transgenic mice containing camelid heavy chain antibody (HCab) loci rearrange properly, result in allelic exclusion, efficiently rescue B cell

development, and undergo class switch recombination and affinity maturation. They generate functional HCabs subsequent to antigenic challenge, providing a new way of producing human HCab when the llama variable heavy chain (VHH) regions are replaced with soluble human VH (Janssens R et al 2006 Proc Natl Acad Sci USA 103:15130).

In invertebrates there are some immune defense molecules. In the *Drosophila*, the *Amalgam* (*ama*, 1–47.5) encoded cell adhesion proteins display some bear immunoglobulin-like domains. The fasciclin II glycoproteins involved in neuronal recognition of grasshoppers have five immunoglobulin-like domains. It is conceivable that the PapD prokaryotic protein involved in pilus assembly has some evolutionary relation to immunoglobulins. The similarity is not in the amino acid sequence but in the overall structure of the domains.

Extremely large phage antibody libraries can be generated in bacteria with the aid of two non-homologous *Lox* sites in a phagemid vector. The exchange among variable heavy and variable light chain genes creates functional recombinants with a diversity of $\sim 3 \times 10^{11}$. Gene conversion generates additional diversity. ►antibody, ►surrogate chains, ►IgNAR, ►immune system, ►immunization, ►lymphocytes, ►complement, ►HLA, ►TCR, ►T cell, ►T cell receptors, ►B cell, ►DNA-PK, ►RAG, ►RSS, ►V(J)D recombinase, ►antibody gene switching, ►class switching, ►AID, ►SCID, ►terminal nucleotidyl transferase, ►repertoire shift, ►affinity maturation, ►CDR, ►somatic hypermutation, ►hypermutation, ►accessibility, ►translin, ►monoclonal antibody, ►hybridoma, ►multiple myeloma, ►macroglobulinemia, ►ELISA, ►tail-piece secretory, ►membrane segment, ►transposons [Tn3, ►Tn5, ►Tn7, ►Tn10], ►hemolin, named diseases under separate entries, ►*Cre/LoxP*; Bross L et al 2000 Immunity 13:589; Arakawa H et al 2002 Science 295:1301; immunoglobulin diversification paths: Maizels N 2005 Annu Rev Genet 39:23; immunoglobulins and T cell receptors: <http://imgt.cines.fr>; variable genes: <http://www.vbase2.org/>.

Immunoglobulins in the Human Serum: (mg/mL), IgG1, 146 kDa [γ 1]: ~ 9 ; IgG2, 146 kDa [γ 2]: ~ 3 ; IgG3, 170 kDa [γ 3]: ~ 1 ; IgG4, 146 kDa [γ 4]: ~ 0.5 ; IgM, 970 kDa [μ]: ~ 1.5 ; IgA1, 160 kDa [α 1]: ~ 3 ; IgA2, 160 kDa [α 2]: ~ 0.5 ; IgD, 200 kDa [δ]: ~ 0.03 ; IgE, 200 kDa [ϵ]: ~ 0.0001 . Immunoglobulins also occur in milk, tears, genitourinary and lung secretions.

Immunohistochemistry: ►immunocytochemistry

Immunolabeling: ►immunostaining, ►ELISA, ►immunofluorescence, ►RIA, ►immuno-scintigraphy, ►monoclonal antibody, ►immunocytochemistry, ►immunosensor, ►fluorochromes

Immuno-Liposome: Refers to a liposome that is coated with target-specific antibodies to deliver, e.g., therapeutic agents to cancer cells. ►cancer gene therapy, ►liposome, ►bispecific antibody

Immunological Learning: The quality of the antibody improves as clonal selection progresses. ►clonal selection

Immunological Memory: Survivors of a cell (individual) that mounted an immune response are more effectively protected in the event of a subsequent infection. The mechanism of this protection may be based on the maintenance of specific T or B cells even in the absence of the antigen or some types of lymphocytes have the ability to remember the antigen. Recurrent low levels of infection may maintain some lymphocytes or some regulatory networks of cytokines respond in case of subsequent infection. ►immune system, ►lymphocytes, ►T cell, ►B cells; Utzny C, Burroughs NJ 2001 J Theor Biol 211:393; HU H et al 2001 Nature Immunol 2:705.

Immunological Privilege: At some tissue sites (such as the central nervous system, maternal—fetal interface, adrenal cortex, testis, ovary, hair follicles, liver) the immunological reaction is not elicited either by acquiring tolerance or by failure of the antigens to communicate effectively with the other sites.

Immunological Surveillance: This is one of the defense mechanisms against cancerous body cells. The surface antigens of the transformed (cancer) cells are different from their normal counterparts. The immune system continuously monitors the body for invading microorganisms and other foreign antigenic material (macromolecules, grafts, etc.) and also recognizes the cancer cells at an incipient stage and with the aid of the immune system (Rousseau Merck MF et al 1996 J Exp Med 183:725) gets rid of them. Experimental data in support of this idea indicated that antibodies produced against mammary cancer preferentially recognized the metastatic cells without reacting with the normal cells. The CCR7 chemokine receptor is an organizer of the immune response (see Fig. 111). Cancerous transformation may be initiated by a single mutation although for the development of neoplasias additional events are required. Mutation rates per cell are in the range of 10^{-9} , because the human body may have 4 to 5 times more cells, cancer mutations may affect each person numerous times during his lifetime. Nevertheless, the incidence of death due to cancer is about 0.2 of all deaths. If no biological protection was available, all individuals would have had cancerous transformation(s). The general validity of immunological surveillance for protection against cancer has been questioned because several types of cancers occurred at the

same frequency in immune-compromised or genetically weak immune system animals as in normal individuals. In a nude mouse with a defective immune system the incidence of cancer did not increase. When naive $CD4^+$ T cells specific for an antigen expressed by tumor cells were transferred into tumor-bearing mice transient clonal expansion occurred early after transfer, accompanied by phenotypic changes associated with antigen recognition (Stavely-O'Carroll K et al Proc 1998 Natl Acad Sci USA 95:1178). In recent years immunosurveillance has attracted renewed attention (Dunn GP et al 2004 Immunity 21:137).

Figure 111. The small lymphocyte (L) is attacking a large tumor cell (T). As the cancer cell begins to lyse, first the microvilli dilate, then surface vesicles (V) appear and eventually it shows blebbing before destruction. (Courtesy of Dr. A. Lepins. See also Lepins A et al 1978 Cell Immunol 36:331)

In transgenic mice where T lymphocytes and tumor-associated antigens could be monitored in some tumors a degree of immune tolerance developed. Recent information (Ochsenbein AF et al 2001 Nature [Lond] 411:10558) has revealed that (i) tumor-specific induction of protective cytotoxic T cells (CTLs) is contingent on how many tumor cells reach the secondary lymphatic organs early and stay there long enough; (ii) diffusely invading systemic tumors can eliminate CTLs; (iii) tumor cells which are either located outside the lymphatic organs or are not within the reach of T cells stay on; and (iv) the major histocompatibility class I molecules may not be protective. Killer cells, $CD8^+$ T cells and activated macrophages express the stimulatory NKG2D lectin-like receptors and this may also contribute to the rejection of tumor cells.

In BALB/c mouse ascites-injected animals may exhibit complete resistance to different types of cancer determined by a dominant factor. Advanced cancer cells are destroyed by innate leukocytes without damaging the normal cells (Cui Z et al

2003 Proc Natl Acad Sci USA 100:6682). ▶immune system, ▶cancer, ▶chromosome breakage, ▶genetic tumors, ▶cancer prevention, ▶CCR, ▶cancer therapy, ▶T cell, ▶MHC, ▶tumor suppressor factors; Diefenbach A et al 2001 Nature [Lond] 413: 165; Shastri N et al 2002 Annu Rev Immunol 20:463; Dunn GP et al 2002 Nature Immunol 3:991.

Immunological Synapse: Refers to the TCR engagement with the antigen-presenting cells with the aid of integrin family adhesion molecules. ▶TCR, ▶antigen-presenting cell, ▶integrin

Immunological Tests: These tests are extremely sensitive for the detection of the presence of a particular protein or other molecules, which can form cross-reacting material (crm) with specific antibodies. Frequently, if the quantity of the material is very low and standard biochemical assays are not sensitive enough for identification, immunoprobes are used for testing. ▶antibody preparation, ▶immunoprobe, ▶immunoscreening, ▶immunofluorescence, ▶pathogen identification

Immunological Tolerance: ▶immune system

Immunomicelles: These are polyethylene glycol-phosphatidylethanolamine conjugate tumor targeting vehicles for the delivery of poorly soluble drugs (e.g., taxol). To the micelle mouse an anti-tumor antibody (mAb2C5) is attached for specific recognition of the target. ▶liposome; Torchilin VP et al 2003 Proc Natl Acad Sci USA 100:6039.

Immunomodulators: Refers to viral encoded proteins regulating antigen presentation, regulators of cytokines, cytokine antagonists, inhibitors of apoptosis and interfering with the functions of the complement. ▶antigen-presenting cell, ▶cytokines, ▶apoptosis, ▶complement

Immunopanning: This is a cell separation technique used in neurobiology. (Gard AL et al 1993 Neuroprotocols 2:209).

Immuno-PCR: This is a polymerase chain reaction version resembling Capture-PCR. It detects specific antibody-DNA conjugates with high sensitivity. ▶Capture-PCR, ▶polymerase chain reaction; Sano T et al 1992 Science 258:120.

Immunophilins: These two classes of proteins bind immunosuppressants such as either rapamycin and FK506 (FKBP) or cyclosporin. All known immunophilins display rotamase (peptidyl-prolyl *cis-trans* isomerase) activity in vitro. The 59-kDa member of the FKBP family is a component of the inactive glucocorticoid receptor. Immunophilins apparently interact with protein kinases of the signal transducing paths and with the heatshock protein 90,

a chaperone. Immunophilins FKBP12 bind to the GS domain of the TGF β receptors and stabilize them in an inactive form. Activation occurs upon phosphorylation. The implantation of blastocysts into the uterus requires estrogen and progesterin and immunophilin FKBP52 serves as a co-chaperone for the steroid nuclear receptors in this process (Daikoku T et al 2005 Proc Natl Acad Sci USA 102:14326). ▶FK506, ▶cyclosporin, ▶rapamycin, ▶cyclophilin, ▶T cell, ▶immunosuppressants, ▶estrogen, ▶progesterin, ▶implantation nuclear receptors, ▶photosystems; Ivery MT 2000 Med Res Rev 20:452.

Immunopolymorphism: Denotes variation in T cell receptors, major histocompatibility system and antigens. <http://www.ebi.ac.uk/ipd/>.

Immunoprecipitation: The reaction of an antigen with a cognate antibody may lead to blood coagulation or to the selective precipitation of a protein. From a mixture of proteins the interactive molecules (enzyme-substrate, proteins of signaling pathways, etc.) may be co-precipitated. Chromatin immunoprecipitation (ChIP) can identify the protein components of the transcriptional machinery (Zhou Q-P et al 2004 Nucleic Acids Res 32:884). Co-immunoprecipitation occurs when two cross-reactive molecules are isolated together. ▶affinity chromatography, ▶ChIP, ▶ChIP-chip, chromatin transcription factor immunoprecipitation detection method: <http://chip.dfci.harvard.edu/~wli/MAT>, ▶Western blotting, ▶microcalorimetry, ▶gel retardation assay, ▶protein complexes, ▶pull-down assay, ▶paired-end ditag

Immunoprobe: This is also known as immunoblot. Bacterial colonies are immobilized on a filter and a specific antibody is added. This antibody can bind the epitope of a second antibody or an antibody plus protein A that may be labeled by a radioactive isotope (I^{135}) or a biotinylated molecule. The complex can then be detected by autoradiography on the dot blot or separated in SDS-polyacrylamide gel and the labeling identifies the substance of interest. ▶Western blotting, ▶colony hybridization, ▶protein A, ▶probe, ▶DNA probe

Immunoproliferative Disease, X-Linked: ▶Epstein-Barr Virus

Immunoprophylaxis: Refers to the use of vaccines or antisera for the prevention of infection (disease).

Immunoproteasomes: These are used for degradation of foreign antigens by cytotoxic T cells. The proteins are ubiquitinated and partially degraded by immunoproteasomes. In these proteasomes some of the subunits of the constitutive proteasomes are replaced by other polypeptides induced via interferon γ (IFN γ). Thus, immunoproteasomes are different from

the constitutive ones in structure and also in stability because after the disappearance of the foreign antigens and IFN γ the cells return to the constitutive state. This cytokine also induces the proteasome activator PA29, which facilitates antigen presentation through a more open proteasome structure. IFN γ induces the formation of proteasome maturation protein (POMP) and the proteasomal $\beta 5i$ subunit low-molecular weight protein 7 (LMP7) and $\beta 2i$ multicatalytic endopeptidase-like 1 protein (MECL1). These subunits replace the constitutive proteasome homologs $\beta 1$, $\beta 2$ and $\beta 5$. LMP7 activation leads to degradation of POMP and a decrease of proteasome activity, reduction of the MHC class I surface expression and induction of apoptosis (Heink S et al 2005 Proc Natl AcadSci USA 102:9241). Immuno-proteasomes have a strong influence on the repertoire of T cells in antigen-specific immune response (Osterloh P et al 2006 Proc Natl Acad Sci USA 103:5042). ▶T cells, ▶antigen processing and presentation, ▶proteasome, ▶interferon; Klotzel P-M 2001 Nature Rev Mol Cell Biol 2:179.

Immunoscintigraphy: By using a scintillation camera (capable of detecting the flashes emitted by radioactive isotopes) radioactively labeled monoclonal antibodies can be localized in the body or tissues by even a three-dimensional image.

Immunoscreening: The product of a gene is identified on the basis of a cognate antibody.

Immunosensor: This is a solid-state apparatus capable of detecting antigen-antibody binding, based on changes in mass or electrochemical or optical properties. It may be employed in clinical, environmental or food analysis.

Immunostaining: Purified antibodies can be labeled by fluorochromes and their specific recognition sites can be visualized in situ with the aid of fluorescence light microscopy. Also, antibodies labeled by colloidal gold permits their analysis by electronmicroscopy.

Immunostimulatory DNA (ISS): This contains within short stretches of plasmid vehicles CpG dinucleotides: 5'-GACGTC-3', 5'-AGCGCT-3' or 5'-AACG% %'-3'. Such sequences promote the production of interferon- α and - β and interleukin-12. The significance of this finding for gene replacement therapy is that ISS may cause the production of proinflammatory cytokines and thereby down regulate gene expression. Immunostimulatory gene expression boosts immunological surveillance and also facilitates cancer therapy. It may be achieved by the use of IL-2, with a tumor-specific antigen, or an anti-erbB-2 single chain antibody. ▶therapy, ▶cytokines, ▶T cells, ▶erbB, ▶single-chain Fv fragment, ▶cancer gene therapy;

Uchijima M et al 2001 Biochem Biophys Res Commun 286:688.

Immunosuppressant: Blocks or reduces the immune response by irradiation, specific antimetabolites or specific antibodies. ▶cyclosporin, ▶cannabinoids, ▶calcineurin, ▶immunophilins

Immunosuppression: The activation of the immune system generally involves the activation of cytokines and cell adhesion. In tumor cells the immune system is suppressed and this suppression is suspected to involve the inhibition of lymphocytes (CTL, NK, B cells) by IL-2, IL-10, TGF- β , etc. Repression of this process calls for the inhibition of the transcription factors required to develop the key elements of the immune system (see Fig. 112). Glucocorticoids, prednisone (also a glucocorticoid), the fungal cyclic oligopeptides, e.g., cyclosporin, mycophenolic acid (C₁₇H₂₀O₆), acidcyclophosphamide (carcinogen), azathioprine (an arthritis drug), cytarabin (cytosine analog), mercaptopurine (a purine analog), methotrexate (a folic acid antagonist), muromonab-CD3 (a murine monoclonal antibody [IgG_{2a}] targeted to the lymphocyte membranes), etc. are used. The new suppressants may prevent stimulation of the T cell receptors (TCR) or the co-stimulatory responses or down regulate the amplification of the specific antigen-responding T cells.

Specific Janus kinase-3 inhibitors (CP-352.664, CP-690.550) may also prevent allograft rejection. Janus kinase signals to several cytokines (Changelian PS et al 2003 Science 302:875). ▶glucocorticoids, ▶cyclosporin, ▶cyclophosphamide, ▶methotrexate, ▶immune tolerance, ▶immune system, ▶hyperacute reaction, ▶Gal α 1-3Gal, ▶IL-2, ▶IL-10, ▶TGF, ▶CTL, ▶killer cell, ▶Jak kinase, ▶transplantation in utero; Kahan BD, Koch SM 2001 Curr Opin Crit Care 7(4):242.

Figure 112. Immunosuppressor molecules

Immunotherapy: This includes immunization, the use of immunopotentiators, immunosuppressants, hyposensitization to allergens, monoclonal antibodies and transplantation of bone marrow or thymus. In rats heatshock proteins prepared from the same cancer (but not from others) retarded the progression of the primary cancer, reduced metastasis and prolonged

life. Another possibility is to fuse antigen-presenting dendritic cells with carcinoma cells and the cell hybrids are used for immunization of syngeneic animals. When surgically removed cancer cells (surface antigens) were delivered to the same animal the mouse body immuno- rejected the cancer. In some instances both CD4⁺ and CD8⁺ T cells responded favorably and the primary tumors as well as the metastatic cells were rejected. Immunotherapy of cancer may use IL-2, IL-4, IL-5, IL-6, IL-1 receptor antagonists, interferon, tumor necrosis factor (TNF α), granulocyte-macrophage colony stimulating factor (GM-CSF) or interferon (IFN γ) to boost the host effectors and the MHC class I and II molecules or apply tumor-specific antigens in order to activate cytotoxic T cells against the cancer cells. GM-CSF appears to be particularly effective. When it is difficult for the antibody to access sensitive tissues in the tumor, a novel approach is to target the blood vessel internal epithelium with the immunoglobulins through intravenous injection (Oh P et al 2004 Nature [Lond] 429:629). In humans TNF (tumor necrosis factor) and $\alpha_4\beta_1$ integrin are the most successful targets for the treatment of several autoimmune diseases. mentioned concepts as separate entries, ►[bacillus Calmette-Guerin](#), ►[vaccinia virus](#), ►[SER-EX](#), ►[statins](#), ►[cancer gene therapy](#), ►[adoptive cellular therapy](#), ►[autoimmune diseases](#), ►[plantibody](#); Chen ZN et al 2001 Cell Biol Int 25:1013; McLaughlin PM et al 2001 Crit Rev Oncol Hematol 40:53; Blattman JN, Greenberg PD 2004 Science 305:200.

Immunotherapy, Active Specific: This therapy boosts the immunogenic response by immunization with endogenous antigenic determinants of the cells. This is expected to result in immunological memory and thus have a long-lasting effect. ►[immune response](#), ►[memory immunological](#); Pol S et al 2001 J Hepatol 34:917.

Immunotherapy, Adoptive (passive): Ex vivo-selected allogeneic transgenic donor lymphocytes are employed against viral infection or leukemia. After reintroduction it may become necessary to select against the introduced lymphocytes in case host—graft incompatibility occurs. The negative selection requires the activation of a special suicide gene. ►[ex vivo](#), ►[allogeneic](#), ►[leukemia](#), ►[suicide vector](#); Bathe OF et al 2001 J Immunol 167:4511.

Immunotherapy, Passive: If a patient does not have an active immune system, preformed specific antibodies may be employed.

Immunotoxin: This may be an antitoxin or a specific antibody equipped with a bacterial, fungal or plant toxin. The monoclonal antibody (Fab domains, Fv) provides the means of homing on the special target cell(s) of cancer (lymphoma, melanoma, breast and colorectal carcinomas) or graft rejection (bone marrow transplant) or T cells responsible for autoimmune disease (arthritis, lupus or HIV infected T cells). In addition it may carry cytokine and soluble receptors to assist targeting. The toxin (*Pseudomonas* exotoxin, diphtheria toxin, ricin, abrin, α -sarcin) then specifically destroys the target by inhibiting local protein synthesis without affecting the other cells. Lysosome targeting (lysosomotropic) amines (NH₄Cl), chloroquine and carboxylic ionophores (monesin) protect the cells from some immunotoxins (e.g., diphtheria toxin) but make them more sensitive to others (e.g., ricin). The clinical applicability of this therapy is still very limited. The toxins may damage to some extent other cell types too. ►[magic bullet](#), ►[antitoxin](#), ►[monoclonal antibody](#), ►[antibody engineering](#); Knechtle SJ 2001 Philos Trans R Soc Lond B Biol Sci 356:681; Manzke O et al 2001 Med Pediatr Oncol 36:185.

Impact Factor: This is a scientometric index monitoring the citation frequency of “average articles” in particular journals within a specific period of time (Garfield E. 1972 Science 178:471). It is calculated by dividing the number of cited articles in a journal by the number of articles published in that journal during a period of two years. The information is available in the Journal Citation Reports (Science Citation Index) in alphabetical order and by grouped fields. It is commonly used for the evaluation of the performance of individuals or departments because it indicates the impact of the publications. It is a useful tool of evaluation within a discipline although papers describing methods are cited more frequently than those dealing with data and theory. It is not entirely suitable for comparison across different disciplines because “glamorous” journals are commonly cited more frequently than the traditional ones. The Institute of Scientific Information carrying out the tallying may also be affected by some human errors (Nature [Lond] 2002 vol. 415:101, *ibid.* 726, *ibid.* 731). Nevertheless, it is probably the most objective tool for rating the prestige of a journal. The Citation Index is also used to assess the impact of the authors of the scientific papers. Another proposed factor for the evaluation of scientific output is the *h* index, which considers the number of papers with higher *h* value and ignores those which are below; i.e. it considers the number of publications that received a certain number of citations. For example, eight

journal research papers of the author of this book received (995) an average of 124 citations since his retirement. It was suggested that such an index permitted realistic comparisons across scientific disciplines (Hirsch JE 2005 Proc Natl Acad Sci USA 102:16569). The latter approach has obvious merits relative to counting only the number of publications irrespective of their impact that may yield only a *trash index*. Obviously large numbers of publications which are not useful to the scientific community are definitely harmful because the reader may not be able to judge their merit before reading them and wastes his valuable time that could be spent on meritorious publications. There are increasing problems, however, in determining the number of citations because there are too many scientists with the same name. Also, older papers even if they continue to be very useful may not be included in the bibliographies just because of the date of publication. Mendel's Versuche paper is rarely cited today and Watson and Crick's epoch-making 1953 paper in Nature is infrequently mentioned in current research publications. Books and review papers may be of great value to scientists yet the Citation Index does not adequately cover these contributions. Some papers may be cited because of factual errors or they may be even fabrications but the Index does not reveal these details. There is no index for papers withdrawn by journals or authors. Recently, Google's PageRank index (PR) as well as a combination with the Impact Factor (IF) such as $PR \times IF = Y\text{-factor}$ have been proposed (Ball P 2006 Nature [Lond] 439:770). Google's PageRank can be found at <http://www.iprcom.com/papers/pagerank/>. There is no perfect criterion for the impact of a scientist's contribution and the impact may also vary with time. ▶ [citation index](#); Butler L 2002 Nature (Lond) 419:877; Lehmann S et al 2006 Nature [Lond] 444:1003, <http://scientific.thomson.com/products/wos/>.

Impala (*Aepyceros melampus melampus*): $2n = 60$.

Impaternalate: Refers to offspring originated by parthenogenetic reproduction. ▶ [parthenogenesis](#)

IMPDH (inosine-5'-monophosphate dehydrogenase): This is involved in lymphocyte replication. Mycophenolic acid (MPA), an approved immunosuppressive drug, is its potent inhibitor (Desmoucelles C et al 2002 J Biol Chem 277:27036).

Imperfect Flower: This has either male or female sexual apparatus, it is monoecious or dioecious but not hermaphroditic. ▶ [flower differentiation](#); ▶ [hermaphrodite](#); ▶ [monoecious](#); ▶ [dioecious](#) (see Fig. I13).

Figure I13. Asparagus flowers (After J.A. Huyskes & J. Sneep)

Imperfect Fungi: These do not have a known sexual mechanism of reproduction. ▶ [fungal life cycles](#)

Impetigo: This is a pus-forming skin infection caused by the plasmid-carrying *Staphylococcus aureus* bacteria.

Implant: Denotes a grafted addition to the body or an inserted artificial object or an implanted zygote.

Implantation: Refers to the attachment of the blastocyst to the lining of the uterus after about a week of fertilization and embedding it into the endometrium (in humans). In mice lysophosphatidic acid receptor (LPA3) and cyclooxygenase 2 (COX2) are involved in the control of implantation and prostaglandin biosynthesis (Ye X et al 2005 Nature [Lond] 435:104). ▶ [blastocyst](#), ▶ [uterus](#), ▶ [prostaglandin](#), ▶ [cyclooxygenase](#), ▶ [lysophosphatidic acid](#), ▶ [Sta](#), ▶ [immunophilins](#), ▶ [steroids](#); Paria BC et al 2002 Science 296:2185.

Importin and β : These are protein factors mediating the passage through the nuclear pore by binding the α subunit to a nuclear localization sequence of a protein, Ran-GTP. Importin β has a positive regulatory role in nuclear import and as a motor adaptor to move molecules along the microtubules; it has negative roles in mitotic spindle assembly, centrosome dynamics, formation of the nuclear membrane, and nuclear pore assembly (Harel A, Forbes DJ 2004 Mol Cell 16:319). ▶ [nuclear pore](#), ▶ [nuclear localization sequence](#), ▶ [karyopherin](#), ▶ [transportin](#), ▶ [RNA export](#), ▶ [Ran](#), ▶ [GTP](#), ▶ [NuMA](#), ▶ [TPX2](#); Mingot J-M et al 2001 EMBO J 20:3685; Gruss OJ et al 2001 Cell 104:83; structure: Matsuura Y, Stewart M 2004 Nature [Lond] 432:872.

Impotence: This is the inability to initiate or maintain erection of the penis due to organic or psychological factors. nitric oxide, phosphodiesterase; Renaud RC, Xuareb H 2002 Nature Rev Drug Discovery 1:663.

Imprecise Alignment of DNA Strands: There is only limited homology between the strands.

Imprinting: The expression of behavioral or other traits may be influenced by the parental source of chromosomes, i.e., the paternal and maternal genomes may have a different effect (imprinting) on the developing offspring because of the modification of an allele by a cis-element or different methylation of the sequence (Kaneda M et al 2004 Nature [Lond] 429:900). More than 150 mammalian genes are subject to imprinting. Methylation also affects the organization of the chromatin. The generation of antisense transcript may be a means of imprinting (Runte M et al 2001 Hum Mol Genet 10:2687). In mice, the insulin-like growth factor gene (*IGF-2*) transmitted through females is not transcribed (imprinted, turned off) in most of the tissues and only the one transmitted through the male is active. In colorectal cancer there is ~30% loss of imprinting (biallelic expression) whereas in healthy individuals this is only ~10% (Cui H et al 2003 Science 299:1679). If the offspring receives a mutant copy of the gene through the male and a normal copy through the female, the heterozygote is crippled. The choroid plexus (the brain tissue secreting the cerebrospinal fluid) and the leptomeninges (the innermost of the three membranes covering the brain and the spinal cord) were not subject to *IGF-2* gene imprinting in mice. The *IGF-2* is a single chain polypeptide and an autocrine regulator of hormone response and growth. The deletion of a silencer element from the mouse *Igf2* involves loss of imprinting (LOI) and increases the chances of multiple intestinal neoplasias in mice (Sakatani T et al 2005 Science 307:1976). It appears that methylation takes place in CG-rich islands of 200 to 1,500 base pairs and notably, several of the imprinted genes are either in chromosome 11p or 15q in humans, or in mouse chromosome 7. At the telomeric end of mouse chromosome 7 there is a differentially methylated CpG island (KvDMR) that is responsible for imprinting several maternal genes. Intron 10 in this island (Kcnq1) of KvDMR contains the paternally expressed, non-coding antisense transcript, Kcnq1ot1. When 244 base pair is deleted from there the silenced genes are derepressed (Mancini-DiNardo D et al 2006 Genes & Development 20:1268). The maternally expressed gene, MEG3 is in human chromosome 14q. In mouse chromosome 17, in *IGF-2* gene a 113-bp methylation imprinting box has been identified. In mice imprinted genes are located at nine regions in six autosomes. In human chromosome 15q11-q13 an *imprinting center* (IC) has been found, involved in epigenetic resetting of this 2-Mb domain. The IC is part of the promoter and the first exon of the

small nuclear ribonucleoprotein peptide N (SNRPN) gene. When the untranslated *H19* mouse gene was disrupted, *Ins-2* and *Igf-2* genes —100-kb upstream of *H19*—were transmitted by the female. It has been suggested (but not verified) that the chromosomal choice of imprinting is determined by a competition for a nearby enhancer. The actual *H19* regulator, *Afr1* affects the fetoprotein- α transcription as well. *Igf* is preferentially expressed in the male because a germ line-inherited methylation silences the promoter of the *H19* gene. The 5' upstream region of *H19* contains an imprinting methylation signal (mark) in the male rodent. This ~42 bp element is conserved by evolution. In the offspring, 27% higher weight was observed compared to animals that received the same chromosome from their father. In mouse chromosome 11 *mash-2* encodes a helix-loop-helix protein and it is maternally expressed only in the placenta. If this gene is deleted maternal lethality results but there is no consequence if transmitted through the male. Placenta-specific mouse genes are imprinted but in humans their expression is biallelic due to the absence of dimethylation of H3 histone lysine 9 and lysine 27 (Monk D et al 2006 Proc Natl Acad Sci USA 103:6623). If the mouse conceptus receives two paternal or two maternal chromosomes 12, intrauterine death results. Uniparental conceptuses are also inviable. Normally, *Ins-2* (insulin) is expressed paternally in the embryo yolk but biparentally in the pancreas. The tissue-specificity of imprinting of the insulin-like growth factor is determined by which of the four promoters of the gene was used. The human gene, *GNAS1* (chromosome 20q13.2-q13.3) displays biallelic inheritance as well as imprinting in both paternal and maternal directions, depending on the promoter used and alternative splicing (Hayward B. E. et al., 1998 Proc. Natl. Acad. Sci. USA 95:15475). The upstream *Nesp* and *Nesp/Gnasxl* promoters are methylated maternally and paternally. The downstream G protein α -subunit is unmethylated with rare exception. Upstream of $G_s\alpha$ there is an imprint mark where methylation is established in oogenesis; thus this imprinting is tissue-specific (Liu J et al 2005 Proc Natl Acad Sci USA 102:5513).

Several paternally inherited X chromosomal genes are inactive in early embryonic tissues. Although differential inactivation is a common property of X chromosomal genes, asynchronous replication has been observed between homologous autosomes in mice (Singh N et al 2003 Nature Genet 33:339). An exception is the *Xist* gene, which is expressed only from the paternally derived X chromosome. In some cases the demonstration of true imprinting is difficult because in human diseases the penetrance and expressivity of the genes may vary widely. Imprinted genes frequently carry special repeats, display

unusual sex-specific rates of recombination and the size of their introns are relatively short. Parthenogenesis may cause embryonic lethality in mouse if the imprinted paternal genes are not expressed. During tumorigenesis both the paternal and maternal copies of the IGF-2 gene are expressed. Imprinted genes usually replicate asynchronously from the rest of the gene pool. Although it appears that expressed genes replicate early, this rule does not hold for imprinting because early replicating paternal genes may be still silent. Imprinting appears mainly in mammals, however imprinting-like phenomena have been observed in the plant *Arabidopsis* (Choi Y et al 2002 Cell 110:33). Imprinting of the late-flowering epimutation in the *FWA* gene of *Arabidopsis* is limited to the endosperm and its activation depends on the DNA glycosylase gene (*DME*) *DEMETER* (Kinoshita T et al 2004 Science 303:521). Gene *MEDEA* (*MEA*) is imprinted in the *Arabidopsis* endosperm and it is activated by hypomethylation of the maternal allele by the *DME*. *METHYLTRANSFERASE* (*MET1*) maintains CG methylation of the *MEA*. The active *MEA* Polycomb-like complex (*MEA* + *FIE* + *PcG*) in the endosperm silences the paternal *MEA* allele by methylation (Gehring M et al 2006 Cell 124:495).

In mammals 0.1–1% of the genes may show some degree of imprinting; in mice and humans only about three dozen imprinted genes had been identified by 2000 (see Verona RI et al 2003 Annu Rev Cell Dev Biol 19:237).

There is no generally valid interpretation of the evolutionary utility of imprinting. It has been hypothesized the imprinting has a *dosage compensation* purpose. Loss of imprinting may predispose to sporadic colorectal cancer. Also, imprinting may permit the expression of an oncogenic allele. Alternatively, the *conflict/kinship theory* has been proposed. According to this theory, if the female produces offspring by more than one male during her period of fertility, the more vigorous pregnancy places greater demands on the female and thus weakens the mother and thereby potentially harms the future offspring sired by other male(s). To resolve this conflict the mother activates on growth promoting genes. The male silences genes that suppress growth. Some of the facts seem to support this conflict theory, others do not. According to the conflict hypothesis, there should be no imprinting in monogamous species. However, this expectation is not realized in the monogamous *Peromyscus polionotus* rodents. Imprinted genes, because of monoallelic expression, may be at a higher risk to contribute to tumorigenesis because a single recessive mutation may trigger the process. ▶methylation of DNA regulation of gene activity, ▶Xist (Tsix), ▶IGF, ▶Angelman's

Imprinting, Behavioral: A response learned during the early phase of life has a lasting effect on the behavior of an animal throughout its life.

Imprinting Box: This is responsible for imprinting of genes situated in the region 15q11-q13 of the human chromosome (and in the homologous chromosome 7 segment of the mouse). The human imprinting box extends to ~200 bp of the promoter/exon 1 site of the small ribonucleoprotein peptide N (SNRPN, 15q12) gene and a 1-kb sequence about 35 kb upstream including the short regions of overlap (SRO) of Angelman's syndrome (AS-SRO) and Prader-Willi syndrome SRO (PWS-SRO). The insulin-like growth factor receptor gene (IGF2R) can act alone as a methylation initiating imprinting box. ▶Angelman's syndrome, ▶Prader-Willi syndrome, ▶insulin-like growth factor, ▶imprinting; Shemer R et al 2000 Nature Genet 26:440.

Imprinting, Molecular: Biological molecules are coated by polymers that preserve their three-dimensional structure (imprint) in order to facilitate their manipulation (breaking up at selective locations, fractionation from complex mixtures).

Imputation: Refers to estimation of the missing values in a set of data using the information available. For this purpose multiple regression may be used.
▶regression

In Silico Biology: Describes the identification of genes in databases with the aid of bioinformatics. (Harris SB 2002 Embo Rep 3:511).

In Situ Hybridization (ISH): The DNA double strands within the cells (chromosomes) are separated (denaturation) in cytological preparations on microscope slides and labeled (radioactively or by fluorochromes or by immunoprobes) and complementary DNA or RNA strands (probes) are annealed (see Fig. I14). The cells are then visualized by microscopy as usual for cytological microtechniques and can either be autoradiographed or viewed through fluorescence microscopy to ascertain the position of the hybridized ↑ probe. Thus, the chromosomal location of molecular markers can be determined. ▶DNA hybridization, ▶somatic cell hybrids, ▶probes, ▶fluorochromes, ▶chromosome painting, ▶FISH, ▶immunoprobe, ▶nick translation, ▶in situ PCR, ▶PRINS, ▶GISH, ▶MFISH; Pardue ML 1973 Cold Spring Harbor Symp Quant Biol 38:475; Carpenter NJ 2001 Semin Pediatr Neurol 8(3):135.

Figure I14. In situ hybridization

In Situ PCR: PCR technology is used within single cells. The DNA is amplified followed by in situ hybridization. By treating the cells with reverse transcriptase before PCR enhances its utility. Such a procedure permits the detection of cellular genic activity, viral infection and the expression of just introduced transgenes for gene therapy. ▶PCR, ▶RT-PCR, ▶PRINS, ▶FISH; Kher R, Baccalao R 2001 Am J Physiol Cell Physiol 281:C726.

In Vitro: The reaction or culture is carried out in a “glass” vessel rather than in an intact cell or in natural culture conditions, respectively such as in vitro culture, in vitro fertilization or in vitro enzyme assay.
▶ART, ▶cell genetics

In Vitro Fertilization (IVF): Extracted mammalian eggs can be fertilized by competent sperms (AID or AIH) outside the body and then surgically implanted into

the uterus. Such a procedure may have over 40% chance of success and helps to overcome sterility in many women with infertility problems caused by factors other than the ova. In vitro fertilization produces normal babies but the chance of having non-identical twins is greatly increased if the gynecologist implants more than a single fertilized egg to assure a reasonable degree of success. When single blastocysts stage (5 days old, in 175 individuals) and cleavage stage (3 days old, in 176 individuals) embryos were used for in vitro fertilization in women under 36 years of age, the blastocysts stage implantation resulted in higher pregnancy (32%) than in at the cleavage stage (21.6%). In the latter group there were two cases of monozygotic twins (Papanikolaou EG et al 2006 New Engl J Med 354:1139). IVF of women above 35 years of age had disappointingly low success (~37%). The low rate was attributed to increasing aneuploidy in older eggs. Preimplantation elimination of chromosomally defective eggs resulted in even lower frequency (25%) of fertilization presumably because the removal of single blastomeres for cytological tests harmed the embryos (Mastenbroek S et al 2007 New England J Med 357:9).

Concerns have been expressed about a slight increase in genetic defects among the offspring produced with the aid of these techniques, particularly the ICSI (Powell K 2003 Nature [Lond] 422:656; Gicquel C et al 2003 Am J Hum Genet 72:1338). IVF has applied significance in animal breeding. For example, from the ovaries of cows eggs can be retrieved in slaughterhouses and after in vitro fertilization can be re-implanted into any (even some sterile) cows. Through this procedure more beef can be produced. There is an opportunity to obtain more offspring from genetically superior individuals of domestic animals by the use of surrogate mothers. It has applications in wildlife preservation of endangered species (in zoos) or in species with an unsatisfactory natural rate of reproduction. ▶twinning, ▶artificial insemination, ▶insemination by donor, ▶preimplantation genetic, ▶GnRFA, ▶ART, ▶ICSI, ▶test tube baby; Elder K, Dale B 2000 In Vitro Fertilization, Cambridge Univ. Inactive-X Hypothesis: ▶Lyon's hypothesis

Inborn Error of Metabolism: This is a historical term for biochemical genetic defects. Generally mutation in single genes blocks or changes the metabolic pathways at a single specific step. The photograph shows the response of an auxotrophic mutant of *Arabidopsis* unable to synthesize the pyrimidine moiety of thiamine. On basal medium it germinates but fails to grow; its growth is fully restored on the appropriate pyrimidine, PY and thiamine, TH. A slight growth is also seen on the thiazole moiety of thiamine TZ (Rédei, 1965 unpublished). The consequences of the mutation may be alleviated either by providing the missing compound or by avoiding the supply of the accumulated precursors that cannot be further processed because of the defect in the enzymatic step. Although a single enzymatic step is often involved, the lack or overproduction of a metabolite can affect more than a single metabolic process in complex diseases (see Fig. 115). Inborn errors of metabolism include defects in quantitative genes and other intrauterine lesions and infections. In plants auxotrophic mutations are very rare; the number of identified metabolic defects due to genetic causes (mutation, deletion, insertion, rearrangement) is increasing in humans. Defects in humans may be caused by the absence or decrease of a metabolite, the adverse effect of accumulated precursor(s), overproduction, faulty regulation of a pathway and/or adverse effects on more than one pathway in a metabolic network. The defect can be cell autonomous, i.e., affects only a particular cell or it may be non-autonomous and its consequence spreads to other tissues either by diffusion or secretion and active

transport. The presence of a metabolic defect can be discovered by simple means; Garrod identified alkaptonuria by the brown spots on the diapers of newborns. The nature of the defect can be identified by chemical analysis, the use of isotope or fluorochrome labeled metabolic tracers, enzymes assays of body fluids or tissues, by microarray hybridization, two-dimensional electrophoresis or mass spectrometry, nuclear magnetic resonance spectrometry (NMR) and other tools of proteomics. The treatment of the disease varies according to its nature. Phenylketonuria or fructose intolerance requires metabolic restrictions, in Wilson disease avoidance of copper helps. In other cases dietary supplements can help, e.g., consuming starch in glycogen storage diseases or taking biotin in biotinidase deficiency or avoiding fasting in some forms of fatty acid metabolism disorders. In Gaucher disease enzyme replacement, in Hurler's syndrome enzyme replacement and bone marrow transplantation are used. For several diseases somatic gene therapy is available. The implantation of embryonic stem cells may be helpful for a range of human lesions and disease. Avoidance of several diseases is possible by genetic counseling, screening for carriers and neonatal screening. Screening newborns for inborn metabolic errors by tandem mass spectrometry revealed a frequency of 1.57×10^{-4} (Wilcken B et al 2003 New England J Med 348:2304). ▶auxotrophy, ▶one gene — one enzyme theorem, ▶biochemical genetics; Garrod AE 1902 Lancet 2:1616; see individual entries for diseases and other terms; excellent review: Lanpher B et al 2006 Nature Rev Genet 7:449.

Figure 115. *Arabidopsis py* mutants respond only to the pyrimidine moiety of the thiamine or to thiamine

Inbred: Denotes a line developed by continued inbreeding until the majority of the genes become

homozygous. In mice usually 20 generations of brother × sister (or parent × offspring) mating is done to produce such lines. In species where self-fertilization is feasible (e.g., plants) ten generations of inbreeding results in more than 0.999% homozygosity ($1 - 0.5^{10}$), unless the genes are very tightly linked in repulsion. ▶coefficient of inbreeding, ▶coisogenic, ▶congenic, ▶substrain, ▶subline, ▶linkage disequilibrium

Inbreeding: Refers to mating among biological relatives, including self-fertilization, brother-sister mating and mating with ancestors or offspring. ▶coefficient of inbreeding, ▶inbreeding in autopolyploids, ▶inbreeding and death rates, ▶inbreeding and population size, ▶inbreeding progress; Fisher RA 1949 *The Theory of Inbreeding*, Oliver & Boyd, Edinburgh.

Inbreeding and Death Rates: Inbreeding results in homozygosity of deleterious and lethal genes which in turn increase spontaneous abortions, infant mortality and the frequency of hereditary diseases (see Table 11). The frequency of the adverse consequences depends upon the frequency of these undesirable genes in the population concerned and the degree of inbreeding. When infant mortality in first cousin marriages and that in the general population marriages is compared the frequency in the former is

Table 11 Infant mortality and inbreeding

| Ethnicity | First-cousin marriages % | General population % |
|-----------|--------------------------|----------------------|
| Canadian | 8.8 | 4.1 |
| French | 9.4 | 4.4 |
| Japanese | 6.2 | 3.9 |
| Swedish | 8.5 | 4.0 |

(After Fraser, F. C. & Biddle, C. J. 1976. *Am. J. Hum. Genet.* 28:522.)

Table 12 Arriving at homozygosity after backcrossing as a function of recombination frequency

| Recombination | Number of Backcrosses → | 2 | 3 | 6 | 9 | 12 |
|---------------|-------------------------|-------|-------|-------|-------|-------|
| 0.5 | | 0.500 | 0.750 | 0.969 | 0.996 | 0.999 |
| 0.3 | | 0.300 | 0.510 | 0.832 | 0.942 | 0.980 |
| 0.1 | | 0.100 | 0.190 | 0.409 | 0.569 | 0.686 |

(After Klein, J. 1975. *Biology of the Mouse Histocompatibility-2 Complex*. Springer, Berlin.)

almost double. Some of the variation within columns may also be due to random statistical error:

In a recent analysis the excess death rate — up to age 10 — of the progeny of first cousin marriages in Japan, Pakistan, India and Brazil combined appeared to be 4.4%. ▶coefficient of coancestry, ▶inbreeding coefficient, ▶inbreeding depression, ▶incest, ▶genetic load, ▶lethal equivalent

Inbreeding and Linkage: The probability of homozygosity after backcrossing to an inbred line varies according to the intensity of linkage and the number of backcrosses performed (see Table 12).

Inbreeding and Population Size: Inbreeding increases more in smaller populations than in large ones. The increase can be reduced by controlled mating, i.e., when the mating pairs are selected from different families or if an equal number of mates is selected from each family of the herd. The rate of inbreeding (Δ_F) = $1/2N_e$. If the actual size of the population is say 10, then $\Delta_F = 1/(2 \times 10) = 0.05$. In case the effective population size is only 0.75 of the total population then $\Delta_F = 1/2N_e = 1/(2 \times 10 \times 0.75) = 1/15 = 0.066$. The coefficient of inbreeding becomes $F_g = 1 - (1 - \Delta_F)^g$ where F_g is the inbreeding coefficient of the g^{th} generation and Δ_F is the rate of inbreeding. ▶inbreeding coefficient, ▶inbreeding depression, ▶inbreeding rate, ▶population size effective

Inbreeding Autopolyploids: Since autopolyploids have more alleles present per locus, homozygosity at a locus is achieved only after a larger number or several generations. Many of the autopolyploid species reproduce by self-fertilization and the deleterious consequences of inbreeding have been eliminated by natural selection. Since many of the crop plants are polyploid, plant breeders rely on crossing for improvement. In allopolyploids the consequences of inbreeding may vary according to the species. A comparison of the proportion of homozygotes in diploids and tetraploids of the initial genetic constitutions *Aa*, *Aaaa* and *AAaa*, respectively, after five generations of self-fertilization is presented in the table (see Table 13).

Table I3 Progress of inbreeding in autotetraploids compared to diploids

| Generation | Aa (diploid) | Aaaa Chrom. segr. ¹ | Aaaa Max. equat. ² | AAaa Chrom. segr. ¹ | AAaa Max. equat. ² |
|----------------|--------------|--------------------------------|-------------------------------|--------------------------------|-------------------------------|
| F ₂ | 0.500 | 0.250 | 0.295 | 0.050 | 0.099 |

| F ₄ | 0.875 | 0.493 | 0.581 | 0.326 | 0.442 |
| F ₅ | 0.938 | 0.558 | 0.674 | 0.438 | 0.566 |
| F ₆ | 0.969 | 0.648 | 0.747 | 0.531 | 0.662 |

(After Burnham, C. R. 1962. *Discussions in Cytogenetics*. Burgess, MN.)

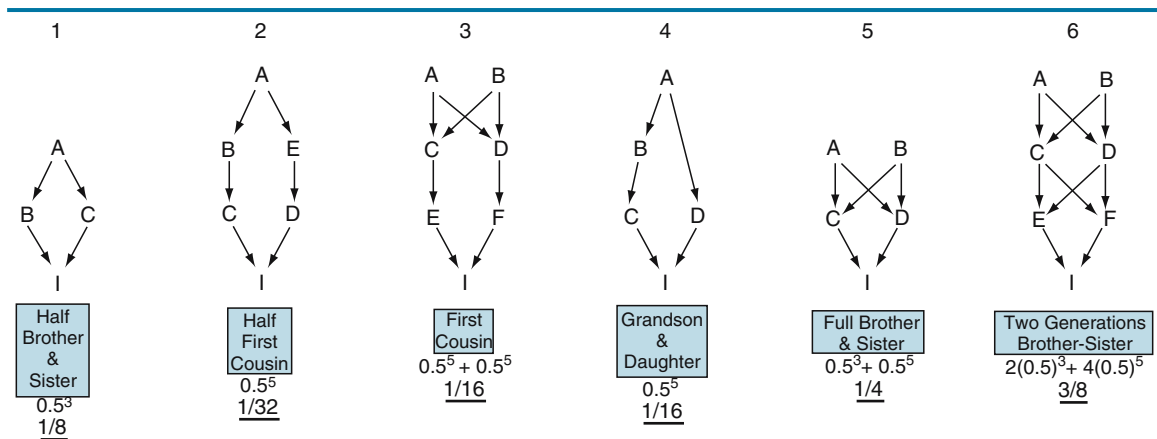

¹Chromosome segregation indicates that the gene is absolutely linked to the centromere.

²Maximal equational segregation occurs when the gene segregates independently from the centromere.

Inbreeding Coefficient: Denotes the probability that *two alleles at a locus in an individual* are identical by descent from a common ancestor, i.e., the chance that an individual is homozygous for an ancestral allele by inheritance (not by mutation). The inbreeding coefficient for second cousins is 1/64 and for third cousins it is 1/256. In case only one of the parents is common at the starting generation the inbreeding coefficient of half-sibs at uncle-niece or aunt-nephew marriage is 1/16, for first cousins 1/32, for second cousins 1/128, and for third cousins 1/512.

Consanguinity (coancestry) is a similar concept but the coefficient of coancestry indicates the chances that *one allele in two individuals* would be identical by descent. F symbolizes the coefficient of inbreeding. The calculation of F is based on the fact that in a diploid at each locus there are two alleles and only one is contained in any gamete (either one in a particular egg or sperm). Thus, each individual has 0.5 chance for passing on a particular allele to a particular offspring. To illustrate the method of calculation examples will be discussed (see Fig. I16).

Brother (X) and sister (Y) have two common parents (W) and (V). An offspring of the mating (X) × (Y) → (X)→(I) or (W)→(Y)→(I), therefore his chances for homozygosity for one allele derived from (W) is $0.5^2 = 0.25$. In other words, in F₂ the chance is 1/4 for homozygosity for any allele according to the Mendelian law. In a half-brother and half-sister progeny grandparent (A) can transmit a particular allele to (I) either through (B) or (C) parents and the inbreeding coefficient of (I) is $0.5^3 = 1/8$ because three individuals are involved in the transmission route (A), (B) and (C). Similarly, the inbreeding coefficient of other types of matings can be calculated as indicated in the chart. In half first cousin mating individuals (C), (B), (A), (E) and (D) are involved in the transmission path, each with a 0.5 chance thus the coefficient of inbreeding becomes $0.5^5 = 0.03125 = 1/32$. In two generations of brother-sister matings (see scheme 6), the transmission of alleles may follow the routes [E-C-F, F-D-E], {E-C-A-D-F, F-D-B-C-E, E-D-A-C-F and F-C-B-D-E}, i.e., [2] and {4} paths of $[0.5]^3$ and $\{0.5\}^5$, respectively. The coefficient of

**Figure I16.** Calculation of the coefficient of inbreeding on the basis of the paths of allele transmission

inbreeding is $2[0.5]^3 + 4\{0.5\}^5 = 0.375 = 3/8$. If there are multiple paths through the same ancestor, all the paths through the shared ancestors must be included in the calculation with the precaution that the same ancestor must be counted only once in the same path. The method can be illustrated by another example where (Z) and (U) are the common ancestors and again the inbreeding coefficient of individual (I) is sought. There are two routes through (Z): T-Z-L-K and T-Z-M-K and also two paths through (U): K-M-U-T and K-L-U-T. Each of these four paths involves four ancestors contributing genes to (I). Therefore, the coefficient of inbreeding of (I) is $4(0.5)^4 = 0.25 = 1/4$. Under practical conditions of breeding far more complicated schemes may be encountered yet their solution can be sought in terms of these simple examples. It is easier to determine the loops of gamete contribution by working backwards from the critical individual, (I) in this case. It is conceivable that the common ancestors are not completely unrelated, contrary to the assumption in the calculations here, but they may have some degree of relatedness and their inbreeding coefficient, F_A (ancestral coefficient of inbreeding) must also be taken into account. Therefore, the general formula for the coefficient of inbreeding is $F = \Sigma[(0.5)^n(1 + F_A)]$ where Σ is the sum of the paths through which an individual can derive identical alleles from his ancestors and n = the number of individuals in the paths. $1 + F_A$ is the correction factor for the inbreeding coefficient of the common ancestor in the path. Calculating the coefficient of inbreeding may not only be very important in a breeding project, but it may also be relevant to human families. It is assumed that the frequency of a recessive genetic disorder is $q^2 = 1 \times 10^{-6}$ and if the population is in a genetic equilibrium the frequency of that allele is $q = \sqrt{q^2} = \sqrt{0.000001}$. Then the risk related parents face of having an afflicted child is: $q^2(1 - F) + q(F)$. Since the inbreeding coefficient of the offspring of first cousins is $F = 1/16 = 0.0625$ (see Figs. I17 and I18), after substitutions one obtains: $0.000001 \times 0.9375 + (0.001 \times 0.0625) \approx 0.000063$. Since 0.000063 is ~63 fold higher than 0.000001 (the frequency of individuals with this affliction in the general population), first cousin parents are at a >63 fold greater risk than unrelated parents to have an offspring afflicted with a hereditary disease that has a gene frequency of 0.001. In some cases inbreeding may be detected by DNA fingerprinting or by nucleotide sequence of the genome. ▶F, ▶coefficient of coancestry, ▶consanguinity, ▶relatedness degree, ▶inbreeding progress, ▶inbreeding rate, ▶fixation index, ▶genetic load, ▶homozygosity mapping, ▶DNA fingerprinting, ▶inbreeding depression; Fisher RA 1965 The Theory of Inbreeding, Academic Press, New York.

Figure I17. Coefficient of inbreeding among cousins

Figure I18. Multiple paths of allele transmission

Inbreeding Depression: When inbreeding and the deleterious recessive genes become homozygous, the viability, vigor and fitness of the individuals and the population decline in normally outcrossing or dioecious or monoecious species. The degree of depression varies according to the species and traits affected. Some degree of inbreeding takes place in human populations. Inbreeding is common (~50%) in parts of Pakistan and India where uncle-niece or first cousin marriages are often seen (see Fig. I19). In Japan and South America inbreeding varies between 1% and 10% whereas in Europe and North America consanguinity is about 1% except in some isolated religious groups. The major religions (Christianity, Judaism, Buddhism and Zoroastrian) approve first cousin marriages with some restrictions. In Sweden even half-sibs can legally marry if the government approves of such a union. In eight states of the US first cousin marriage is considered criminal whereas in 22 states it is illegal. In ancient Egypt the pharaoh frequently married his sister; this probably explains the relatively large number of mummies of infants at the burial places. Consanguineous marriages increase homozygosis and the frequency of inborn errors of metabolism, malformations and other physical or mental genetic load. In many societies consanguineous marriages are preferred to ensure that the family estate remains intact. As industrialization and urbanization advance the frequency of consanguineous marriages declines. In animal husbandry inbreeding is used with the purpose of fixation of desirable traits. In plant breeding, maximal hybrid vigor of some

crops (heterosis) is achieved by using inbred lines.
 ►inbreeding progress, ►inbreeding coefficient,
 ►inbreeding and death rates, ►heterosis, ►controlled mating, ►Marfan syndrome; geographic distribution of human consanguinity: Bittles AH 2001 *Clinical Genet* 60(2):89.

Figure I19. Pharaoh and wife, close relatives (Courtesy of C.S. Gowans)

Inbreeding, Progress of: The proportion of homozygosity of any selfed or inbred generation for any number of allelic pairs can be computed by the formula (see Fig. I20):

Figure I20. Consequences of repeated inbreeding (selfing) on the frequency of heterozygotes for 1, 5, 10 and 15 allelic pairs. (Redrawn after Jones, D.F. 1925 *Genetics in Plant and Animal Improvement*. Wiley, New York)

$[1 + (2^g - 1)]^n$ where g is the number of generations selfed (note: e.g., by F_5 there are 4 selfings because F_1 is the result of crossing) and n is the allelic pairs involved. An example of expansion of the binomial in case of 3 pairs of alleles in F_5 :

$$[1 + (2^4 - 1)]^3 = [1 + (16 - 1)]^3 = 1^3 + 3(1)^2(15) + 3(1)(15)^2 + 1(15)^3 \text{ or rewritten as } 1^3(15)^0 + 3(1)^2(15)^1 + 3(1)^1(15)^2 + (1)^0(15)^3$$

where the first exponent in each term indicates the number of heterozygous genes and the second exponent denotes the number of homozygous genes in each class of individuals. In this example 1 is heterozygous for all 3 loci and homozygous for none (3×15). Further, 45 is heterozygous for 2 loci and homozygous for 1 (3×15^2), i.e., 675 is heterozygous for 1 locus and homozygous for 2. 1×15^3 , i.e., 3375 is heterozygous for none of the 3 loci but is homozygous for all 3 in a total population of 4096 ($1 + 45 + 675 + 3375 = 4096$). ►heterozygote proportions, ►binomial, ►coefficient of inbreeding, ►fixation index

Inbreeding Rate: This is determined as $\Delta_F = 1/(2N_e)$, where N_e = effective population size. If the actual size of a population is 10 then $\Delta_F = 1/(2 \times 10) = 0.05$. In this computation the effective population number is considered to be equal to the total number. Under practical circumstances this is rarely the case. If it is assumed that the effective size is only 3/4 of the actual number then $\Delta_F = 1/(20 \times 0.75) \cong 0.066$, a higher fraction. The coefficient of inbreeding can also be calculated as: $F_g = 1 - (1 - \Delta_F)^g$ where g = the number of generations of inbreeding and F = inbreeding coefficient.

Accordingly, after 25 generations, $F_{25} = 1 - (1 - 0.066)^{25} \approx 1 - (0.934)^{25} \approx 0.819$ whereas if 10 is the effective size, $F_{25} = 0.723$ in this hypothetical case.

►effective population size, ►inbreeding progress, ►inbreeding coefficient, ►fixation index

INCENP: ►sister chromatid cohesion

INCEST: Refers to legally prohibited sexual intercourse between close (biological) relatives. Incest is primarily a legal, ethical and moral concept. From the viewpoint of genetics, the consanguinity of the parents is considered and legal restrictions may not be adequate to avoid the deleterious consequences of such matings for the offspring. In ancient Egypt the pharaohs frequently (and legally) married their sisters and this may explain the large number of mummies of children at the burial places. Relatively scarce data are available on children of first-degree relatives (parent \times child, brother \times sister) yet it is clear that nearly 40% of them have more or less severe physical and/or mental defects. Interestingly, in populations where uncle–niece and cousin marriages have been practiced for centuries the number of birth defects is not as high as would be expected. Apparently, the inbreeding continued for many generations purged the gene pool of the most deleterious alleles that are maintained at random mate selection. ►coefficient of coancestry, ►coefficient of inbreeding, ►genetic load

Inchworm Model: During transcription the RNA polymerase is flexibly connected to the template. The front-end domain is tightly associated with the DNA (~10 bases) and that is followed by a loose association (~15–20 bases), including the catalytic domain, which in turn is followed by another tight association (~10 bases) to the transcript. Thus, the movement of the polymerase displays a variable discontinuous pattern. A somewhat similar mechanism is seen in an *end-to-end template switching*. When the nucleotide supply is low the polymerase can jump from a single-strand template to 7–9 bases of another linear double-stranded DNA. The upstream electrostatic interaction involves the C-end of the β subunit whereas the downstream interaction involves the N-end of the β subunit of the polymerase. The polymerase ternary complex may also move backward and the catalytic site may be involved in the cleavage of the RNA strand. Kinesin may move either by inchworming or by the hand-over-hand mode. ▶RNA polymerase, ▶transcription, ▶transcript elongation, ▶protein synthesis, ▶promoter clearance, ▶TCF, ▶kinesin; Uptain SM et al 1997 Annu Rev Biochem 66:117.

Incidence: This is the frequency of occurrence of a genetic alteration or disease in a population. ▶prevalence, incidence and prevalence database: <http://library.dialog.com/bluesheets/html/bl0465.html>.

Incipient Species: Refers to a group of organisms in the process of speciation. ▶speciation, ▶evolution

Inclusion Body (IB): This is a protein aggregate in *E. coli* cells expressing at a high rate some foreign gene(s), in the presence of amino acid analogs or antibiotics. They appear to be the products of processing of proteins and degradation of defective polypeptides. These proteins can be examined by a phase contrast microscope and can be concentrated by the centrifugation of lysed or sonicated cells. Some RNA viruses replicate within cytoplasmic inclusion bodies. Inclusion bodies are formed by the aggregation of huntingtin and other proteins in Huntington's chorea. In this disease, the role of inclusion bodies has been controversial in as much as both deleterious and beneficial effects have been reported. Recent evidence has indicated that IB formation reduces the level of huntingtin and the risk of neuronal death (Arrasata M et al 2004 Nature [Lond] 431:805). In mice shortstop inclusions themselves may not be pathogenic as such but they may enhance excitotoxicity (caused by neurotoxic glutamate-like substances) and thus mediate neurodegeneration (Slow EJ et al 2005 Proc Natl Acad Sci USA 102:11402). ▶phase contrast microscope, ▶sonicator, ▶Ibp, ▶Huntington's chorea; Rattenholl A et al 2001 Eur J Biochem 268:3296.

Inclusion Body Myopathy (cytoplasmic body myopathy):

This is a late-onset non-progressive muscle weakness. The muscle fibers contain microscopically visible inclusions in the cytoplasm. Both autosomal dominant and recessive inheritance have been reported. Dominant inclusion body myopathy 3 (IBM3, 17p13.1) displays rimmed vacuoles and ophthalmoplegia. The recessive IBM2 (9p12-p13) shows amyloid-like inclusions. The latter is relatively frequent among Jews of Kurdish and Iranian origin. This disease is caused by mutation in the UDP-N-acetylglucosamine-2-epimerase/N-acetylmannosamine kinase. ▶amyloid, ▶ophthalmoplegia, ▶Lewy body; Eisenberg I et al 2001 Nature Genet 29:83.

Inclusive Fitness: This is a type of altruistic behavior.

Parents defend their children—at their own risk—for the sake of maintenance of their genes, which the offspring shares with them. This altruistic behavior is positively correlated with the degree of relationship. According to Hamilton's rule the closer the genetic relationship, the greater is the degree of altruism. R.A. Fisher and J.B.S. Haldane discussed this phenomenon earlier. Siblings—on the average—are expected to share half of their genes and fitness whereas cousins share only 1/4. Hamiltonian medicine shows that infection caused by multiple microbial strains may either increase or decrease virulence. In some instances large colonies are formed which because of kin selection (i.e., altruistic behavior among relatives) increase the harm to the host. In other instances the different microbes turn against each other and reduce the risk to the host (Foster KR 2005 Science 308:1269). While brushing teeth different bacteria are mixed on the gums which reduces the extent of dental corrosion. ▶fitness, ▶altruistic behavior, ▶kin selection, ▶inbreeding coefficient, ▶microbiome; Sundstrom L, Boomsma JJ 2001 Heredity 86(pt 5):515; Griffin AS, West SA 2003 Science 302:634.

Incompatibility: See for plants ▶S alleles, ▶incompatibility alleles for mammals. ▶ABO blood group, ▶Rh blood group, ▶erythroblastoma, ▶immune tolerance, ▶histocompatibility [in tissue and organ transplantation], ▶plasmid incompatibility, ▶fungal incompatibility, ▶heterokaryon incompatibility, ▶cytoplasmic incompatibility, ▶maternal tolerance, ▶eclampsia; incompatibility mechanisms among plants: Bomblies K, Weigel D 2007 Nature Rev Genet 8:382.

Incompatibility Alleles: Self-incompatibility in a large number of plant species (tobacco, clover, crucifer, fescue, beet, cherry, etc.) may prevent self-fertilization or formation. The number of different incompatibility alleles may run into hundreds in some species. A plant pollen carrying a particular incompatibility allele may not successfully develop a pollen

tube in the stylar tissue of the same genetic constitution but may successfully fertilize another plant of a different allelic constitution (see Fig. I21). A sperm with a S1 allele is incompatible with a stylus of S1S1 type but may fertilize a S2 egg. In a S1S2 heterozygote neither a S1 nor a S2 sperm may be successful but they have no barriers in S3S3 plants. In some species compatibility may be determined by the sporophytic tissue; in a S1S2 stylus, if the S2 allele is dominant, the S1 pollen may be successful and produce a S1S1 seed. In some cases the S1S2 pollen of a tetraploid plant may be compatible with a S1S1 egg if the S2 allele is dominant. In the *Brassicaceae* the S alleles extend to several hundred kb and include several closely linked transcriptional units, often referred to as the S haplotype.

Incompatibility may also be based on different timing of pollen release and receptivity of the stigma. Compatible combinations may arise through induced mutations. Heterostyl (different height of the stylus and stamen) may also prevent self-fertilization. S-specific glycoproteins and ribonuclease enzymes cause self-incompatibility. In the *Brassicaceae* two tightly linked genes, mediating incompatibility, encode the S locus receptor serine/threonine protein kinase (SRK) and the secreted glycoprotein (SLG, 431 amino residues). It is assumed that a pollen-borne ligand ties SLR and SLG into a signaling complex that prevents germination or the growth of the pollen tube on the stigma or in the style. An interesting observation is that a SRK incompatibility protein provides protection against *Pseudomonas syringae* infection. In the *Solanaceae* the S locus encodes another type of glycoprotein with ribonuclease

activity (S-RNase) and this ribonuclease may inhibit the growth of the incompatible pollen tubes. In wild poppy (*Papaver rhoeas*) Ca^{2+} signaling inhibits incompatible pollen tip growth and actin depolymerization and apoptosis follow (Thomas SG et al 2006 J Cell Biol 174:221).

The *Hmr* (hybrid male rescue) gene determines hybrid incompatibility among the sibling species of *Drosophila melanogaster* (Barbash DA et al 2003 Proc Natl Acad Sci USA 100:5302). It encodes a MYB-related DNA-binding transcriptional regulator protein. The gene evolved by base substitutions, deletions and insertions especially in the DNA-binding domain may be a main factor of sexual isolation and speciation. ►mentor pollen effect, ►male sterility, ►apomixis, ►gametophyte, ►genetic load, ►fungal incompatibility, ►Rh blood group, ►ABO blood group, ►self-incompatibility, ►MYB oncogene, ►actin; Wang X et al 2001 Plant Physiol 125:1012.

Incompatibility Load: ►genetic load

Incompatibility, Mother–Fetus: During gestation the paternal alloantigens of the fetus should not permit an immune reaction by the mother to ensure the survival of the fetus. Several mechanisms are believed to be involved in this. It has been observed that HLA-G, Fas–FasL or TRAIL–TRAILR control apoptosis of maternal leukocytes during pregnancy. Indolamine 2,3-dioxygenase, a tryptophan-catabolizing enzyme, suppresses maternal T cell activity and rejection of allogeneic fetus (Munn DH et al 1998 Science 281:1191). The complement regulator decay accelerating factor protein, Crry in the placenta controls tolerance in mice and humans (Xu C et al 2000 Science 287:498). The inhibitory co-stimulatory programmed cell death (PD1) protein and its ligands (PL1, PDL2) are also critically involved (Guleria I et al 2005 J Exp Med 202:231).

Incompatibility is genetically determined in erythroblastosis fetalis in the case of wrong Rh allele combinations or to some extent in other blood groups. Incompatibility may be mediated by the activation of the complement. Decay accelerating factor (DAF) inactivates the C3 complement component convertase protein that activates C3. Membrane cofactor protein (MCP) is required for degradation of the activated C3 and C4. In murines a regulatory protein suppresses C3 deposition but if it becomes homozygous for an inactive mutation fetal loss may ensue. ►erythroblastosis fetalis, ►genetic load, ►killer cells, ►complement, ►decay accelerating factor, ►MCP, ►incompatibility, ►Rh blood group, ►eclampsia, ►HLA, ►Fas, ►TRAIL, ►apoptosis, ►allogeneic

Figure I21. (A) The compatibility of the diploid pollen in a duplex tetraploid plant. (B) Incompatibility associated with dimorphism of style and stamen length. (After Linskens HF, Kroh M 1967. Encyclopedia of Plant Physiology. Vol. 18. Springer. Berlin, Germany)

Incompatibility Plasmids: These utilize the same system of replication and cannot co-exist. When they are introduced into the bacterial cell they have to compete with each other and consequently one is eliminated. Plasmids (phages) that carry the same replicon belong to the same incompatibility group. RNA I, RNA II and the Rop protein determine incompatibility. There are more than 30 plasmid compatibility groups. ▶RNA I; Miller CA, Cohen SN 1993 Mol Microbiol 9:695.

Incompatibility, Vegetative (somatic incompatibility): Refers to the blocking of hyphal fusion and the formation of heterokaryons. ▶hypha, ▶heterokaryon, ▶fungal incompatibility

Incomplete Digestion: The reaction with restriction enzymes is terminated before all potential cleavage sites are cut. A greater variety and a few large fragments are cut because some neighboring sequences are not cleaved apart. ▶restriction enzymes

Incomplete Dominance: This is also known as semi-dominance and it is observed when the expression of the gene does not entirely mask or prevent the expression of the recessive allele at the same locus in a hybrid. ▶dominance, ▶epistasis

Incomplete Linkage: Recombination takes place between or among the syntenic genes in question. ▶recombination, ▶crossing over, ▶synteny, ▶linkage

Incongruence: This may be construed as evidence of horizontal gene transfer because the variation at certain loci is higher than that of the flanking regions. ▶transfer lateral; Farris JS et al 1995 Cladistics 10:315.

Incontinentia Pigmenti (Bloch-Sulzberger syndrome, IP1): Human X-linked (Xp11) dominant “marble-cake-like” dark pigmentation on the skin of the trunk is generally preceded by an inflammation. It may begin soon after birth and may fade by the age of 20. The condition may be associated with eye, tooth, bone and heart anomalies. Most of IP2 cases are apparently due to mutation/chromosomal breakage at the gene NEMO (NF-κB essential modulator)/IKKγ (IκB kinase-γ) closely linked to antihemophilia factor VIII at Xq28. Mutation/chromosome breakage in both IP1 and IP2 is lethal in the case of males before or around birth whereas in the heterozygous females survive to adulthood and the severity of the symptoms varies. Some of the rare cases of males with IP1 may be mosaics or of XXY constitution. ▶hypomelanosis of Ito, ▶pigmentation defects, ▶erythrokeratoderma variabilis, ▶antihemophilic factors, ▶NF-κB, ▶ectodermal dysplasia, ▶NEMO; Aradhya S et al 2001 Hum Mol Genet 10:2171.

Incorporation Error: This is a mechanism of mutation when a nucleic acid base analog or a wrong base is inserted into nucleic acid during replication. As a consequence one base pair replaces another. The meaning of the codon may change and it appears as a visible mutation if the codon change leads to an amino acid substitution at a critical site in the protein. For example: during replication a 5-bromouracil is inserted into the DNA at a C site resulting in a BrU—G base pair. During the next replication the BrU—A pair is formed and during a subsequent replication a T=A pair is substituted at a site where originally a C=G pair existed. ▶replication error, ▶base substitution mutations, ▶hydrogen pairing; Freese E 1963 in Molecular Genetics, p. 207, Taylor JH ed. Acad. Press, New York.

Incremental Truncation for the Creation of Hybrid Enzymes (ITCHY): ▶iterative truncation

Incross: Refers to hybridization between two strains that have the same genetic background.

Indel: An insertion or deletion in the DNA nucleotide sequences can be illustrated by the simple example below the alignment score (see Fig. 122). $Pr = p^3 q^2 r^1$ where p is the probability of identity (match), q is the probability of substitution (mismatch) and r is the probability of an indel. The alignment score can be derived as follows:

$S' + \log Pr = 3(\log p) + 2(\log q) + (1(\log r))$ and $S = S' - \log s = S' - 6(\log s)$ S' = a constant satisfying $\log(p/s) = 1$). And $S = 3 - 2\mu - 1\delta$ where $\mu = \log(q/s)$, $\delta = \log(r/s)$ and S = number of identities - μ number of substitutions - δ number of indels. Computer programs based on high level mathematics that cannot be presented here can resolve the problem.

```

Figure 122. Indel

The average size of indels among taxonomically diverse species was found to be about 36 nucleotides but some indels extended to 10 kb. The frequency of unpaired nucleotides due to indels was almost three times more than those caused by base substitutions (Britten RJ et al 2003 Proc Natl Acad Sci USA 100:4661). Comparison of the DNA sequences between the corresponding human chromosome 21 and chimpanzee chromosome 22 revealed that the single nucleotide mismatches represented only 1.44% of the sequence whereas 68,000 small or large

stretches of indels were found. The initial map of human indels contains 415,436 unique polymorphisms within the range of 1 to 9989 base pairs. On an average, there was 1 indel/7.2 kb human DNA. Further, 148,000 indels were found within genes and 5542 of these were within promoters or exons where they had the maximal effects on function (Mills RE et al 2006 *Genome Res* 16:1182). (See Waterman MS, Joyce J, Eggert M 1991 *Phylogenetic Analysis of DNA Sequences*, pp 59–89; Miyamoto MM, Cracraft J eds. Oxford University Press, New York; ►DNA sequence information, ►databases, indel scanning: <http://indelscan.genomics.sinica.edu.tw/IndelScan/>.

Independence: Two events are independent when the occurrence of one does not affect the chance of occurrence of the other. Genes at a distance of 50 map units or more segregate independently, the sex of the first child is (normally) independent of the sex of the next one, if two pennies are tossed they can land on their head or their tail independently from each other unless they are defective or biased.

Independence Test: ►association test (contingency chi square).

Independent Assortment: Alleles of different loci (non-allelic genes) may re-assort freely in the gametes and therefore segregate independently in zygotes in the absence of a linkage. The independent assortment of alleles is one of the most essential discoveries of Mendel and it is frequently called Mendel's third law. ►Mendelian laws

Independent Events: These events do not affect or influence each other.

Indeterminate Inflorescence (raceme): The main axis can elongate indefinitely but the branches terminate in a flower bud. ►raceme

Index: Refers to an alphabetical or other ordered set of files or symbols or numbers distinguishing particular things in an array. For example: allele a^1 , "1" distinguishes this allele among all other a alleles, or *NK3* homeobox 3 of *Drosophila* or *adp^{fs}* an *adipose* allele conveying female sterility, or the second asymmetric leaf locus as_2 (*AS-2*) of *Arabidopsis*.

Index Case: ►proband (propositus, proposita).

Index Locus: ►polymorphism information content (PIC)

Index Value: This is a concept used for selection in animal breeding. A score weights each trait and these scores are summed in an index value. The use of this index acts as a safeguard against the possibility of selecting one particular trait only and thus

jeopardizing the overall success of the program because disease susceptibility or low fertility, etc. frequently accompany high performance. ►gain, ►selection; Falconer DS 1960 *Introduction to Quantitative Genetics*, Ronald, New York.

Indexers: This is an amplification system for specific DNA fragments from whole genome digests without the need for cloning. It uses restriction enzymes class-IIIs. The non-identical cohesive ends can be selectively modified by ligation to synthetic oligodeoxy-ribonucleotides with the corresponding complementary ends. This permits the introduction of PCR and sequencing primer sites and labels into small fragments of the genomic digest. An advantage over cloning is that fragment losses, rearrangements can be avoided without cloning, probes or libraries. The procedure is applicable to small prokaryotic and large eukaryotic genomes for analyzing sequence tagged sites, restriction mapping, RFLP, sequencing and DNA diagnostics. ►restriction enzymes class-IIIs, ►PCR, ►sequence tagged site; RFLP; Unrau P, Deugau KV 1994 *Gene* 145:163; Guilfoyle RA et al 1997 *Nucleic Acids Res* 25:1854; SibsonDR, Gibbs FEM 2001 *Nucleic Acids Res* 29(19):e95.

Indians: ►Native Americans

Indicator Mice: This is transgenic for a recombinase (*Cre* or *Flp*). When it is crossed to another transgenic line carrying a construct with a FRT sequence in front of the structural gene *LacZ*, on Xgal medium develops blue color only when the recombinase flipped out the FRT stop codon. The test indicates the functionality of the recombinase and its utility for targeting. ►targeting genes, ►Cre/LoxP, ►Flp/FRT, ►Xgal

Indirect Diagnosis: Denotes identification of a gene by linkage rather than by direct evidence.

Indirect End-Labeling: Determines the distance of a DNase hypersensitive site from a restriction enzyme cleavage site. The chromatin is first digested by a Klenow fragment of DNAase I and then it is isolated and treated with a restriction endonuclease. The double digest is subsequently separated by electrophoresis and probed with a sequence adjacent to the restriction site. The size of the fragment generated by the double cuts indicates the distance of the DNase hypersensitive site from the site of restriction. This procedure can localize in the DNA the sites where transcription may be initiated because hypersensitive sites are correlated with the position of transcriptionally active genes. ►DNase hypersensitive site, ►Klenow fragment, ►restriction endonuclease; Li S et al *Methods* 2000 22(2):170.

Indirect Suppression: Some suppressor mutations do not correct the primary change in the gene rather they modify the translation process and thereby suppress the expression of the mutation. ▶ [suppressor mutation](#)

Indole: This is a heterocyclic compound present in many organic associations in biological materials (see Fig. I23). When excited by ultraviolet light, it displays a characteristic fluorescence spectrum that facilitates its rapid detection. Among other roles it is a precursor of tryptophan synthesis: anthranilate → indole + serine → tryptophan.

Figure I23. Indole

Indole Acetic Acid (IAA): This is a plant hormone synthesized from tryptophan via the pathway Trp→indole-3-acetaldoxime→indole acetonitrile →IAA or Trp→ indolepyruvic acid→indole-3-acetaldehyde→IAA. (See formula at ▶[IAA](#)).

Indophenoloxidase: See under the new name ▶[super-oxide oxidase](#)

Induced Fit: This fit of enzymes (proteins, ribozymes) occurs when the conformation is so modified that the activity improves; this may be caused by binding to a ligand or substrate. Both the substrate and ligand may change conformation for the fit. The crystal structure of the encounter complex on the pathway of ligand binding by IgE antibody SPE7 is formed by a wide range of ligands that initially bind with identical affinity. Non-specific ligands rapidly dissociate, whereupon the antibody isomerizes to a nonbinding isomer. Specific ligand complexes, however, slowly isomerize to give a high-affinity complex (James LC, Tawfik DS 2005 Proc Natl Acad Sci USA 102:12730). ▶[ligand](#), ▶[key-lock](#), ▶[DNA binding proteins](#), ▶[Lac operon](#)

Induced Helical Fork: After the binding protein contacts a few bases of the DNA, it keeps apart the double helix. ▶[Watson and Crick model](#), ▶[binding proteins](#)

Induced Mutation: This is obtained by exposure to a mutagen and is presumably generated by the mutagen itself rather than by an incidental spontaneous event. ▶[spontaneous mutation](#), ▶[mutation](#)

Induced Replicosome Reactivation: ▶[replication-restart](#)

Inducer: A substrate or an analog of a substrate of an enzyme prevents a repressor protein from attaching to

the promoter (operator) of a gene and thus facilitates its expression. ▶[induction](#), ▶[gratuitous inducer](#), ▶[repression](#), ▶[activator proteins](#), ▶[inducible gene expression](#)

Inducible Enzyme: The presence of a substrate or a substrate analog is required for their synthesis. ▶[Lac operon](#), ▶[Ara operon](#); Monod J, Audureau A 1946 Ann Inst Pasteur 72:868.

Inducible Gene Expression: This is required in many instances to stimulate the expression of a particular gene (transgene) in a specific tissue or cells. Inducible promoters are useful tools in biotechnology as they can be employed for turning on/off genes in response to special, physiological or developmental factors. ▶[metallothionein](#), ▶[transcriptional activators](#), ▶[transactivator](#), ▶[VP16](#), ▶[two-hybrid hybrid method](#), ▶[split-hybrid system](#), ▶[three-hybrid system](#), ▶[tetra-cycline](#)

Induction: This term has several meanings. Phage induction refers to the facilitation of the transition from the prophage stage to the lytic phase. The induction of enzymes set into motion the catalytic activity. The assembly of the pre-initiation complex of transcription induces gene expression. Embryonic development is induced by the transmission of various exogenous and endogenous signals. In *reciprocal induction* in development an inducer may be positively affected by the tissue that is formed by its inducing action. ▶[prophage](#), ▶[enzyme induction](#), ▶[regulation of gene activity](#), ▶[transcription](#), ▶[signal transduction morphogenesis in Drosophila](#), ▶[organizer](#), ▶[photomorphogenesis](#)

Induction, Developmental: The fate of a cell or tissue is affected by the interaction of the embryonic cell or tissue with its neighbors. ▶[embryonic induction](#)

Induction of a Lysogenic Bacterium: This is the process of liberating phage particles by first inducing a change from a prophage to a vegetative state of the phage. ▶[zygotic induction](#), ▶[prophage](#)

Induction of an Enzyme: This initiates the synthesis of new enzyme molecules by the presence of an inducer that may be the substrate or an analog of the substrate of that enzyme. ▶[derepression](#), ▶[gratuitous inducer](#)

Indusium: This is a membrane-type layer over the sorus (sporangial cluster) of ferns.

Industrial Melanism: As industrialization (coal-burning pollution) advanced (in Britain) the dark variants (dominant) of the black peppered moth (*Biston betularia*) increased as a selective trend to camouflage the insect on soot covered tree barks. ▶[natural selection](#), ▶[adaptation](#); *Biston betularia*; Kettlewell HBD 1961 Annu Rev Entomol 6:245.

Infantile Amaurotic Idiocy: ▶Tay-Sachs disease

Infarction: Refers to blood vessel necrosis caused by coagulation (thrombus) obstructing proper circulation. ▶necrosis, ▶thrombosis

Infection: Denotes invasion of a host by a virus or another organism. The invader may establish a mutually beneficial or neutral relation with the host (symbiosis). Many bacterial species regularly inhabit the host without causing any harm. In the infected host different sets of host genes are either activated or repressed than in the uninfected controls (Falkow S 2006 Cell 124:699). Infection by some bacteria frequently results in pathogenic consequences. The microbial agent generally subverts the host defense system on the surface and adheres to the special receptors. They engage the cytoskeleton to facilitate penetration and disable the phagocytotic mechanisms of the host cell. In order to maintain itself the infective agent must overcome the immune system of the host. After the invasion the pathogen may redirect the host metabolism to its own interest and produces disease symptoms. If the host quickly succumbs to the disease a frequency-dependent selection may eventually work against the invader or over time the host may develop resistance. In *Listeria* the transcription of the virulence factor is controlled by the activator PrfA that is thermoregulated by a 5' secondary structure of PrfA. It blocks its ribosome binding at a temperature below (37°C) that of the host (Johansson J et al 2002 Cell 110:541).

In *latent infection* the virus remains in a few copies and a few viral proteins are expressed so that the host defense is not evoked temporarily. At an opportune moment the virus may enter a lytic stage. In *chronic infection* the pathogen invades the host repeatedly or the infection persists for a prolonged period. Latent agents *cause opportunistic infection* when the immune system is compromised.

For epidemic spread the basic reproductive number, R^0 is used to define the mean number of infections caused by an infected individual in a susceptible population. However, there are large individual differences in the infectiousness and several mathematical procedures have been developed for the prediction of disease spread (Lloyd-Smith JO et al 2005 Nature [Lond] 438:355). ▶host-pathogen relationship, ▶epidemiology, ▶frequency-dependent selection; Knodler LA et al 2001 Nature Rev Mol Cell Biol 2:578; Hill AVS 2001 Annu Rev Genomics Hum Genet 2:373; Kazmierczak BI et al 2001 Annu Rev Microbiol 55:407; Gruenheid S, Finlay BB 2003 Nature [Lond] 422:775; virus entry into animal cell: Smith AE, Helenius A 2004 Science 304:237; bacterial invasion: Cossart P, Sansonetti PJ 2004 Science 304:242; bacterial invasion machinery: Pizarro-Cerdá J,

Cossart P 2006 Cell 124:715; parasite invasion: Sibley LD 2004 Science 304:248; reviews of viral infection mechanisms: Marsh MS Helenius A 2006 Cell 124:729; Greber UF, Way M 2006 Cell 124:741.

Infectious Center: This is a spot from where infectious phage or bacteria can be produced.

Infectious Diseases: These diseases are not hereditary as was assumed before the emergence of genetics yet susceptibility may be genetically determined. Infectious agents, however, undergo evolutionary changes and new diseases emerge and re-emerge. They are the major cause of human mortality worldwide. In 2002, ~57 million deaths were caused by infectious agents, especially among people under age of 50 years. Three-quarters of the infections emerge from animals and adapt to humans by new mutations. Pathogens acquire the means to evade the human immune system and develop resistance to antibiotics, medication and vaccines. ▶host-pathogen relation, ▶matrix diseases; Cooke GS, Hill AV 2001 Nature Rev Genet 2:967; Morens DM et al 2004 Nature [Lond] 430:242; Merrell DS, Falkow S 2004 Nature [Lond] 430:250; Boes M, Ploegh HL 2004 Nature [Lond] 430:264; host and pathogen models of plants and animals: Pradekl E, Ewbank JJ 2004 Annu Rev Genet 38:347; http://databases.biomedcentral.com/browsesubject/?sub_id=2011.

Infectious Drug Resistance: Drug-resistant genes are carried on the conjugative plasmids of bacteria. ▶conjugation bacterial, ▶plasmid

Infectious Heredity: ▶symbionts hereditary, ▶Wolbachia, ▶segregation distorter, ▶plasmid, ▶prions

Infectious Nucleic Acid: This may be a purified viral DNA or RNA that may propagate in the host cell and code subsequently for viral particles.

Infectious Protein: ▶prion, ▶encephalopathies, ▶kuru

Inference, Statistical: Refers to conclusion(s) drawn about a population on the basis of a random sample of the population. The conclusions are generally based on statistical tests such as significance and likelihood. Inference in general means reasoning; prediction of an unknown on the basis of known or assumed facts. ▶significance level, ▶confidence intervals, ▶likelihood, ▶Bayes' theorem, ▶Bernoulli process

Infertility: This may be due to various causes such as anatomical abnormalities of the sexual organs (hermaphroditism, dysgenesis, testicular feminization and polycystic ovary disease). Infectious diseases, hormonal abnormalities, malfunction of CREM, psychological factors, organic diseases, medications, alcoholism or other substance abuse, malnutrition and chromosomal defects (trisomy, translocations,

inversions, deletion, duplications and aneuploidy) may also lead to infertility. Hereditary abnormalities (cystic fibrosis, mental retardation, Kallman's syndrome, Kartagener syndrome and myotonic dystrophy) may involve infertility. In the US nearly 15% of couples are involuntarily infertile. In about 20–50% of human infertility cases males are involved; 70–90% of them have defects in spermatogenesis or spermiogenesis. After the age of 50, semen volume and sperm concentration gradually decrease (in some cases increase), sperm motility is reduced and fertility rate is lower. Male infertility may be due to the absence of a 10 repeat CAG microsatellite within the mitochondrial DNA polymerase γ gene (Rovio AT et al 2001 Nature Genet 29:261).

Spermatozoa with large heads, a variable number of tails and an increased chromosome number is a common cause of sterility in men. A genome-wide microsatellite scan of 10 infertile men with this phenotype revealed that they were homozygous for single nucleotide deletion in a common region harboring the aurora kinase C gene (*AURKC*, 19q13.3). This founder mutation results in premature termination of translation, yielding a truncated protein that lacks the kinase domain (Dietrich K et al 2007 Nature Genet 39:661).

About 38% women may be infertile. The consequences of the long-term use of fertility drugs on the incidence of ovarian cancer may not be entirely clear (Parazzini F et al 2001 Hum Repr 16:1372). Women who smoke have an early menopause that may be due to exposure to the polycyclic aromatic hydrocarbons (PAH) in the smoke. PAH binds to its receptor (AHR) in the promoter of the BAX gene and promotes apoptosis of the egg, leading to infertility (Matikainen T et al 2001 Nature Genet 28:355). By tissue transplantation between two sterile male mouse lines, fertility may be restored because of complementation. ▶fertility, ▶fertilization, ▶sex hormones, ▶ART, ▶fecundity, ▶gametogenesis, ▶spermiogenesis, ▶PN-1, ▶sterility, ▶azoospermia, ▶cell cycle, ▶CBAVD, ▶CREM, ▶asthenozoospermia, ▶smoking, ▶claudin-11, ▶miscarriage, ▶microsatellite, and the other entries; Aurora Ogawa T et al 2000 Nature Med 6:29; Moore FL, Reijo-Pera RA 2000 Am J Hum Genet 67:543; Kidd S et al 2001 Fertility & Sterility 25:237; Cooke HJ, Saunders PTK 2002 Nature Rev Genet 3:790.

Infiltration: This means the introduction of various substances into the biological tissues by diffusion, frequently facilitated by evacuation (under negative pressure).

Infinite Allele Mutation Model (IAM): Among the practically infinite number of genetic variations of nucleotide sequences each mutation creates a new

allele that did not exist earlier in the genome. It predicts that evolutionary alterations in (microsatellite) DNA occur either by addition or deletion of one copy (of tandem repeats) in a novel fashion. ▶stepwise mutation model, ▶microsatellite; Kimura M, Crow JF 1964 Genetics 49:725.

Infinitesimal Model: When a linkage is sought between quantitative trait loci (QTL) and other genetic markers, the analysis is conducted on the basis of a null hypothesis that a particular chromosome or chromosome segment segregates independently from a QTL. ▶QTL, ▶interval mapping, ▶null hypothesis, ▶adaptation

Inflammasome: This is a protein complex activating inflammation reactions (Mariathasan S et al 2004 Nature [Lond] 430:213). Essential components of the complex in response to bacterial RNA are cryopyrin (encoded by the CIASI/NALP3 gene, 1q44), caspases-1 (a cysteine protease [ASC] encoded at 11q22.2-q22.3), interleukin-1 β [IL-1 β , 2q14] and IL-18 [11q22.2-q22.3], Toll-like receptor [4q32] and ATP. Caspase-1 activation promotes cell survival in case of infection by bacteria, which produce pores on the cell wall with the aid of secreted toxins (Gurcel L et al 2006 Cell 126:1135). Macrophages deficient in cryopyrin can activate caspases-1 and secrete IL-1 β and IL-18 when infected with gram-negative *Salmonella typhimurium* and *Francisella tularensis*. Macrophages exposed to gram-negative *Staphylococcus aureus* and *Listeria monocytogenes* require both cryopyrin and ASC to secrete IL-1 β (Mariathasan S et al 2006 Nature [Lond] 440:228; Kanneganti T-D et al 2006 Nature [Lond] 440:233). ▶caspases, ▶IL-1, ▶IL-18, ▶Toll, ▶macrophage, ▶gram negative, ▶Salmonella, ▶tularemia, ▶Listeria, ▶Staphylococcus, ▶Muckle-Wells syndrome, ▶gout, minireview: Ogura Y et al 2006 Cell 126:659.

Inflammation: This is a physiological response to infection by pathogens or to adverse environmental chemical or physical agents. Immunoglobulin G (IgG) mediates proinflammatory responses. Sialylation of the Fc (fragment crystalline) of IgG switches the response to an anti-inflammatory mode (Kaneko Y et al 2006 Science 313:670). Despite being an initial healing response, inflammation may eventually lead to a chronic state such as observed in autoimmune diseases and cancer. In nearly 20% of sporadic cancer inflammation plays a role and NF- κ B promotes it (Pokarsky E et al 2004 Nature [Lond] 431:461). Soluble epoxide hydrolase inhibitors (e.g., AUDA-BE = 12-(adamantan-1-yl-ureido)-dodecanoic butylester) (see Fig. 124) reduce lipopolysaccharide-induced mortality, systemic hypotension and tissue injuries without any adverse

side effects (Schmelzer KR et al 2005 Proc Natl Acad Sci USA 102:9772). Systemic inflammatory response is a life threatening condition caused by an increase of proinflammatory cytokines such as IL-1 and TNF- α (without microbial infection). Toll-like receptors are involved in gene-specific chromatin modifications and are associated with transient silencing of one class of genes, which includes proinflammatory mediators, and priming of the second class, which includes antimicrobial effectors (Foster SL et al 2007 Nature [Lond] 447:972). ▶NF- κ B, ▶cancer, ▶nitric oxide, ▶cyclooxygenase, ▶immunoglobulins, ▶antibody, ▶Toll, ▶sialic acid; Nature [Lond] 420:846–891[2002]; <http://pstiing.licr.org/>.

Figure I24. AUDA-BE

Inflammatory Bowel Disease: ▶Crohn disease, ▶ulcerative colitis; review: Xavier RJ, Podolsky DK 2007 Nature [Lond] 448:427.

Inflorescence: This is a cluster of flowers, characteristic for the taxonomic classification of plants. Inflorescence branching in maize is under the control of trehalose enzymes (see Fig. I25) (Sato-Nagasawa N et al 2006 Nature [Lond] 441:227). ▶trehalose; Vollbrecht E et al 2005 Nature [Lond] 436:1119; evolution of inflorescence: Prusinkiewicz P et al 2007 Science 316:1452.

Figure I25. Inflorescences

Influenza Virus: This is a group of commonly spherical (120-nm) single-stranded RNA (12900–14600-nucleotides) viruses. The genome of the A strain is segmented and consists of eight molecules, a central one surrounded by seven others. When its density becomes high, defective interfering particles, containing deletions, may slow down viral multiplication (see Figs. I26 and I27).

Figure I26. Influenza

Figure I27. Structure of the influenza virus

Their major surface glycoprotein is hemagglutinin (560 amino acids), which is usually modified by mutation (Plotkin JB, Dushoff J 2003 Proc Natl Acad Sci USA 100:7152). Hemagglutinin, after cleavage by the host proteases, mediates the attachment of the virus to the cell and the transfer of the ribonucleoprotein into the cell. The other common surface glycoprotein is neuraminidase (460 amino acids) which is anchored to the lipid membrane by its amino end. The virus is classified/typed into subtypes according to the hemagglutinin (H) and neuroaminidase (N). In humans, H1N1, H2N2, H3N2 and H5N1 subtypes were so far commonly responsible for epidemics. The H5N1 virus caused the bird influenza outbreak in Vietnam in 2003–2004. The transmission of the avian virus from birds to pigs and humans has been verified but no human to human transmission has been found although the potential human-to-human infection is possible (Hien TT et al 2004 New England J Med 350:1179) (see Fig. I28). Mouse is infected with the influenza virus but it is not a suitable model for the study of transmission. Guinea pigs can spread the virus by droplets to other animals (Lowen AC et al 2006 Proc Natl Acad Sci USA 103:9988). The avian and the human strains differ in the anatomical distribution of the preferred binding molecules sialic acid linked to galactose: SA α 2,3Gal and SA α 2,6Gal. The latter is dominant on the epithelial cells in the nasal mucosa but SA α 2,3Gal is rare there. In the paranasal sinus epithelium, pharynx and bronchi mostly express SA α 2,6Gal. The human-derived H5N1 recognizes preferentially SA α 2,6Gal bound extensively to bronchial epithelium and less to alveolar cells. In contrast avian

Figure 128. Peking duck source of the famous roast and flu

viruses bind extensively to alveolar SA α 2,3Gal. This difference may be the basis of the relatively inefficient human-to-human transmission of H5N1 (Shinya. K. et al. 2006 Nature [Lond] 440:435). Hemagglutinin receptor mutations at amino acids 182 and 192 independently convert hemagglutinin of H5N1, the avian virus into the human-recognizing form and the human form still recognizes the avian host (Yamada S et al 2006 Nature [Lond] 444:378). Two amino acid changes in the HA receptor may abolish transmission in ferrets (Tumpey TM et al 2007 Science 315:655).

The H7 type is extremely pathogenic to poultry and can jump over to humans (Webby RJ, Webster RG 2003 Science 302:1510). Equine influenza virus (H3N8) can jump to dogs (Crawford PC et al 2005 Science 310:482). Migratory birds may pose a great risk for the rapid spread of diseases. The evolution of the virus depends primarily on the antigenic variations. That is not exactly the same as the nucleotide replacements in the genetic material because some of the mutations do not involve amino acid replacements and some amino acids have disproportionately large antigenic effects (Smith DJ et al 2004 Science 305:371). All the major human influenza pandemics seem to have originated by mutation from avian viruses (Taubenberger JK et al 2005 Nature [Lond] 437:889). The reconstructed virus causing the lethal worldwide epidemic of 1918 owed its virulence – compared to the current influenza viruses (H1N1) – to a few mutations, its ability to replicate in the absence of trypsin, caused death in mice and embryonated chicken eggs and increased growth in human bronchial epithelial cells. The RNA for the 8 viral genes were preserved and isolated from in formalin fixed lung autopsy samples and from unfixed, frozen samples of a corpse buried in permafrost in 1918 (Tumpey TM et al 2005 Science 310:77).

The C type flu virus has another single surface glycoprotein, HEF that destroys the cellular receptor by neuraminatase-O-acetylase. The viral M1 protein (M_r ~28K) controls the nuclear traffic of the

virus. The virus has several types, designated by place of origin such as Spanish, Hong Kong and Russian strains or as Type A (most common and reoccurring in 2–3 year cycles), Type B (causes epidemics in 4–5 year cycles), and Type C (a sporadically occurring one). In Type A virus the hemagglutinin HA1 plays an important role for infectivity. The nucleotide substitution in this domain is high (5.7×10^{-3} per site). At least 18 amino acids are critical for evading the host immune response. The expected mutation rate at these sites has predictive value for the pharmaceutical industry for the production of inoculation for the following year. The Spanish Flu of 1918 was particularly devastating as it killed 675,000 Americans and reduced the average life expectancy by 10 years. Influenza virus A encodes and translates, by an alternative reading frame, an 81-residue protein PB1-F2, which promotes apoptosis. It appears that upon infection this mitochondrially-localized protein kills the host immune cells (Chen W et al 2001 Nature Med 7:1306). Birds, horses, swines and cats also have influenza-type infections by different viruses.

The bird influenza virus posed a threat to human populations only in 1997. The highly virulent flu strains usually develop from reassorted viruses of the human and avian types sometimes via the pig flu virus. The nucleotide sequences of 169 H5N1 strains, including 2,196 genes, have been reported (Obenauer JC et al 2006 Science 311:1576). The avian flu spreads to various species of birds, including migratory birds, which may carry it to long distances, and it infects humans but at present time (by 2008) there is no firm evidence that infected humans would transmit this avian virus to other human beings. Swans are particularly susceptible to H5N1 and among the domestic poultry ducks are probably less susceptible than chickens. Viral infection of the respiratory tract occurs with possible secondary infection by *Streptococcus*, *Staphylococcus* and *Haemophilus* bacteria. Vaccination against the influenza virus may be effective. However, there are problems because of the annual variations in the subtypes and the best methods of manufacturing effective vaccines against the variations in the prevailing types. Also, a few unprotected individual birds can reignite the epidemics (Saville NJ et al 2006 Nature [Lond] 442:757). Because of the frequent variations the industry must produce a new type of vaccine every year that provides limited protection when the virus changes. Amino acid changes in hemagglutinin by converting at site Serine 223 to Asparagine improved the hemagglutinin titer and effectiveness of the H5N1 vaccine (Hoffmann E. et al. 2005 Proc. Natl. Acad. Sci. USA 102:12915). The prevention of virus transmission is of major importance. Targeted prophylaxis, quarantine and

pre-vaccination may effectively contain a pandemic (Longini IM et al 2005 Science 209:1083). Several vaccines may elicit adverse reactions in some individuals because of host genetic factors. Antiviral drugs have not been widely exploited. Neuraminidase inhibitors such as Zanamivir, Ralenza, Oseltamivir and Tamiflu may restrict all types of influenza viruses (Laver G 2005 Nature [Lond] 434:821; Matrosovich MN et al 2004 J Virol 78:12665). These drugs are effective in prevention and generally do not have any serious side effects except in cases of cirrhosis of the liver or poor general health (Kaji M et al 2005 J Infect Chemother 11:41). Recent findings have revealed around 10% increase in psychoneurotic side effects following the use of Tamiflu in Japan. Mutation to Oseltamivir had been observed in humans (Mai Le Q et al 2005 Nature [Lond] 437:1108; Moscona A 2005 New England J Med 353:2633). X-ray crystallography has revealed a cavity adjacent to the active site of neuraminidase 1 that closes on ligand binding. This observation has brought to light a new potential target for antiviral drug development (Russell RJ et al 2006 Nature [Lond] 433:45). ▶reassortant, ▶hemagglutinin, ▶neuraminidase deficiency, ▶Newcastle virus, ▶prophylaxis, ▶quarantine; Gibbs MJ et al 2001 Science 293:1842; Bae S-H et al 2001 Proc Natl Acad Sci USA 98:10602; Steinhauer DA, Skehel JJ 2002 Annu Rev Genet 36:305; Ferguson NM et al 2003 Nature [Lond] 422:428; Palese P 2004 Nature Medicine 10:S82; large-scale sequence variation in the human A virus: Ghedin E et al 2005 Nature [Lond] 437:1162; Fauci AS 2006 Cell 124:665; evolution of influenza virus: Nelson MI, Holmes EC 2007 Nature Rev Genet 8:196; Influenza virus problems: Science 2006 312:379; influenza virus resource: <http://www.ncbi.nlm.nih.gov/genomes/FLU/FLU.html>; <http://influenza.genomics.org.cn>; virus A genotyping: <http://www.flugenome.org/>, annotation of virus A and B: <http://www.ncbi.nlm.nih.gov/genomes/FLU/Database/annotation.cgi>.

Informatics: This is a system of databases and electronic retrieval. ▶bioinformatics, ▶databases

Information: It is obvious that the more the information that is available about a population the easier and more reliable is the decision of the geneticist about a parameter of that population(s). Statistically, the information $I_p = \frac{1}{V_p}$ indicating that the total amount of information is inversely proportional to the variance (V) of the statistic employed. The calculation of the information for a particular set of data can be carried out by:

$$I = \sum \left(\frac{1}{m} \left[\frac{dm}{d\theta} \right]^2 \right)$$

where m is the expectation in terms of parameter θ , and Σ is the sum of all classes. R.A. Fisher pointed out that

maximizing the likelihood function provides an estimate of T , which has the limiting value of $1/nV_T = I$. The reciprocal of the variance of the maximum likelihood estimate permits assessing the value of other estimates. If the variances obtained by other methods are not $1/nI$, they do not provide the complete possible information and are therefore inferior to the maximum likelihood statistics. ▶maximum likelihood, ▶variance; Mather K 1957 The Measurement of Linkage in Heredity, Methuen, London.

Information (in statistics): It is sometimes called “support” or “lod-score”. ▶lod score

Information Retrieval: Refers to the procedures to obtain information from a set of stored data, such as a specific nucleotide sequence in the database. ▶databases; Yandell MD, Majoros WH 2002 Nature Rev Genet 3:601.

Information Theory: <http://www.lecb.ncifcrf.gov/~toms/paper/primer>.

Informational Macromolecules: Denote DNA, RNA, proteins that can convey genetic, developmental, biochemical and evolutionary instructions to a cell or organism.

Informative Mating: This reveals the inheritance or linkage relationship of a gene or an allele.

Informativeness: Refers to the usefulness of a test for making a distinction between/among alternative hypotheses. ▶robustness

Informed Consent: A genetic counselor may face a dilemma regarding the information he/she may wish to withhold from the counselee because of the psychological impact. Legally, all the dangers associated with the professional evaluation should be shared with the individual, and within the legal limits of confidentiality. Action to be pursued requires informed consent. Organ donation for direct use for human treatment involves different ethical considerations and informed consent for organ donation for medical or basic biological research. Both may involve risk for the donor and in the latter case (e.g., oocytes donation for stem cell research) the beneficial effects for society may not be seen for years or ever (Magnus, D. & Cho, M.K. 2005 Science 308:1747). ▶counseling genetic, ▶genetic privacy, ▶confidentiality, ▶bioethics, ▶gene therapy, ▶cancer gene therapy, ▶public opinion, ▶morality, ▶biopiracy; US Office for Protection from Research Risks (OPRR) 1993, Dept. of Health and Human Services, Washington DC; Greely HT 2001 Annu Rev Genet 35:785.

Informosome (masked RNP): Refers to mRNA complexed with protein and thus having a very low

turnover rate and stability. (Spirin AS 1994 Mol Reprod Dev 38:107).

INGI: ►p53

ingi: ►hybrid dysgenesis, ►I-R

Ingression: This is the movement of cells from the surface into the inner region. ►gastrulation

INH: A protein complex that contains at least six species, isolated from oocytes. It inhibits the activation of pre-MPF. ►maturation protein factor

INHAT: Refers to an inhibitor of histone acetyltransferases CBP and PCAF. ►CBP, ►PCAF

Inherency: Genes that are important for organogenesis in higher evolutionary forms usually have some comparable representatives in more primitive forms.

Inheritance: This is the process of receiving genes from one's ancestors and passing them on to one's offspring. DNA codes these genes in eukaryotes and prokaryotes; in some viruses the transmitted genetic material is RNA. The genetic material may be located in the nucleus (nuclear inheritance) or carried by the nucleoid in prokaryotes. The genetic material in mitochondria and chloroplasts mediates extranuclear inheritance. Prokaryotes and cytoplasmic organelles may also have plasmid vehicles of heredity. Colloquially people may say that a certain trait of the children is inherited from one or the other parent. Actually, traits are not inherited, only the genes, which determine them, are transmitted. Epigenetic modification of histone proteins may, however temporarily be maintained in the offspring. ►genotype, ►phenotype, ►heredity, ►genetics, ►reverse genetics, ►DNA, ►RNA, ►prions, ►genealogy, ►pedigree, ►acquired characters inheritance, ►epigenetics, ►dauermodification

Inheritance, Cortical: ►cortical inheritance

Inheritance, Cultural: This refers to information transfer by non-biological means such as customs, traditions and behavior. Cultural inheritance plays a significant

role in the phenotype but the genes of the organism determine its genetic significance. The genes involved may have different selective values. ►fitness

Inheritance, Delayed: ►delayed inheritance

Inhibin: This is an antagonist of activin. Inhibins are glycoproteins (A and B) in the seminal and follicular fluids and inhibit the production of follicle-stimulating hormone and regulate gameto-genesis, embryonic and fetal development as well as blood formation (hematopoiesis). ►activin, ►FSH

Inhibition: ►inhibitor

Inhibition of Transcription: Any inhibitor of the RNA polymerase protein can block transcription. Bis ([1,10]-phenanthroline) cuprous chelate ($[OP]_2Cu^+$) is one such inhibitor. On its own it is not gene-specific, however, it can cut oxidatively single-stranded DNA templates and is suitable for mapping transcription initiation sites (see Fig. I29). Gene-specific inhibition of transcription can be accomplished by antisense RNA, triple-helix formation and DNA-binding polyamides. Gene-specific inhibition is feasible by targeting $[OP]_2Cu^+$ to the promoter in an open transcription complex with the aid of template-specific oligonucleotides with $[OP]_2Cu^+$ attached to the oligonucleotides at various positions at either ends or interstitially. The template strand is then interrupted by the $[OP]_2Cu^+$ position, e.g., OP-5'-GUGGA-3', 5'-GUGGA-3'-OP or 5'-GU[OP]GGA-3'. The inhibition is most efficient with 5 nucleotides representing one-half turn of A or B DNA-type double helix. The preferred cleavage site is 2–3 nucleotide from the OP linkage toward the 3' end. 2'-aminouridine appears to increase the specificity of the intercalation. The presence of the RNA polymerase is essential for the binding. ►antisense RNA, ►TFO, ►triple helix formation, ►polyamides, ►transcriptional repression, ►transcription corepressor, ►RNAi, ►DNA types; Milne L et al 2000 Proc Natl Acad Sci USA 97:3136.

Figure I29. Inhibition of transcription

Inhibitor: This is a substance that interferes with the *activity* of an enzyme versus a repressor that prevents the *synthesis* of the enzyme. ►[regulation of enzyme activity](#)

IN1 (integrase interacting protein): This tethers the retroviral (HIV) integrase enzyme and facilitates the integration at or near the DNase hypersensitive site of the eukaryotic chromosome. ►[integrase](#), ►[DNase hypersensitive site](#), ►[Cre/loxP](#), ►[FLP](#), ►[resolvase](#), ►[retroviruses](#), ►[HIV](#)

Initial Sequence Contig: Refers to the assembly of overlapping sequences from a single clone.

Initiation Codon: This is the first translated codon. In prokaryotes it is commonly AUG (90%) translated into formylmethionine but GUG (8%) and UUG (1%) can also be used. AUU is rarely employed because IF3 discriminates against this *non-canonical* codon versus the above three *canonical* codons. In prokaryotes the non-formyl AUG is prevented from initiation by the secondary structure in the mRNA and the interaction between mRNA and ribosomal RNA. In eukaryotes AUG does not code for formylmethionine but for methionine. In some rare cases in mammals the initiation codon is CUG or GUG (Tailor, C.S. et al. 2001 J. Biol. Chem. 276:27221, Schwab, S.R. et al. 2003 Science 301:1367). In some insect viruses the initiator codon is CAA (glutamine) and an initiator tRNA is not required. The initiation codon is charged to a specific initiator tRNA. ►[aminoacyl-tRNA synthetase](#), ►[elongation factors](#), ►[Shine-Dalgarno sequence](#), ►[ribosome scanning](#), ►[translation initiation](#), ►[transcript elongation](#), ►[modified bases](#), ►[genetic code](#)

Initiation Complex: This contains the small subunit of the ribosome with associated mRNA, aminoacylated tRNA and the various initiation protein factors and energy donor nucleotide triphosphates. In prokaryotes the initiation complex, comprising three single polypeptide chains proteins, has a mass of ~150 kDa. In eukaryotes about 10 initiation factors comprising >25 polypeptide chains has an aggregate mass of ~1,200 kDa. Although both types of systems require the ternary complex of Ifs (initiation factors)•GTP•tRNA, several differences exist in the details of executing the functions. In eukaryotes the ternary complex usually binds the 40S ribosomal subunit before the mRNA binding although the reverse sequence of events is possible. In prokaryotes there is a near equal chance of selection of either of these possible routes of binding the 30S subunit. In eukaryotes the 40S ribosomal subunit recruits to the 5' cap of the mRNA, the initiation factors eIF3 and eIF2-GTP and the initiator tRNA. EIF3 then interacts with the cap-binding complex eIF4F and the 40S

subunits scan for the appropriate start codon in the mRNA. Factor eIF5 releases eIF2 and in the presence of eIF5B-GTP both 40S and 60S ribosomal subunits are assembled into the 80S ribosome. Then the start codon Met-tRNA₁ instead of the ribosomal P site eIF5B is released from GTP to proceed with peptide extension. The Cricket Paralysis Virus can initiate translation without this complete machinery by the placement of the IRES (internal ribosomal entry site) at the A site of the ribosome. Other insect viruses, however, require most of the regular initiation factors and Met-tRNA₁ (Jan, E. et al. 2003 Proc. Natl. Acad. Sci. USA 100:15410). ►[protein synthesis](#), ►[preinitiation complex](#), ►[initiation factors](#); Kimball SR 2001 Progr Mol Subcell Biol 26:155.

Initiation Factor for Transcription: ►[initiation complex](#), ►[IF](#), ►[eIF](#)

Initiation Factors of Protein Synthesis: These are involved in initiation of translation. ►[eIF](#), ►[IF](#) and ►[iIF](#); Sonenberg N et al eds. 2000 Translational Control of Gene Expression, Cold Spring Harbor Lab. Press, Cold Spring Harbor, New York.

Initiator (Inr): ►[promoter](#), ►[core promoter](#)

Initiator Codon: This is the starting site of translation in the mRNA; it is generally 5'-AUG-3' but sometimes it can be 5'-GAG-3', 5'-GUG-3' or 5'-GUA-3'. ►[protein synthesis](#), ►[translation](#)

Initiator tRNA: This carries formylmethionine (prokaryotes) and initiation methionine (eukaryotes) to the P site of the ribosome to begin translation. The structure of this tRNA can be distinguished from the rest of the transfer RNAs. This rRNA in bacteria, besides the AUG, may recognize GUG and UUG as a formylmethionine codon. Not all proteins begin with a methionine because of processing. Mutation in the anticodon of tRNA^{fMet} may start translation with amino acids other than formylmethionine or methionine. The eIF2 initiation protein distinguishes between the initiator and the elongation tRNA^{Met} on the basis of several criteria: the A1:72 base pair at the bottom of the amino acid acceptor stem, three G:C pairs in the anticodon stem, initiators do not have the TψC in the T arm and A54 rather than T54 is in the T arm and within the T loop A60 replaces pyrimidine-60. In plants and fungi, at position 64 a phosphoribosyl group is attached to the 2'-OH of the ribose. Additional variations may exist in some species. ►[protein synthesis](#), ►[ribosome](#), ►[transfer RNA](#), ►[IRES](#), ►[initiation codon](#), ►[eIF2](#), ►[pseudoknot](#); O'Connor M et al 2001 RNA 7:969.

Injectisome: This is an apparatus of pathogenic bacteria for delivering type III secretions into the host (see Fig. 130). The tip of a long injection needle of *Yersinia*

composed of several proteins is diagramed after Mueller (Mueller CA et al 2005 Science 310:674).

Figure I30. Injecting needle tip

INK (p^{INK}): Polypeptide inhibitors of cyclin-dependent kinases involve and cause cell cycle G1 phase arrest. The INK family includes proteins p15, p16, p18 and p19 bind Cyclin D/CDK4. ▶cancer, ▶cell cycle, ▶CDK, ▶p15, ▶p16, ▶p18, ▶p19

Innate: This means inherited, congenital. ▶congenital

Innate Immunity (natural immunity): This is based on cell surface receptors (pattern recognition receptors, PRR) and other protein molecules encoded by the germline. The Toll-like receptors (TLR) through their TLR/IL-1 receptor domains (TIR) recognize extra-cellular or membrane-enclosed foreign organisms. The NOD-like (nucleotide-binding oligomerization proteins, NLR) include different families of proteins. NOD1 and NOD2 recognize bacterial peptidoglycans. The NALP3 “inflammasomes” control proinflammatory cytokines IL-1 β and IL-18. They respond to PAMPs (pathogen-associated molecular pattern recognition proteins) and DAMPs (danger-associated molecular pattern). Viruses are recognized RIG-like helicases. (See details of function reviewed by Meylan E et al 2006 Nature [Lond] 442:39).

These systems generally recognize carbohydrate structures and then stimulate the synthesis of various molecules such cytokines, interleukins and tumor necrosis factor. Some natural killer cells (neutrophils, macrophages) recognize inimical cells by lectin-like membrane receptors. This innate immunity is a rather fixed, rigid system in comparison to the acquired immunity mediated by immunoglobulins which are greatly adaptable and variable. Innate immunity can shape the development of the acquired immunity by interacting with it. The protein fragments cut up by the macrophages may be presented to the adaptive immune system represented by the B and T cells. It may guide the selection of antigens by lymphocytes and the secretion of cytokines by the helper T lymphocytes. Innate immunity is the first line of defense by initiation of inflammation through recruiting phagocytic and bactericidal neutrophils and macrophages. The innate immune system recognizes foreign bodies with the aid of pattern-recognition

receptors. In mouse double-strand RNA viruses are recognized by retinoic-acid-inducible protein I (RIG-I) and by the melanoma-differentiation-associated gene 5 (MDA5) that encodes another antiviral protein. RIG-I responds to dsRNA by the production of interferon whereas MDA5 is specific for polyinosinic-polycytidylic acid. RIG-I responds to paramyxoviruses, influenza virus and Japanese encephalitis virus. MDA5 is critical for picornaviruses (Kato H et al 2006 Nature [Lond] 441:101).

The complement is part of innate immunity but it also cooperates with the acquired immunity system. Innate immunity is also present in insects (*Drosophila*) although they lack the adaptive immunity system found in vertebrates. The innate defense system of bacteria recognizes non-methylated DNA and cleaves the foreign DNA by restriction endonucleases. Mammals possess relatively few CG pairs and the C is commonly methylated within the PuPuCGPyPy sequence. The unmethylated bacterial, fungal and insect CG pairs then activate macrophages, dendritic and B cells without normally attacking the self-DNA. Through the mediation of the MEK signal transduction pathway and NF- κ B the genes of the acquired immune system are turned on. The specificity of the discrimination is attributed to the different Toll-like receptors, which recognize bacterial lipopolysaccharides, glycolipids, flagellin, etc. Another signaling route is through DNA-PK. These two pathways may anastomose. The defense system in *Drosophila* relies on phagocytosis, proteolytic cascades, melanin formation, opsonization and the synthesis of antimicrobial peptides. ▶immune system, ▶natural antibody, ▶complement, ▶acquired immunity, ▶vaccine, ▶lymphocytes, ▶antibody, ▶interferon, ▶opsonins, ▶antimicrobial peptides, ▶Toll, ▶siderophore, ▶flagellin, ▶signal transduction, ▶NF- κ B, ▶DNA-PK, ▶CD14, ▶host-pathogen relationship, ▶T-bet; Aderem A, Ulevitch RJ 2000 Nature [Lond] 407:782; Aderem A, Hume DA 2000 Cell 103:993; Kimbrell DA, Beutler B 2001 Nature Rev Genet 2:256; Roger T et al 2001 Nature [Lond] 414:920; Janeway CA Jr, Medzhitov R 2002 Annu Rev Immunol 20:197; relationship between innate and adaptive immunity: Hoebe K et al 2004 Nature Immunol 5:971.

Innervation: Refers to the development of the nervous system in an organ or tissue.

Innexins: These are invertebrate gap-junction proteins which are functionally similar to connexins in vertebrates. ▶gap junction, ▶connexins

INO80: This is a chromatin remodeling complex participating in the DNA double-strand break repair. (Morrison AJ et al 2004 Cell 119:767; DN repair).

Inoculum: Usually a small microbial cell sample is used for starting a culture (see Fig. I31).

Figure I31. Inoculation loop

INOH: This is a biochemical pathway database (<http://www.inoh.org/>).

Inorganic Pyrophosphatase: This cleaves off 2 molecules of phosphates from molecules.

Inosine: ►hypoxanthine (see Fig. I32).

Figure I32. Inosine

Inosinic Acid: ►hypoxanthine

Inositides: ►phosphoinositides

Inositol: This occurs in cells as myoinositol as part of the vitamin B-complex. It is formed through cyclization from glucose-6-phosphate (see Fig. I33). It is an indispensable constituent of some lipids (phosphoinositides). In some forms of diabetes it may accumulate in the urine. ►signal transduction, ►diabetes

Figure I33. Inositol

Inositol Triphosphate: ►phosphoinositides

Inparalog: This is a gene(s) evolved through more recent duplications. Gene comparisons between species are identified by INPARANOID algorithm (Remm, M. et al. 2001 J Mol Biol 314:1041). ►paralogous loci, ►outparalog

In-Planta Transformation: ►transformation genetic

Input Trait: In genetic engineering of plants the goal of research is to facilitate the culture of plants (e.g., increase resistance to herbicides, pathogens, parasites, cold, etc.). The *output traits* include higher nutrient content, modified plant products (e.g., lipids, fatty acids) manufacturing special proteins (e.g., antibodies) and synthesizing special industrial raw materials (e.g., silk fibroin, plastics). ►genetic engineering

Inr: ►promoter

INSDC (International Nucleotide Sequence Database Collaboration): <http://www.insdc.org/>; ►XML

Insect Control, Genetic: ►genetic sterilization, ►holo-centric chromosomes

Insect Control, Physiological: This uses chemicals as well as biological agents such as viruses, bacteria, fungi, protozoa and natural parasites. Chemicals include alkylating agents (e.g., methyl bromide) that alter the DNA, organophosphates and carbamates that inhibit choline esterases and thus the nerve function, nicotine and derivatives act similarly as acetylcholine mimics. Arsenics inhibit glycolysis, cyanides poison the respiratory system. DDT, pyrethrins activate sodium channels, growth regulators may inhibit chitin synthesis, hormone synthesis, etc. However, the effectiveness of many compounds may be diminished over time because of mutation to resistance. (Wimmer EA 2003 Nature Rev Genet 4:225; biological insect control: <http://www.ent.iastate.edu/list/directory/108>).

Insect Resistance in Plants: Some plant species contain genes for insect tolerance and these are being incorporated into plant breeding material by conventional techniques. The most successful insect resistance gene, the *Bacillus thuringiensis* toxin gene, has been transformed into several species of dicots and provides almost complete defense when it is expressed under the control of efficient promoters. Pea plants transgenic for α -amylase inhibitor 1 and 2 are protected from the pea weevil (*Bruchus pisorum*). α Al-1 causes larval mortality at the 1st and 2nd instar stages whereas α Al-2 is responsible for blocking the maturation of the larvae. Maize plants defend themselves against the armyworm (*Spodoptera exigua*) caterpillars by releasing a sesquiterpene and indole. These volatile compounds encoded by the *stc1* and *Igl* genes, attract parasitic wasps, which deposit their eggs and eventually destroy the caterpillars. Some of these volatile defense compounds (cis-3-hexen-1-ol, linalool, cis- α -bergamotene) perform multiple tasks, e.g., repel herbivorous invaders, decrease their rate of oviposition and recruit their natural predators (Schnee, C et al 2006 Proc. Natl.

Acad. Sci. USA 103:1129). Another species of fall armyworm (*Spodoptera frugiperda*) is perceived by the cowpea (*Vigna unguiculata*). Upon attack the insect secretes a disulfide-bridged peptide ($^+ICDINGVCVDAS^-$) called inceptin, that promotes ethylene production in the plant and triggers the production of phytohormones salicylic acid and jasmonic acid that have a defense function. Inceptins are proteolytic fragments of the γ subunit of chloroplast ATP synthase. Only insects that earlier fed on cowpeas produce inceptin in sufficient quantity to defend against the herbivore (Schmelz, EA et al. 2006 Proc. Natl. Acad. Sci. USA 103:8894).

Spidermite-infected plants may release terpenoids (β -ocimene) that may stimulate defense-related genes in uninfected lima bean plants. Plants transgenic for the cyanogenic glucoside, dhurrin (see Fig. I34) become resistant to the flea beetle *Phyllotreta nemorum*. Host plant specialization of pea aphids may be affected by an endosymbiotic bacterium (Tsuchida, T. et al. 2004 Science 303:1989). *Arabidopsis* plants transgenic for sesquiterpene synthase targeted to the mitochondria use cytochrome oxidase subunit IV (CoxIV)-linalool/nerolidol synthase construct emitted nerolidol and its derivative 4,8-dimethyl-1,3(E),7-nonatriene ([E]-DMNT) against insects (see Fig. I35).

Figure I34. Dhurrin

Figure I35. Insect resistance substances in plants

These compounds attract the carnivorous predatory mites (*Phytoseiulus persimilis*) to the plants and provide defense against herbivorous insects (Kappers IF et al 2005 Science 309:2070). Maize (corn) earworm (*Helicoverpa zea*) is a pest of maize and several solanaceous plants (tomato, potato). The host plants produce a carboxypeptidase inhibitor to prevent the pest from feeding on the plant tissues but the pest can adapt by producing an inhibitor-resistant protease. The crystal structure of the *H. zea*

B-type metallocarboxypeptidase has been revealed that has shed light on its properties (Bayés A et al 2005 Proc Natl Acad Sci USA 102:16602). The β -subunit of SnRK1 (SNF-related kinase) protein kinase, GAL83, transcripts rapidly down regulate sugars in the leaves of tobacco upon attack by herbivores and move them to the roots. This defense increases the root reserves and prolongs life and facilitates survival (Schwachtje J et al 2006 Proc Natl Acad Sci USA 103:12935). Secreted proteins encoded by parasitism genes expressed in esophageal gland cells mediate infection and parasitism of plants by root knot nematodes. The ingestion of *16D10* dsRNA in vitro silenced the target parasitism gene in root knot nematode and resulted in reduced infectivity in *Arabidopsis* (Huang G et al 2006 Proc Natl Acad Sci USA 103:14302). Insect have chemosensors for the detection of their animal or plant targets (van der Goes van Naters W, Carlson JR 2006 Nature [Lond] 444:302). [▶*Bacillus thuringiensis*](#), [▶chitin](#), [▶wound response](#), [▶host–pathogen relations](#), [▶selection types](#), [▶high-dose/refuge strategy](#), [▶lotaustalin](#), [▶herbivore](#), [▶jasmonic acid](#); De Moraes CM et al 2001 Nature [Lond] 410:577; Farmer EE 2001 Nature [Lond] 411:854; Palumbi SR 2001 Science 293:1786; Tattersall DB et al 2001 Science 293:1826; Schriber JM 2001 Proc Natl Acad Sci USA 98:12328; Kessler A, Baldwin IT 2002 Annu Rev Plant Biol 53:299; Kennedy GG 2003 Annu Rev Entomol 48:51; insect genomes: Heckel DG 2002 Annu Rev Entomol 48:235; grasshopper elicitor: Alborn HT et al 2007 Proc Natl Acad Sci USA 104:12976.

Insect Viruses: These viruses are of diverse types. The enveloped Baculoviridae and the Poxviridae have double-stranded DNA. The mosquito iridescent virus has non-enveloped dsDNA. The genetic material of the Parvoviridae is non-enveloped single-stranded DNA. The Reoviridae carry non-enveloped double-stranded RNA. The Flaviviridae are single-stranded, enveloped RNA viruses. The *Drosophila C* virus is a non-enveloped ssRNA virus. The Baculoviruses are important for engineering genetic vectors. [▶baculoviruses](#); Friesen PD, Miller LK 2001 p. 443 in Fundamental Virology, Knipe DM, Howley PM eds. Lippincott Williams & Wilkins, Philadelphia, PA.

Insecticide Decay: Insecticides, pesticides and herbicides may decompose spontaneously in soil at different rates; 1,2-dichloroethane in 72 years, paraoxon in 13 months, atrazine (herbicide) in 5 months and aziridine (synonym ethylenimine, carcinogen) in 52 h. The nematocide 1,3-dichloropene is converted into transchloro-3-chloroacrylic acid in $\sim 10,000$ years at 25°C. However, when it is exposed to the enzyme 3-chloroacrylate dehalogenase of *Pseudomonas*

pavonaceae hydrolytic dechlorination proceeds at a half-time of 0.18 s, an increase of about 10^{12} (Horvat CM, Wolfenden R V 2005 Proc Natl Acad Sci USA 102:16199)

Insecticide Resistance: Such resistance usually develops rapidly in various populations of pests as a response to detoxification of the pesticides. In several insects mutations in one (*Cyp6g1*) of the P-450 cytochrome genes (90 in *Drosophila*) is responsible for resistance to DDT as well as other chemicals (organophosphates, neonicotinoids, benzoylphenylureas). In mosquitos amplification of the detoxifying carboxylesterase may occur. Point mutations in the genes encoding γ -aminobutyric acid-gated chloride channel nerve membrane convey resistance to cyclodienes. ▶DDT, ▶organophosphates, ▶cholinesterase, ▶pyrethrin, ▶nicotine; Denholm I et al 2002 Science 297:2222.

Insemination by Donor (DI): This is a therapeutic process to secure offspring in the case of male infertility. In the USA, this method accounts for ~30,000 birth/year. Generally, cryo-preserved semen of sperm banks is utilized. To avoid potential consanguinity and the transmission of hereditary diseases it is advisable to limit the number of inseminations to less than 10 per donor. If the donors are genetically screened the incidence of genetic abnormalities may decline from 2–5% to about half of that in the general population where DI is not used. ▶ART, ▶sperm bank, ▶in vitro fertilization; Kuller JA et al 2001 Hum Reprod 16:1553.

Insert Restriction Site into Plasmid: In this process the restriction endonuclease gene is amplified by the PCR and then the plasmid is opened up by the restriction enzyme. After the primers are removed the target DNA is inserted into the plasmid and ligated to circularize the plasmid.

Insertion Elements: DNA sequences generally shorter than 2000 bases, which can insert into any part of a genome transposons are common in all organisms from prokaryotes to eukaryotes (see Table 14). Some of the bacterial insertion elements have the following characteristics.

They do not carry any genetic information beyond that needed for insertion. Viruses can act as insertion elements in cells. Insertion elements are the major factors of “spontaneous” mutability. According to some estimates, 5–15% of the spontaneous mutations in bacteria are caused by *IS* elements. The presence of *IS1* may increase deletion frequency of the *gal* operon 30 to 2,000 times. *IS* elements also cause chromosomal rearrangements. Many *IS* elements have a large number of potential target sites, others exhibit clear preferences. The mechanism of transposition is either

Table 14. A few insertion elements

| Name | Size (bp) | Inverted Repeats (bp) | Terminal (bp) | Target Duplication |
|-------------|-----------|-----------------------|--------------------------------------|--------------------|
| <i>IS1</i> | 768 | 18/23 | (<i>E. coli</i>) | 8–11 |
| <i>IS2</i> | 1,324 | 32/41 | (<i>E. coli</i>) | 5 |
| <i>IS3</i> | 1,258 | 29/40 | (<i>E. coli</i>) | 3 |
| <i>IS5</i> | 1,250 | 16 | (<i>E. coli</i>) | 4 |
| <i>IS10</i> | 1,329 | 17/22 | (<i>Tn10</i>) | 9 |
| <i>IS66</i> | 2,548 | 18/20 | (<i>Agrobacterium tumefaciens</i>) | 8 |

dependent on replication and the new copy is transposed or it simply involves a relocation of the existing element. The movement of the *IS* elements is affected by host genetic factors (DNA polymerase, gyrase, histone-like proteins, dam methylase, DnaA protein and proteins mediating recombination).

The presence of *IS* elements may alter not just mutation, but also gene expression by their presence in the control regions of genes. In *Drosophila melanogaster* the average insertion density (average number of large insertions/kb/chromosome) is about 0.004 and the average frequency of their movement is 0.023. Some of the historical insertions have been modified and have become permanent regulatory elements of the genes. ▶hybrid dysgenesis, ▶copia elements, ▶retrotransposons, ▶Ti plasmids, ▶LIN, ▶Tn, ▶transposable elements, ▶illegitimate recombination, ▶Ty, ▶pathogenicity islands, ▶RNA insertion element, ▶DD(35)E, ▶site-specific recombination, ▶*Francisella*; Chandler M, Mahillon J 2000 p. 306 in Mobile DNA II, Craig N et al eds. American Society of Microbiology Washington, DC; Mahillon J et al 1999 Res Microbiol 150:675; bacterial insertion elements: <http://www-is.biotoul.fr/>.

Insertion Vectors: These have selectable marker(s) and restriction enzyme site(s) on the vector and chromosome where the foreign DNA can be inserted. The insertion involves a single reciprocal recombination and may generate duplication because the insert has homology to the target. However, the homology does not have to be complete.

Insertional Inactivation: The insertion of any type of DNA into an antibiotic resistance or other gene may inactivate the function (e.g., becomes antibiotic sensitive) because of the disruption of the gene's continuity. ▶insertional mutation, ▶pBR322; McClintock B 1951 Cold Spring Harbor Symp Quant Biol 16:13; Koncz C et al 1992 Plant Mol Biol 20:963.

Insertional Mutation: The insertion of a transposable genetic element within a gene disrupts its function and as a consequence, leads to lethal effects or altered functions (see Fig. I36). The insertion may modify the expression of the target genes by overexpression, suppression of the mutant phenotype or alter it. It has been recently demonstrated that many of the insertions do not lead to an observable change in the expression of the genes or their effect is minimal and only sequencing of the target loci reveals their presence. Labeled probes for the insert can selectively isolate the gene carrying the insertion. Although it was initially believed that the insertions occur at random sites, it has now been documented that the target sites upstream of the promoters or other locations where no essential functions are disrupted are preferred.

Figure I36. Insertional mutation of *Arabidopsis* knocked out the stem but fertility of the fruits is retained. (Rédei, unpublished)

The target selection is mediated by integrase or transposase functions. In some cases only DNA elements are involved in the insertions but retro-transposons sever the target DNA and the free 3'-OH end primes the reverse transcription of the template RNA element and the DNA is then inserted. Generally, there is no homology-dependent pairing requisite for recombination except for the type 2 introns. The insertion also requires protein co-factors such as IHF, HU, MuA and MuB (an ATP-dependent activator of Mu phage protein MuB). The IS10/Tn10 bacterial and the TC1/TC3 *Caenorhabditis* elements interact specifically with a target site consensus. TC transposase recognizes and is inserted at TA dinucleotides. In IS10 the interaction with the target catalyzes the excision of the element from the original location.

Retroviral as well as some other elements preferentially choose nucleosomal sites where the DNA is bent. Tn7 preferentially inserted to a conserved attachment site in *E. coli*, located outside the boundary of the *glmS* gene (glucosaminophosphate isomerase, map position 83). The yeast element Ty3 has high specificity for the promoters of RNA pol III-transcribed genes whereas Ty1 and Ty5 express less stringent specificities (although not exclusively) within the same region. Ty1 also prefers insertion when transcription is (potentially) active whereas Ty5 selects transcriptionally inactive sequences. Therefore, Ty1 is well suited for the induction of insertional mutations. Transposition is generally targeted to sites outside the transposon yet it may occur within the elements and often results in its destruction but it may lead to the evolution of a new element. The maize transposable elements and the *Drosophila* P element move preferentially to nearby sites although they may jump to other chromosomes. Agrobacterial vectors can also produce insertional mutations in plants. The position of insertions can be defined by various polymerase chain reaction techniques. By the use of microarray hybridization insertion libraries can be screened with the aid of capture PCR (Mahalingam R, Fedoroff N 2001 Proc Natl Acad Sci USA 58:7420) and on the basis of homologies to expressed sequence tags. ▶insertion elements, ▶transposons, ▶scanning insertion mutagenesis, ▶GAMBIT, ▶T-DNA, ▶gene isolation, ▶REMI, ▶MICER, ▶integrase, ▶transposase, ▶introns, ▶IHF, ▶HU, ▶Tn7 Tn10, ▶*Caenorhabditis*, ▶DNA bending, ▶Ty, ▶Ac-Ds, ▶hybrid dysgenesis, ▶transposition immunity, ▶Alu family, ▶LINE, ▶EST, ▶microarray hybridization, ▶capture PCR, ▶gene therapy, ▶cancer gene therapy, ▶*Agrobacterium*; Vidan S, Snider M 2001 Curr Opin Biotechnol 12:96; insertion mutagenesis in mouse: Carlson CM, Largaespada DA 2005 Nature Rev Genet 6:568; TRIPLES.

Inside-Out-Signaling: Signals emanating from within the cell control the affinity of ligands and the ligands in turn affect the physiological processes in the cell (outside-in signaling). ▶signal transduction; ligand; Takagi J et al 2002 Cell 110:599.

Inspection Bias: This denotes a bias toward biological interest.

Instability, Genetic: This is caused by high rate of mutation, defects in genetic repair, recombination among repeated sequences (trinucleotide repeats, inverted repeats), palindromes, the presence of transposable elements, illegitimate recombination and double-strand breaks. Exonucleases may degrade misaligned tandem repeats and thus favor DNA stability (Feschenko VV et al 2003 Proc Nat Acad Sci USA 100:1134). ►mutator genes, ►mutagens, ►chromosome breakage, ►chromosomal aberration, ►DNA repair, ►trinucleotide repeats, ►repeats inverted, ►at-risk-motif, ►transposable element, ►cancer, ►stress; Myung K et al 2001 Nature [Lond] 411:1073.

Instar: In this phase the insect larvae are between the processes of molting (shedding the outer cover layer). In *Drosophila* three moltings take place after hatching and before pupation. The first and second instars last for ~ one day each, whereas the third instar lasts for ~ two days. ►*Drosophila*

Instincts: A variety of innate behavioral patterns that develop without learning although learning may reinforce them, e.g., motherly love, nursing, fearing for life, conforming to some standards. ►behavior genetics, ►ethics, ►ethology, ►aggression

Institutional Biosafety Committee: This committee must approve genetic engineering projects in terms of (1) the source of the DNA used, (2) the nature of the inserted DNA, (3) the hosts and vectors contemplated, (4) the protein products expected, (5) the nature of the containment facilities and compliance with the regulations of the National Institutes of Health. ►recombinant DNA, ►recombinant DNA and biohazards

Instructive Signal: This is receptor-mediated and involves a signal transduction cascade. ►signal transduction

Insulator: DNA element(s) of 0.5 to 3 kbp that prevent(s) interactions between enhancers and the target promoter but it (they) may/may not permit the expression of stably integrated transgenes. The chicken hypersensitive site 4 DNA is an insulator that protects X-linked mouse gene from repression but not from X chromosome inactivation (Ciavatta D et al 2006 Proc Natl Acad Sci USA 103:9958).

Transcriptional activators may suppress transgene silencing as chromatin insulators (Sutter NB et al 2003 Proc Natl Acad Sci USA 100:1105). However, they must be located between the enhancer and the promoter to be able act. When there is a spacer DNA between the enhancer and the promoter the structural gene is expressed as illustrated by the light bulb switched on. When the spacer is replaced by an insulator element the expression of the structural gene is markedly reduced or eliminated. The insulator may affect the organization of the chromatin or it may act as a regulator of transcription. Such elements are Fab-7 and Fab-8 or the HMR and HML elements controlling sex determination in yeast.

An insulator may prevent position effect. Insulators may show some sort of position effect and two cis insulators may facilitate transcription rather than blocking it. The boundary between heterochromatin and euchromatin reveals a distinct pattern of methylation of histone H3. The gypsy retrotransposon can serve as an insulator by the use of two zinc finger proteins (Su[Hw] and Mod[mdg4]) as well as the centrosomal protein CP190 (Pai C-Y et al 2004 Mol Cell 16:737). The TFIIC transcription factor complex recruited to tRNA genes (located in the pericentric heterochromatin) checks heterochromatin from spreading into the euchromatin. The same transcription factor is also localized between divergent promoters. The TFIIC complex seems to tether

heterochromatin to the nuclear periphery where transcription is limited (Noma K-i et al 2006 Cell 125:859). ▶promoter, ▶enhancer, ▶silencer, ▶boundary element, ▶sex determination in yeast, ▶CTCF, ▶position effect, ▶enhancer competition, ▶histones, ▶epigenesis, ▶transcription factors, ▶transcription factories, ▶chromosome territories; Sun F-L, Elgin SCR 1999 Cell 99:459; Bell A et al 1998 Cold Spring Harbor Symp Quant Biol 63:509; Bell AC, Felsenfeld G 1999 Curr Opin Genet Dev 9:191; Bell AC et al 2001 Science 291:447; Noma K-I et al 2001 Science 293:1150; Gerasimova TI, Corces VG 2001 Annu Rev Genet 35:193; Oki M, Kamakaka RT 2002 Current Opin Cell Biol 14:299; West AG et al 2002 Genes Dev 16:271; mechanisms: Gaszner M, Felsenfeld G 2006 Nature Rev Genet 7:703; chromatin insulators: Valenzuela L, Kamakaka RT 2006 Annu Rev Genet 40:107; see Fig. I39.

Figure I39. Insulator effect

Insulin: This is one of the most important peptide hormones (MW \approx 5,700) in the body and it is synthesized in the pancreas. The pancreas is a large gland behind the stomach. The islets of Langerhans produce and secrete this hormone into the blood. Insulin regulates glucose uptake into the muscles by glucose transporters, and into the liver by glucokinase. With the assistance of glycogen synthase, glycogen is made in the muscles and the liver. The breakdown of glycogen is mediated by the insulin-regulated glycogen phosphorylase. Glycolysis and acetyl coenzyme A synthesis is boosted by insulin through the enzyme phosphofructokinase and the pyruvate dehydrogenase complex. Fatty acid synthesis in the liver is promoted by acetyl-CoA carboxylase and neutral fat (triacylglycerol) is stimulated by insulin with the aid of lipoprotein lipase. Insulin deficiency leads to the hereditary diabetes mellitus.

Diabetes is a very complicated disease which is controlled by several genes involved either in the differentiation of the islets of Langerhans or at various stages in the synthesis and regulation of the hormones. About 5 to 10% of the population in western countries suffers from one or another form of this disease. Of these cases, however, only 1/10 is insulin-dependent. Insulin-dependent diabetes (IDDM) is largely familial and occurs early in life. The non-insulin-dependent form of the disease (NIDDM) generally affects those who become diabetic after the age of 40. The latter has a relatively small hereditary component and it is most common among obese individuals in the age group of 50 to 60 years. One of the most important clinical manifestations of the disease is hyperglycemia (excessive amount of sugar in the blood), but there are many other complex characteristics. Symptoms of diabetes are manifested in nearly 60 known human diseases. A well-controlled diet and a continuous supply of insulin can effectively manage the early onset diabetes. The treatment of the other forms (NIDDM) varies according to the causative metabolic defect.

The primary structure of insulin was first determined by the two-time Nobel laureate, F. Sanger in 1953, the same year as the Watson - Crick model of DNA was published. These two events signaled the beginning of molecular biology. Insulin is synthesized as a pre-proinsulin equipped with a "signal sequence" that directs the molecules into the secretory vesicles. After the removal of this signal peptide, proinsulin is formed that is stored in the β cells. When the glucose level in the blood increases insulin-specific peptidases process the protein into the functional final form. The A chain of bovine insulin contains 21 amino acids and the B chain has 30, the two chains are joined by disulfide bridges between A7 and B7 as well as A20 and B19 residues and a third disulfide bridge is formed within the A chain between residues 6 and 11 protein structure. The A chain is identical in humans, dogs, pigs and rabbits, and the bovine B chain is identical to that of pigs, goats, dogs and horses. The function of insulin requires the presence of a receptor.

The insulin receptor protein is made of two α and two β chains. The identical α chains bind insulin above the surface of the plasma membrane, whereas the two β chains reach inside the cell through the membrane with their carboxy termini. Upon binding of insulin, the β chains become a specific protein tyrosine kinase that first autophosphorylates and then phosphorylates other proteins in a cascading series of events. As a consequence a number of enzyme activities are altered by the phosphorylation of tyrosine and serine residues. These multiple reactions explain why diabetes occurs in many forms and is

part of numerous other syndromes under the control of a variety of genes and manifested in aneuploids (Turner's syndrome, Klinefelter's syndrome and Down's syndrome). Insulin receptor substrate-1 tends to the integrin family of surface receptors and in this way integrin and growth factor signaling are connected (White MF 2003 Science 302:1710).

The various forms may be under the control of autosomal dominant genes (diabetes insipidus nephrogenic Type II, diabetes mellitus juvenile with early onset). The latter was attributed, in one case, to a substitution of serine for phenylalanine at the 24th position of the β chain. Only a single locus seems to encode the human insulin structural gene in chromosome 11p15.5. The human *INS* and the mouse *Ins* (chromosome 7) are expressed only from paternal allele at some stages of development (imprinting). In rats and mice two distinct loci are involved. Some mutations interfere with the proteolytic processing of proinsulin, resulting in its accumulation (hyperproinsulinemia) without any symptoms of diabetes.

Non-insulin-dependent diabetes was observed to be associated with a mutation of the glucose transporter-4 protein at residue 383 (Val [GTC]→Ile [ATC]) in some cases but not in others. Vasopressin and oxytocin deficiency may also be involved in diabetes. These two octapeptides regulate muscle contraction and renal secretion. Diabetes is generally associated with abnormalities of kidney functions.

Autosomal recessive inheritance appears to account for the juvenile-onset diabetes mellitus Type I and this locus is assigned to human chromosome 6 in close proximity to the HLA Class II genes. This locus is probably a regulatory one, determining insulin susceptibility with a penetrance of 71% for the homozygotes and 6.5% for the heterozygotes. It was reported that if at position 57 of the HLA DQ- β chain has Asp, then most probably diabetes was absent whereas there was a high chance that this 57th residue was non-Asp in diabetics. Other studies have indicated that HLA genes DR3 and DR4 and HLA-DQ have predisposing effects on the expression of diabetes. Apparently HLA-DQw1.2 allele was protective but HLA-DQw8 increased the chances of developing insulin-dependent diabetes. Population genetic studies have also confirmed that having a non-polar amino acid at position 57, the chances of developing diabetes may increase by a factor of about 30.

X chromosomal linkage was observed for nephrogenic diabetes insipidus Type I, and it was proposed that this form of the disease was associated with a defect in the vasopressin 2(V2) receptor.

Till recently, insulin for therapeutic purposes was obtained exclusively from animal pancreas collected at the slaughterhouses. By the use of recombinant

DNA human insulin can be industrially produced with the aid of bacterial cultures and further processing. The industrial production of human insulin by genetic engineering is more successful than that of other proteins because it does not require glycosylation. In yeast, proinsulin mRNA is normally produced but the translation of the message is very inefficient. Human insulin has a definite advantage as some patients may be allergic to the slightly different animal protein. Lower than normal insulin resistance is frequently associated with infections, diabetes, obesity and some forms of cancer. In obese individuals, adipose tissues release increased amounts of non-esterified fatty acids, glycerol, hormones, inflammatory cytokines and other factors that lead to insulin resistance and Type 2 diabetes (Kahn SE et al 2006 Nature [Lond] 444:840). Obesity and diet-induced insulin resistance may be reversed by salicylate or disruption of IKK β (Yuan M et al 2001 Science 293:1673). Insulin resistance is mediated by tumor necrosis factor α and it decreases tyrosine kinase activity in the insulin receptor by activating serine phosphorylation (Kahn BB, Flier JS 2000 J Clin Invest 106:473). White adipocytes transcribe a 750-residue mRNA encoding the protein resistin (resistance to insulin). Neutralization of resistin enhances insulin-stimulated glucose uptake and active resistin reduces the uptake. An increased level of ROS can trigger insulin resistance (Houstis N et al 2006 Nature [Lond] 440:944). Insulin is degraded by an evolutionarily well-conserved Zn²⁺-metalloprotease (Shen Y et al 2006 Nature [Lond] 443:870). ►diabetes, ►HLA, ►TNF, ►IKK, ►obesity, ►insulin-like growth factor, ►insulin-receptor substrates, ►resistin, ►S6 kinase, ►ROS, ►thiazolidinedione, ►p110 α ; Bell GI et al 1980 Nature [Lond] 284:26; Steiner DF et al 1985 Annu Rev Genet 19:463; Lizcano JM, Alessi DR 2002 Current Biol 12:R236; historical: http://www.coreynahman.com/Information_On_Insulin.html.

Insulin-Like Growth Factors (IGF-1, IGF-2): These are required for the passage of the cell cycle from G1 to S phase; they promote cell maintenance, metabolism and cell division. A duplication of the *Igf-1* gene resulted in the development of "mighty mouse", animals with excessive muscle growth and some potential health problems. The human genes for IGF-1 and IGF-2 are located in chromosome 11p15-p11, separated by about 12–13 kbp. The human IGF-2 gene is expressed only from the paternal chromosome. In mice, the IGF genes (chromosome 7) display tissue-specific imprinting and are also expressed from the paternal chromosome. Somatomedin, a mammalian second messenger, has insulin-like functions in regulating bone and muscle growth in conjunction

with the pituitary hormone receptor. A minor 4.8-kb mRNA generates the prepro-IGF2 whereas the major 6-kb mRNA encodes a post-transcriptionally regulated IGF. The insulin-like growth factor receptor (IGF-1R) and the insulin receptor belong to the tyrosine kinase receptor family and regulate both normal and malignant cell proliferation. The paternally expressed IGF2 seems to control—like a QTL—muscle mass and fat deposition in pigs. Mice with deletion of insulin and insulin-like growth factor have normal pancreatic β cell number yet develop diabetes (Ueki K et al 2006 *Nature Genet* 38:583). ▶[signal transduction](#), ▶[insulin](#), ▶[insulin receptor](#), ▶[imprinting](#), ▶[growth factors](#), ▶[pituitary dwarfism](#), ▶[achondroplasia](#), ▶[somatomedin](#), ▶[mannose-6-phosphate receptor](#), ▶[myostatin](#), ▶[pancreas](#), ▶[dog](#), ▶[Simpson-Golabi-Behmel syndrome](#), ▶[prostate cancer](#), ▶[QTL](#); LeRoith D et al 1992 *Ann Intern Med* 116:854; Jiang F et al 2001 *Dev Biol* 232:414; structure of insulin-like growth factor receptor: Ward CW et al 2001 *Mol Pathol* 54:125.

Insulinoma: A relatively benign pancreatic cancer leading to excessive secretion of insulin.

Insulin-Receptor Protein (IR): This heterotetrameric membrane protein is a tyrosine kinase (related to the epidermal growth factor [EGFR] family); its deficiency leads to Donohue syndrome. The enzyme protein tyrosine phosphatase (PTP-1B) dephosphorylates IR and as a consequence in diabetes type II disease, although the cells can make insulin, they are unable to respond to this hormone because of the expression of PTP-1B. The Rabson-Mendenhall disease (INSR, 19p13.2) is due to deficiency of IR. ▶[insulin](#), ▶[diabetes](#), ▶[obesity](#), ▶[Donohue syndrome](#), ▶[Rabson-Mendenhall disease](#), ▶[insulin-like growth factor](#), ▶[GLUTs](#); structure: McKern NM et al 2006 *Nature [Lond]* 443:218.

Insulin-Receptor Substrates (IRS1, IRS2, IRS3, IRS4): After multiple site tyrosine phosphorylation they bind to and activate phosphatidylinositol-3'-OH kinase and other proteins with SH2 domains. Defects in IRS2 may be responsible for insulin-independent diabetes. IRS1 and IRS2 are essential for normal embryonic and post-natal growth. The IRS^{-/-} individuals by 30 days reach less than 1/4 of the wild type weight and the reproductive capability—especially of females—is impaired. ▶[insulin](#), ▶[insulin-like growth factor](#), ▶[SH2](#), ▶[diabetes](#)

Insulinitis: This is an autoimmune inflammation caused by infiltration of the islets of Langerhans by T lymphocytes. ▶[autoimmune disease](#), ▶[Langerhans islets](#), ▶[T cell](#), ▶[lymphocytes](#), ▶[diabetes mellitus](#)

INT Oncogene: INT1 is assigned to human chromosome 12q13 and to mouse chromosome 15. The product of *Drosophila* gene *wingless* (*wg*) is a homolog and therefore the gene is sometimes referred to as WNT. INT4 (human chromosome 17q21-q22, mouse chromosome 11) is also homologous to the *Drosophila* *wg* gene. In mammary carcinomas INT1 is frequently the target site for insertion and inactivation. INT2 is a mammary tumor gene assigned to human chromosome 11q13 and its only relation to INT1 is its presence in mammary tumors. INT2 product shows some relationship to fibroblast growth factor 6. INT3, another mammary tumor gene, encodes a transmembrane protein. ▶[oncogenes](#), ▶[FGF](#), ▶[transmembrane proteins](#), ▶[morphogenesis in *Drosophila*](#), ▶[WNT1](#)

Intasome: A bacterial nucleoprotein complex, including a negative supercoiled phage DNA, wrapped around by several copies of the phage-encoded integrase and the bacterial integration host factor protein (IHF). DNA bending by Xis regulatory proteins promotes the formation of the excisive intasome, but antagonizes the formation of an integrative intasome. Xis stabilizes the synaptic complex by directly interacting with Int bound to the arms of the phage. Xis recognizes a single binding site. Three Xis monomers work in concert to substantially bend the DNA by forming a micronucleoprotein filament (Abbani MA et al 2007 *Proc Natl Acad Sci USA* 104:2109). ▶[integrase](#), ▶[IHF](#); Chen H et al 1999 *J Biol Chem* 274:17358; Esposito D et al 2001 *Nucleic Acids Res* 29:3955.

Integr8: genome and proteome browser: <http://www.ebi.ac.uk/>.

Integral Membrane Protein: Refers to a protein in the membrane without covalent linkage to it and it is bound there by about two dozen uncharged and/or hydrophobic amino acids. The majority of the integral transmembrane proteins contain tightly packed α -helices and they are called helix-bundle class. These membrane proteins insert co-translationally and fold in the endoplasmic reticulum. In eukaryotes insertion is mediated mainly by the Sec61 translocon. ▶[translocon](#), ▶[transmembrane proteins](#)

Integrase: A protein that specifically recognizes transposon or phage (*att*) or yeast integration sites and opens them up for insertion to take place. The integrase makes a staggered cut in the DNA and the enzyme is covalently bound to the DNA via a catalytic tyrosine (Tyr³⁴²). A Holliday intermediate is formed and after a second exchange (and removal of the 40-kDa protein) the recombination product is generated. There is tremendous structural variation among more than 60 integrases yet a four-residue catalytic

unit is highly conserved. The position of the integrase (IN) in the Ty/gypsy group of transposons is 5'-LTR-gag-protease-reverse transcriptase-RNaseH-IN-LTR-3' and among the Ty1/copia-like elements 5'-LTR-IN-reverse transcriptase-RNaseH-LTR-3'. The same enzyme may catalyze both integration and excision as determined by the recombination directionality factors (RDF). Integrases can be used for the insertion of genes in specific locations as a means to gene therapy. ▶ [integration](#), ▶ [Cre](#), ▶ [Flp](#), ▶ [aspartate protease](#), ▶ [att sites](#), ▶ [transposable elements](#), ▶ [lambda phage \[site 27815\]](#), ▶ [IN1](#), ▶ [IHF](#), ▶ [intosome](#), ▶ [Holliday structure](#), ▶ [Holliday model](#), ▶ [integron](#), ▶ [Ty](#), ▶ [copia](#), ▶ [retroviruses](#), ▶ [RAG1](#), ▶ [disintegration](#), ▶ [FRET](#); Hindmarsh P, Leis J 1999 Microbiol Mol Biol Rev 63:836; Craigie R 2001 J Biol Chem 276:23213; Lewis JA, Hatfull GF 2001 Nucleic Acids Res 29:2205; Campbell A et al 2002 Gene 300:13; Radman-Livaja M et al 2005 Proc Natl Acad Sci USA 102:3913; structure and allosteric control: Biswas T et al 2005 Nature [Lond] 435:1059.

Integrated Circuit (chip): This is an electronic circuit within a single piece of semiconducting material. ▶ [semiconductors](#)

Integrated Map: This is based on the combined information on genetic linkage and physical mapping. ▶ [mapping genetic](#), ▶ [physical map](#), ▶ [skeletal map](#), ▶ [unified genetic map](#)

Integrating Vector: ▶ [yeast integrating vector](#)

Integration: A DNA sequence is inserted at both termini by covalent linkage into the host DNA. The DNA structure (bends) affects the site of integration. HIV integrates non-randomly either into purified naked DNA or preferentially into CpG stretches modified by cytosine methylation and within distorted nucleosomal DNA. The murine leukemia virus (MLV) integrates non-randomly, preferably into the major groove of the nucleosomal DNA. Retroviruses most commonly select DNase hypersensitive sites and stretches involved in active transcription. Agrobacterial vectors are usually integrated into the non-translated regions of potentially expressed genes and similar predilections have been observed in the bacterial transposons. The different yeast Ty elements also exhibit preferences. The transfer of foreign DNA into mammalian genomes either by infection or transformation may result in genome-wide methylation at sites remote from that of the integration and may alter the pattern of expression of genes in the recipient genomes. The integration of the DNA into the human genome may be mediated by protein Metnase, which methylates histone H3 lysine 4 and lysine 36, required for opening the chromatin. Metnase increases non-homologous end-joining

repair of double-strand breaks. This protein has a SET domain as well as transposase and nuclease domains required for the uptake of exogenous DNA into chromosomes (Lee S-H et al 2005 Proc Natl Acad Sci USA 102:18075). ▶ [Ty](#), ▶ [T-DNA](#), ▶ [DNase hypersensitive sites](#), ▶ [MLV](#), ▶ [HIV](#), ▶ [transposons](#), ▶ [RIP](#), ▶ [MIP](#), ▶ [methylation of DNA](#), ▶ [transformation](#), ▶ [SET motif](#), ▶ [histones](#), ▶ [non-homologous end-joining](#); Müller K et al 2001 J Biol Chem 276:14271.

Integration: In mathematics, this is the finding of a function of which the integrand is a derivative or finding an equation among finite variables that is the equivalent of the differential equation integrated. $F(x) = \int f(x)dx$ and $\frac{dF(x)}{dx} = f(x)$. ▶ [derivative](#)

Integration Host Factor: ▶ [IHF](#)

Integration Plasmid: This has homologous sequences to the chromosome and after transformation, by recombination, it may be inserted in multiple copies into the yeast chromosome. Linearization of the plasmid may increase its efficiency of integration 10–1000 fold.

Integrative Circuits in Signal Transduction: Multiple kinases initiate a common response. ▶ [signal transduction](#)

Integrative Physiology: This monitors the total function of organs in a non-invasive manner.

Integrative Suppression: Refers to the elimination of the manifestation of a genetic defect by insertion of a normal copy of the gene. (See Brasch MA, Meyer RJ 1988 Mol Gen Genet 215:139).

Integrator: This is a 12 subunit attachment to RNA polymerase II. Two of the subunits are similar to the RNA transcript cleavage and polyadenylation factor complex. The integrator is recruited to the U1 and U2 small nuclear RNA genes and mediates the processing of the 3' end of snRNA and interacts with the C terminal domain of the polymerase. (See Baillat D et al 2005 Cell 123:265).

Integrator Gene: A hypothetical regulator and coordinator of eukaryotic genes. (See Wadgaonkar R et al 1999 J Biol Chem 274:1879).

Integrins (ITG): These are a part of the heterodimeric family of integral membrane proteins that stretch out to the intercellular space and form the extracellular matrix. In connection with fibronectin, other ligands and ICAM integrins control cell adhesion and cell shape, the development of *Drosophila* halteres, legs and wings, signaling, intracellular Ca^{2+} , inositol and lipid metabolism (see Fig. 140). Leukocytes contain a variety of integrins that are involved in inflammatory and immune responses. Integrins have α and β

Figure I40. The integrin-mediated signal transduction pathway. (For symbols see individual entries, Arachid. A = arachidonic acid) After Clark EA and Burggie JS 1995 Science 268:233

subunits that are translated separately and their association is not by covalent linkage. Some of the integrin α and β subunit genes have been assigned to human chromosome 2, whereas β -7 integrin appears to be in chromosome 12. The α -6 integrin forms 991-residue extracellular, 23-amino transmembrane and a 36-amino acid intracellular domain. Integrin is associated in the cells with a 59K-serine/threonine protein kinase, containing four ankyrin-like repeats. This integrin-linked kinase (ILK) possibly regulates integrin-mediated signal transduction. Integrins, by binding to ligands, may control substratum adhesiveness and therefore cell migration (see Fig. I41). Integrins integrate the extracellular signal systems with the cytoskeleton. Focal adhesion complexes, containing β 1 integrin, talin, actin and vinculin, are formed upon activation by the extracellular matrix.

The integrin-mediated signal transduction pathway is shown in the Fig. I41. This complex is attached to the cytoskeleton and localized signal transducing molecules. Pre-existing mRNAs are targeted to cytoskeletal micro-compartments where integrin controls their translation in the vicinity of the signal receptor sites. Integrins appear to be involved in fertilization by binding fertilin molecules. They are involved in the control of the cell cycle and apoptosis. In the absence of integrins β 3 or β 3/ β 5 or selectins mice are susceptible to enhanced tumor growth (Taverna D et al 2004 Proc Natl Acad Sci USA 101:763). They signal to the RAS

and the ERK systems. \blacktriangleright fibronectin, \blacktriangleright cadherin, \blacktriangleright talin, \blacktriangleright CAM, \blacktriangleright SOS, \blacktriangleright ICAM, \blacktriangleright FAK, \blacktriangleright Src, \blacktriangleright Grb2, \blacktriangleright RAS, \blacktriangleright MAPK, \blacktriangleright ERK1, \blacktriangleright GAP, \blacktriangleright cPLA₂, \blacktriangleright ankyrin, \blacktriangleright signal transduction, \blacktriangleright angiogenesis, \blacktriangleright epidermolysis, \blacktriangleright lipoxygenase, \blacktriangleright atresia, \blacktriangleright cell migration, \blacktriangleright CD98, \blacktriangleright calreticulin, \blacktriangleright talin, \blacktriangleright actin, \blacktriangleright vinculin, \blacktriangleright caveolin, \blacktriangleright myopathy, \blacktriangleright metastasis, \blacktriangleright fertilin, \blacktriangleright T cell receptor, \blacktriangleright invasin; Clegg DO 2000 Mol Cell Biol Res Comm 3:1; Calderwood DA et al 2000 J Biol Chem 275:22607; Hynes RO 2002 Cell 110:673; structure: Xiao T et al 2004 Nature [Lond] 432:59; <http://www.geocities.com/CapeCanaveral/9629>.

Integron: This is a mobile DNA element, a transposon with a cassette, flanked by a 5' and a 3' conserved sequence. The internal cassette can accommodate antibiotic resistance genes by site-specific recombinase (integrase, *intI*) located in the 5' element and a closely linked *attI* (attachment) site. It contains several rightward (P2, P2, P4 and P5) and one leftward (P3) promoter sites and a ribosome-binding site. The 3' element includes a conserved sulfonamide resistance gene. Sulfonamide resistance stems from a lack of sensitivity of dihydropteroate synthase to sulfonamide inhibition. Its origin, however, is unclear since sulfonamides are synthetic antibiotics. Dihydropteroate is a precursor of folic acid. The integron is the vehicle of antibiotic resistance genes among various types of bacteria. Integrases bear 43–58% homology to similar sequences of bacteriophages. Super-integrations carry several cassettes and can accommodate multiple antibiotic resistance genes and therefore make fighting disease very difficult. Integrations are an important means of generating genomic diversity in prokaryotes. Determining the crystal structure of integrons has revealed that DNA target site recognition and synaptic assembly do not depend on the canonical DNA sequence rather two flipped-out bases interact in *cis* and *trans* with the integrase (MacDonald D et al 2006 Nature [Lond] 440:1157). \blacktriangleright gene cassette, \blacktriangleright integrase, \blacktriangleright folic acid, \blacktriangleright transposon, \blacktriangleright R plasmid, \blacktriangleright shoufflons, \blacktriangleright pathogenicity island; Rowe-Magnus DA et al 2001 Proc Natl Acad Sci USA 98:652; Gillings MR et al 2005 Proc Natl Acad Sci USA 102:4419.

Integument: Refers to the maternal somatic tissue layers that surround the ovule of plants and give rise to the seed coat. Thus, the integument may show delayed inheritance. ▶ [megagametophyte development](#), ▶ [delayed inheritance](#)

Inteins: These are elements that are inserted into proteins before the completion of its sequence and removed thereafter; they are protein-splicing elements. They are spliced out post-translationally by autocatalytic proteolysis and ligation. The intein system can be used for genetic engineering. Part of a herbicide resistance gene-intein fusion was transformed into the nucleus and the other part of the same gene, equipped with a carboxy-terminal intein, was introduced into the chloroplast genome. The nuclearly encoded herbicide protein-intein fragment migrates to the chloroplasts and reconstitutes the full length herbicide resistance. Since the chloroplast located fragment is not transmitted by out-pollination to plants in the environment there is no effective spread of herbicide resistance (Chin HG et al 2003 Proc Natl Acad Sci USA 100:4510). Some inteins are site-specific endonucleases. They may also function as transposons and insert their coding sequences into intein-less genes. Inteins have different structures and are found in prokaryotes, algal chloroplasts and other lower eukaryotes. Inteins may provide evidence of horizontal transmission of nucleotide tracts during evolution. ▶ [intron](#), ▶ [transmission](#), ▶ [extein](#), ▶ [herbicides](#), ▶ [semi-synthesis](#), ▶ [protein engineering](#), ▶ [homing endonucleases](#); Paulus H 2000 Annu Rev Biochem 69:447; Liu X-Q 2000 Annu Rev Genet 34:61; Gogarten JP et al 2002 Annu Rev Microbiol 56:263; Perler FB et al 1994 Nucleic Acids Res 22:1125; Evans TC et al 2005 Annu Rev Plant Biol 56:375; <http://www.neb.com/neb/inteins.html>.

Intelligence Quotient (IQ): ▶ [human intelligence](#)

Intelligent Design: This theory of organic evolution does not accept either Darwinism or creationism in its entirety and postulates that the evolution/development of the complexity of biochemical structures requires an intelligent design. Genetics can deal only with experimental facts that can be tested with scientific procedures without subjective assumptions or faith. ▶ [evolution](#), ▶ [Darwinism](#), ▶ [creationism](#), ▶ [scopes trial](#)

Intensifier: Refers to an animal or plant gene that intensifies (darkens) color.

Interaction, Molecular: Such interaction generally requires physical contacts between/among the components such as hydrogen bonding and van der Waals forces. There is another type of interaction, interaction without direct contact, governed by linkage

thermodynamics. Macromolecules and biopolymers share a common milieu within the cell conformations. The equilibria are also modulated by the solute solvent interactions. The response of hemoglobin to CO₂ changes the blood pH is one example of through-solution communication. It demonstrates a response in one type of tissue to a metabolic state in another through the shared solution. Such mechanisms seem to play a significant role in cellular regulation. ▶ [ligands](#), ▶ [hydrogen bond](#), ▶ [van der Waals forces](#); Völker J, Breslauer KJ 2005 Annu Rev Biophys Biomol Struct 34:21.

Interaction Trap: This procedure is basically similar to the two-hybrid method where the interaction of two or more molecules permits a biological or physical observation. ▶ [two-hybrid method](#); Toby GG, Golemis EA 2001 Methods 24:201.

Interaction Variance: This is due to epistasis between quantitative traits and the effect of the environment on gene expression. ▶ [analysis of variance](#), ▶ [epistasis](#)

Interactome: Refers to the system in the proteome where proteins interact and cooperatively determine function(s). Using binary protein-protein interactions, mainly yeast, two-hybrid system large-scale interactions can be developed. These interactions of thousand of genes can shed light on interacting proteins in the human genome, including genes responsible for disease. ▶ [proteome](#), ▶ [protein interactions](#), ▶ [gene product interaction](#), ▶ [protein complexes](#), ▶ [genetic networks](#), ▶ [gateway cloning](#), ▶ [protein-nucleic acid interactions](#), ▶ [ORFeome](#), ▶ [E-map](#); Ito T et al 2001 Proc Natl Acad Sci USA 98:4569; Ge H et al 2001 Nature Genet 29:482; Rual J-F et al 2005 Nature [Lond] 437:1173, atlas of yeast interactome: Collins SR et al 2007 Mol Cell Proteomics 6:439; <http://dip.doe-mbi.ucla.edu/>; protein, nucleic acids interactions: <http://biozon.org/>; human interactome: <http://www.mdc-berlin.de/unihi>.

Interactor: In the evolutionary context, this is an individual(s) who interacts with the biotic and abiotic environment and through the interaction his trait(s) imparts reproductive success and the hereditary material is transmitted to the progeny.

Interallelic Complementation: ▶ [allelic complementation](#)

Interband Region: In polytenic chromosomes the relatively lighter stained space between the characteristic darkly stained bands is known as the interband region (see Fig. 142).

Figure I42. Band and interband regions

Interbreeding: Refers to a process where individuals of different genotypes in a population may mate.

►random mating, ►mating systems

Intercalating Mutagens (such as acridines and some nitrogen mustards): These can insert within nucleotide sequences and cause frameshift mutations, short insertions and deletions. Intercalation also leads to the separation of the base pairs, lengthening and untwisting of the double helix. ►acridine dye, ►nitrogen mustards, ►frameshift mutation

Intercellular: Denotes located between cells. ►intra-cellular

Intercellular Immunization: The antibody production is ectopic and their secretion depends on cells other than lymphocytes. The expression of the immunoglobulin genes can be directed to specific cells by employing cell type specific promoters and enhancers in transformation. Such manipulations may block the expression of genes by the antibodies and may reveal the consequences for their function, for development or disorder and possibly for therapy targeted with high specificity. Besides the transgenic approach, grafting specific cells on to an appropriate tissue may be employed. ►ectopic, ►lymphocytes, ►immunization, ►neuroantibody, ►ablation, ►genetic engineering, ►intracellular immunization

Intercept: ►correlation [in a linear regression $a = Y - bx$].

Interchange: This refers to the reciprocal translocation of chromosomes. ►translocations

Interchange Trisomic: ►trisomic tertiary, ►trisomic analysis

Interchromosomal Interactions: Interferon gamma (IFN- γ , 12q14) defines the development T_h1 helper cells and interleukin-4 (IL4, 5q31) defines the development of T_h2 helper cells, which play different roles in the immune system. The locus control region of the T_h2 gene coordinately regulates the cytokine genes *Il4*, *Il5* and *Il13* although these sites are spread over 120 kb region within the same chromosome (intrachromosomal interaction). These elements are closely juxtaposed in the conformational state of the chromatin. In the nucleus each chromosome has its own particular territory, in the mouse the IFN- γ gene in chromosome 10 and the regulatory cytokine region of the T_h2 gene in chromosome 11 also interact despite being in different chromosomes. Such interchromosomal interactions may have general significance for the development of disease.

►interferon, ►interleukin, ►looping of DNA; Spilianakis CG et al 2005 Nature [Lond] 435:637.

Interchromosome Domain Compartment: The space between chromosome territories may be the area of transcription and RNA processing. ►chromosome territory

Intercistronic Region: Refers to the number of nucleotides between the end of one gene and the beginning of the next one. ►cistron

Intercross: Refers to mating between individuals (siblings) of the same parentage.

Interest: This is the rate to be paid for the use of funds.

Interest = (total amount of funds \times interest rate \times years)/100. Compound interest is the total amount of interest due on both the principal investment and the accumulated interest over time. For example: at 5% interest in 20 years \$100 investment will increase in value to $(1.05)^{20} \times 100 = \265.33 . The interest rate is normally compounded monthly or quarterly and more elaborate formulae are used for precise calculations.

In case money is borrowed it is necessary to know the cost. For this purpose a very simple constant ratio formula is: $i = \frac{2mI}{P(n+1)}$ where m = number of payment periods within one year, I = the discharge rate, P = principal amount, n = the total number of payment periods. If \$100 is borrowed and is supposed to be repaid in 12 equal monthly payments at a charge of 6% discount, the effective interest rate is: $i = \frac{2 \times 12 \times 6}{94(12+1)} = \frac{144}{1222} = 0.1178$, i.e., ~11.8%. Financial institutions use a more accurate formula leading to a slightly different outcome.

Interfacial Enzymology: The enzymes act on substrates located on a surface and hence their activity is regulated by the concentration of the substrate on the surface. Such enzymes may be found within or on cellular membranes.

Interference, Bacterial: One strain excludes the others from infection or colonization sites. The interference is usually mediated by the inhibition of the synthesis of virulence factors or surface receptors. ►RNA interference

Interference, Chromatid: ►chromatid interference

Interference, Chromosome: One crossing over may either reduce (positive interference) or increase (negative interference) the occurrence of additional ones. The availability of complete nucleotide sequences of the chromosomes permits a detailed analysis of the molecular basis of the phenomenon. Interference may proceed along one or two pathways according to the organisms. In yeast, the *MSH4* mutations (involved in mismatch repair) eliminate interference although they reduce crossing over by

only 50–70%. The *MSH4* homolog *HIM-14* in *Caenorhabditis* completely prevents crossing over. In the case of humans, there is statistical evidence for the two-pathway model which has implications for the precision of genotyping (Housworth EA, Stahl FW 2003 *Am J Hum Genet* 73:188). ▶coincidence, ▶coefficient of coincidence, ▶mapping function, ▶chromatid interference, ▶mismatch repair; Zhao H et al 1995 *Genetics* 139:1045; Browman KW, Weber JL 2000 *Am J Hum Genet* 66:1911; Tapper WJ et al 2002 *Ann Hum Genet* 66:75.

Interference, Dominant: The interference changes a transcriptional activator into a repressor. ▶activator protein, ▶repressor

Interference, Negative: ▶coincidence

Interference RNA: ▶RNAi, ▶RNA interference

Interferon: Refers to specific cellular glycoproteins that develop after a viral infection or as a reaction to RNA or other compounds, and they show antiviral activity and possibly anti-tumor activity. Double-stranded RNA (dsRNA) and siRNA can activate interferon genes in mammals through the dsRNA-dependent protein kinase (PKR) and through the Jak-STAT signal transduction route (Sledz CA, Williams BR 2004 *Biochem Soc Trans* 32:952). When associated with all-trans retinoic acid IFN is particularly effective in inhibition, including cancer cell growth inhibition. Interferons have three major forms, IFN- α , - β and - γ . Interferons can be produced following transformation in a variety of cells (yeast, silkworm, mouse, hamster, etc.). Interferons produced by leukocytes contain predominantly the α type. Lymphoblastoid cells (lymphocytes stimulated by an antigen) have 90% α and 10% β interferons. Induced fibroblasts mostly contain the β chain. The γ interferon is produced by antigen- or mitogen-stimulated T lymphocytes. Interferon-induced protein genes have been traced to human chromosomes 21, 10, 4, and 1. Interferons may interfere with protein synthesis by causing phosphorylation of eukaryotic peptide chain initiation factor eIF-2.

Interferon α (leukocytic interferon, IFNA1) genes (up to 30) have been located in human chromosome 9p21-p13. One of these genes, activated by the double-stranded viral replication intermediate, is 2'-5'-oligoadenylate synthetase, which in turn activates the latent ribonuclease L. RNase L degrades single-stranded RNA, the viral genome. Another induced enzyme is the dsRNA-activated protein kinase R (PKR). PKR may mediate apoptosis and may assist in establishing persistent infections by several viruses. An *interferon α receptor* (antiviral protein, AVP) has been assigned to human chromosome 21q22. Translocations of the INFA have been identified in leukemia patients. It has been claimed that intranasal

use of interferon α may prevent common cold. Natural IFN-producing cells (dendritic cell precursors) that express CD4 and major histocompatibility class II synthesize IFNA.

Interferon β -1 (fibroblast interferon/IFB1, human chromosome 9p21-pter) is structurally homologous to α interferon. In patients suffering from acute monocytic leukemia, translocations of IFB1 to chromosome 21 were observed and the break point was within this gene at about 17-cM from the site of the ETS-2 oncogene (chromosome 21q22.1-q22.3). Chromosome 9 contains several interferon genes. *Interferon β -2* (IFNB2 (human chromosome 7p21-p15) is induced by the tumor necrosis factor (TNF) and interleukin (IL-1) when interferon β -1 (IFNB1) is not induced. It is identical to the B-cell differentiation factor (BSF2) and hybridoma growth factor. Interferon β -3 (IFNB3) is in human chromosome 8.

Interferon γ (IFNG, human chromosome 12q14) induces the expression of HLA class II genes. The induction is modulated by a factor in human chromosome 16 (probably a receptor) and by another factor in chromosome 21 that may control the transduction of the γ interferon signal. In RAG (recombination activating) cells a human chromosome 6 factor is also required in human-rodent cell hybrids. IFNG induces the production of a 98-residue polypeptide (IP-10, chromosome 4q21) and other activating polypeptides. Hereditary interferon γ receptor deficiency increases the susceptibility to mycobacteria and *Salmonella* infections. The interferon regulatory factor (IRF) family includes the interferon consensus sequence binding protein (ICSBP, expressed constitutively in B lymphocytes) and other transcription factors (IRFs). Their N-terminal region binds to the DNA (IFN-stimulated responsive element, ISRE) and the C-terminal contains the regulatory sequences. ▶lymphokines, ▶leukemia, ▶interferon response element, ▶B cell, ▶hybridoma, ▶modulation, ▶signal transduction, ▶receptor protein, ▶IRF, ▶interleukin, ▶CD4, ▶MHC, ▶dendrocyte, ▶mycobacterium, ▶allergy, ▶PKR, ▶Jak-STAT, ▶granulocyte, ▶killer cell, ▶RNAi; Stark G R et al 1998 *Annu Rev Biochem* 67:227; Taniguchi T, Takaoka A 2001 *Nature Rev Mol Cell Biol* 2:378; Sen GC 2001 *Annu Rev Microbiol* 55:255; interferons in virus-host relationship: Garcia-Sastre A, Biron CA 2006 *Science* 312:879.

Interferon Receptors: IFN α and β share the same 63.5-kDa receptor. The IFN γ , IFN β and IFN receptors are located in the same cluster (21q-q22.1). The IFN γ receptor binds the ligand at the 245-amino acid extracellular domain whereas the 222-amino acid intracellular domain is involved in signal transduction. ▶interferon, ▶interferon regulatory factors, ▶signal transduction Jak-STAT

Interferon Regulatory Factors (IRF): These bind to the upstream regions of both α and β interferon genes and serve as a transcription activator (IRF-1) or (IRF-2) have an antagonistic effect. There are several additional IRFs. IRF1 binds to two regulatory elements (PRDI and II) in the IFN β gene's promoter. These elements respond to Jun and NK- κ B, which bind to the nearby PRDII and IV. They compete for the same cis element. Both factors have been assigned to human chromosome 5q23-q31. The IRF-2 protein is identical to HiNF. The IRF-E DNA-binding site has the consensus G(A)AAA(G/C)(T/C)GAAA(G/C)(T/C). Some IFRs (IURF-4, vIRF) are elevated in certain cancers. ►interferon, ►upstream, ►cis-acting element, ►leukemia, ►macrophage, ►cytokines, ►transcription factors, ►CCE, ►histones, ►HiNF, ►Jun, ►NK- κ B; Taniguchi T et al 2001 Annu Rev Immunol 19:623.

Interferon Sequence Response Element (ISRE): AGTTTCNNTTTCN[C/T]. ►GAS, ►signal transduction Jak-STAT, ►interferon, ►interferon receptors

Interferon-Induced Proteins: Located in different human chromosomes 1, 2, 4, 10, 12, 21. Interferon-inducible cytokine IP-10 (human chromosome 4q21) is located close to the break point associated with monocytic leukemia. (Monocytes are phagocytic mononuclear leukocytes that develop into macrophages in the lung and the liver). IP-10 has substantial homology to several activating peptides and it may control inflammatory responses. ►cytokines, ►leukemia, ►macrophage

Intergenic Complementation: This provides evidence that the two genes are not allelic but belong to separate loci. ►allelic complementation, ►allelism test

Intergenic Regions: These regions represent the bulk of the DNA, which contains in higher eukaryotes only a small percentage of coding sequences. Recent estimates have revealed that in *Drosophila* 15.6% of intergenic transcribed regions function as missed or alternative transcription start sites used by 11.4% of the expressed protein-coding genes. At least 85% of the fly genome is transcribed and processed into mature transcripts (Manak JR et al 2006 Nature Genet 38:1151). The distinction between genic and intergenic regions is becoming blurred because of overlapping transcripts and human genes frequently coalesce into larger genomic domains.

In yeast the histone deacetylase Rpd3, which exists in two forms, RpdC(S) and RpdC(L), are recruited to promoters to repress transcription. Chromatin immunoprecipitation indicates that the Eaf3 subunit of RpdC(S) is recruited to Histone3 lysine 36, which is methylated by a SET domain of RNA polymerase II

resulting in deacetylation. This process subsequently erases transcription elongation-associated acetylation and suppresses intragenic transcription initiation (Carrozza MJ et al 2005 Cell 123:581; Keogh M-C et al 2005 Cell 123:593).

The transcripts of non-coding intergenic sequences seem to play regulatory roles (Schmitt S et al 2005 Genes Dev 19:697). Alternative promoters specify some of the intergenic transcripts to tissues. Nearly half of the differences between humans and chimpanzees are due to intergenic transcription (Khaitovich P et al 2006 PLoS Genet 2(10):e171). A large fraction includes mobile elements with evolutionary significance. ►introns, ►SET domain, ►histone acetyltransferases, ►transposable elements, ►selfish DNA, ►ENCODE; Kondrashov AS, Shabalina SA 2002 Hum Mol Genet 11:669; Cliften P et al 2003 Science 300:71.

Intergenic Spacers (IGS): Sequences between rRNA genes, which have very short transcripts (appear like feathers) but may contribute to initiation of transcription (see Fig. 143). ►ITS, ►tRNA, ►pol III

Figure 143. Intergenic spacers. Image courtesy of Spring et al 1976 J Microsc Biol 25:107

Intergenic Suppressor: One mutation suppresses the expression of another situated in a different locus. The suppressor normally encodes a mutant tRNA. ►suppression

Intergenic Transcript: This contains sequences from two separate genes. The mRNA of a large protein transcribed from 20 exons of chromosome 14 contains the intercalated 188 nucleotides exactly matching a part of chromosome 1. The chromosome 1 sequence has no reading frame and does not code for a protein from its transcript (except from the 188 base within chromosome 14 mRNA). ►gene fusion; Claverie JM 2005 Science 309:1529.

Interkinesis: ►interphase

Interleukins: Proteins secreted by white blood cells, phagocytes, B lymphocytes and are involved in stimulating growth and differentiation of lymphocytes concerned with the natural defense system of the body. ►lymphokines, ►IL-1, ►IL-2, ►IL-3, ►IL-4, ►IL-16, etc.; <http://www.gene.ucl.ac.uk/nomenclature/genefamily/interleukins.html>.

Interlocking Bivalents: When another chromosome passes through the terminalizing chiasmata (ring

bivalents), the non-homologous chromosomes may be trapped (interlocked) within the ring (see Fig. I44).
 ▶ring bivalent Rasmussen; SW 1976 Chromosoma 54:245.

Figure I44. Interlocking bivalent

Interlogs: Refers to the potential interactions of protein based interactome models. ▶interactome, ▶protein interactions

Intermediary Metabolism: In this process, enzymes within the cells produce energy from nutrients and use it to synthesize other compounds or organize cellular components.

"5,0,1,0,105pt,105pt,0,0">Intermediate Filaments: These are ubiquitous 10 nm protein filaments abundant in eukaryotic cells and are encoded by at least 50 genes. They are composed of keratin, desmin, vimentin, neurofilament proteins, glial fibrillary acidic protein (GFAP), lamin, etc. Their anomalies may result in epidermolysis, keratosis and possibly other skin diseases. ▶filament, ▶keratin, ▶keratosis, ▶epidermolysis, ▶desmosome, ▶vimentin, ▶lamins, ▶skin diseases; Kreplak LK, Fudge D 2007 Bioassays 29:26; human intermediate filament database: <http://www.interfil.org/>.

Intermedin: A melanocyte stimulating protein factor.
 ▶melanocyte

Internal Control Regions (ICR): ▶A box

Internal Image Antibody: An anti-idiotypic antibody which binds to the antigen binding site of the complementarity determining region of an antibody rather than to the antigen. ▶anti-idiotypic antibody, ▶immunoglobulin, ▶antibody, ▶complementarity-determining region, ▶antigen

Internal Membrane: Refers to membranes within the cell excluding the plasma membrane.

Internal Promoter: ▶promoter

Internal Transcribed Spacers: ▶ITS, ▶ETS, ▶tRNA

Internalins: These are proteins mediating the bacterial uptake by eukaryotic cells. The internalization requires co-factors such as cadherin, catenin, actin, PI-3 kinase and the reorganization of the cytoskeleton. ▶cytoskeleton, ▶phosphoinositides, ▶cadherin, ▶catenin, ▶actin; Schubert WD et al 2001 J Mol Biol 312:7387.

Internally Eliminated Sequences (IES): During the formation of the macronuclei of *Ciliates* chromosome diminution and fragmentation occurs. The DNA deleted involves repetitive sequences but the IES are not a part of the repetitive sequences, and may even include functional genes. There is a variation in the location and sequences of the IES in different related species. ▶chromosome diminution, ▶Paramecia, ▶Ascaris, ▶macronucleus; Garnier O et al 2004 Mol Cell Biol 24:7370; Huvos PE 2007 J Eukaryot Microbiol 54:73.

International Prognostic Index (IPI): Marks an attempt by the European Society for Medical Oncology to predict the risk/survival of some cancers under standard conditions of treatment. (See Lopez-Guillermo A et al 1994 J Clin Oncol 12:1343).

International Protein Index (IPI): This is an integrated database for proteomics. ▶proteomics; Kersey PJ et al 2004 Proteomics 4:1985; <http://www.ebi.ac.uk/IPI>.

Internet: Refers to a complex system of interconnected electronic communication networks.

Internet2: This is a consortium of more than 200 universities in partnership with industry and government for advanced telecommunications. ▶ABILENE, ▶BIRN; <http://www.internet2.edu/>.

Internode: Refers to a segment of a plant stem between nodes (leaves) (see Fig. I45).

Figure I45. Internode

Interlogs: These are conserved protein-protein interactions facilitating the identification of protein networks. ▶genetic networks; Matthews RL et al 2001 Genomes Res 11:2120.

Interoperability: Refers to different computer programs through which computers can communicate with each other.

Iterons: Denotes the initiator binding sites of the replication origin. ▶iDNA

Interorganismal Genetics: ▶Flor's model

Interphase: This refers to the phase of the cell cycle when mitosis is not in progress. During the interphase between mitoses the cells are actively synthesizing DNA (S phase) and during the G phases other molecules are produced and the cellular organelles are dividing (see Fig. I46). In meiotic divisions the DNA synthesis is limited to repair and all DNA is

produced during the interphase preceding meiosis. According to the traditional view, during interphase the chromosomes are more relaxed and stretched. A high-resolution multicolor FISH banding analysis of human chromosome 5 indicates that in both lymphocytic and HeLa cells the length of interphase chromosomes is about the same as in the metaphase although they display bending and folding (Lemke J et al 2002 Am J Hum Genet 71:1051). Recent data attribute the increased length observed by classical microtechniques to an artifact caused by the fixatives and staining. ►cell cycle, ►mitosis, ►meiosis, ►FISH

Figure I46. Interphase

Interpolation, Linear: See the procedure described under ►*F₂ linkage estimation*

Interpro: This is a database of protein families, domains and functional sites in which identifiable features found in known proteins can be applied to unknown protein sequences. <http://www.ebi.ac.uk/interpro/>.

Interracial Human Hybrids: The genetic distance based on gene frequencies is relatively short ►*evolutionary distance*. among the various human races and despite the theoretical expectation of the deleterious effects of breaking up co-adapted genetic sequences, interracial hybrids suffer no physical harm. Problems may arise, however, in cultural adaptation because the hybrids are normally classified socially with the minority race (whatever the majority is) and discrimination against minorities is not uncommon in all racial, ethnic and cultural groups. Despite the great similarities of the genetic structure of all primates, no hybrids between humans and other primates have been verified. Somatic cells of all types of eukaryotes—including those of humans—can, however, be hybridized but cannot be regenerated into hybrid organisms. ►human races, ►somatic cell hybrids

Interrogation, Genetic: This is an in depth study of the function of a gene or a group of genes.

Interrupted Mating: Bacterial conjugation is halted at definite intervals (by stirring the culture) in order to determine the order of gene transfer and establish the map position on the basis of minutes required for the transfer of a particular gene(s) from the donor to the recipient. The interruption stops the transfer. ►conjugation mapping

Intersectin: An endocytosis protein. ►endocytosis

Intersex: The true intersex types have both male and female gonads which is a very rare condition. More common types are those who have either female or male gonads and chromosomal constitution but they express, to varying degrees, the secondary sexual characteristics normally unexpected for their chromosomal constitution. The intersex phenotype is determined by autosomal genes and in species where the sex chromosome:autosome ratio determines sexuality, the aneuploids appear as intersex types. In *Drosophila* the *tra* (*transformer*, chromosome 3–45) homozygotes of XX chromosomal constitution are sterile males. The *tra2* (chromosome 2–70) mutation in XX background has similar effects as *tra*; in XY background the males look normal and behave in a normal manner yet their sperm is not motile. The *dsx* (*doublesex*, 3–48.1) locus has numerous alleles. The homozygotes for their null alleles (in either XX or XY background) and the heterozygotes for the dominant alleles (in XX background only) are intersexes. The *ix* gene (*intersex*, 2–60.5) makes females intersex with reduced male and irregular female external genitalia. The *ix/ix* males appear to be normal but they are mostly homosexual and the *ix/+* heterozygotes court females and young males but not adult males. The *tra* and *dsx* genes regulate sex expression by alternative splicing of the RNA transcript involved in normal sexuality. In some insects, like the Gypsy moth (*Lymantria dispar*) the sex-determining genes have “strong” and “weak” alleles in some populations and the crosses regularly yield intersex individuals. The crosses between head lice (*Pediculus capitis*) and body lice (*P. vestimenti*) produce intersexes in *F₂* and *F₃*. Further, 98 to 96% of angiosperm plants are hermaphroditic and among 2 to 4% dioecious species intersexes occur, depending on the number of each of the sex chromosomes they carry. In *Melandrium*, for instance, the XXY and XXXY males produce occasionally intersex flowers but the XXXXY individuals are hermaphroditic. ►hermaphroditism, ►pseudo-hermaphroditism, ►sex determination, ►introns, ►gynandromorphs, ►homosexuality, ►relative sexuality, ►gonads, ►anti-Müllerian hormone, ►*Lymantria* for photo, Vaiman D, Pailhoux E 2000 Trends Genet 16:488.

Interspersed Repetitious DNA: Describes nearly 35% of the human genome, including various types of active or inactive transposable elements. ►SINE, ►LINE, ►redundancy

Inter-SS PCR: ►cancer

Interstitial Segment: Refers to the chromosomal region between the centromere and the translocation break point. ► [translocation](#)

$$\text{ELOD} = \left(\frac{1 - 2\theta}{1 - \theta} \right) \frac{n}{2} \log \left(\frac{1}{1 - p} \right)$$

Interval Mapping: Considers pairs of adjacent markers and maximizing the likelihood of quantitatively expressed gene loci (QTL) being in between. ELOD is the expected lod score, θ = recombination fraction, p = the proportion of variance contributed by QTL, n = sample size. The calculation may be difficult under practical conditions because there may be more than one QTL per linkage group. An interval mapping based on the least squares method may be better. ► [QTL](#), ► [lod score](#), ► [least squares](#), ► [ASP analysis](#); Ott J 2001 *Advances Genet* 42:125.

Intervarietal Substitution: This is basically similar to alien substitution except the chromosomes belong to different varieties of the same species. ► [alien substitution](#)

Intervening Sequence (IVS): ► [intron](#)

Intimate Pairing (synapsis): Refers to the very close apposition of the chromosomes at the meiotic prophase that makes possible crossing over (gene conversion) and recombination. ► [recombination mechanisms eukaryotes](#), ► [recombination molecular mechanisms prokaryotes](#), ► [recombination models](#), ► [synapsis](#)

Intimin: An enterobacterial protein that mediates the attachment of the bacterium to the epithelial cells of the intestine and causes erosion facilitating the transport of proteins and intestinal inflammation as a consequence of the infection.

Intine: Refers to the inner layer of the wall of the pollen grain.

Intrabody: An antibody expressed by intracellular immunization in the target cells. ► [intracellular immunization](#), ► [gene therapy](#), ► [tumor vaccination](#); Duff RJ et al 2000 *Methods Enzymol* 313:297. ► [inradiabody](#)

Intracellular: This means located within a cell(s).

Intracellular Clock: The differentiation of particular cells into a particular type of tissue during embryonal development is controlled by the timing of the signal received for differentiation. For example, an animal epithelium excised at the gastrula stage grafted on to the eye disc of an embryo may differentiate into a neural tube but if the same tissue is grafted on to the same position a few hours later it may differentiate into an eye lens.

Intracellular Immunization: This involves the targeting of the antibody to a specific cellular compartment. This can be accomplished by signal peptide sequences specific for, say, the endoplasmic reticulum, mitochondria, the cell nucleus, cytoplasm in general, specific membranes, etc. The function of proteins at the target sites may be modulated leading to alteration of susceptibility to viral infection and replication, modifying cells' surface receptors, altering light receptors, affecting mitosis, etc. ► [differentiation](#), ► [biotechnology](#), ► [intrabody](#), Chames P, Baty D 2000 *FEMS Microbiol Lett* 189:1.

Intrachromosomal Gene Locus Association: ► [inter-chromosomal interaction](#)

Intrachromosomal Recombination: May be responsible for deletions and duplications. ► [sister chromatid exchange](#), ► [transposition](#), ► [ectopic recombination](#), ► [recombination intrachromosomal](#)

Intraclass Correlation: A form of analysis of variance used for the estimation of heritability on the basis of variances between and within classes, e.g., in the progeny of a larger number of different males mated to a smaller number of females, each of which has several offspring (see Table 15). Thus, the degree of variance within the litter of a male mated (sired) to the same female (within "sires") can be compared to the variance among the total offspring of individual males mated to different females (between "sires"). The intraclass correlation of the sires is 1/4 of the heritability for the trait considered because each male contributes half of the genetic material to the offspring quantitatively analyzed, and these again contribute only half of their chromosomes through their haploid sperm. The procedure of calculation is illustrated by the hypothetical example given here.

ANALYSIS OF VARIANCE

| | df | SS | MS |
|--------------------------|----|------|-------|
| Between Males (SS_S) | 3 | 6.5 | 2.17 |
| Within Males (SS_P) | 20 | 21.5 | 1.075 |

$\hat{\sigma}^2_S = \frac{MSS - MSP}{n_i} = \frac{2.17 - 1.075}{6} = 0.1825$ (the male's variance component) $\hat{\sigma}^2_P = MSP = 1.075$ (the progeny variance component)

The Males Intraclass Correlation (r_1), $\hat{\sigma}^2_S / (\hat{\sigma}^2_S + \hat{\sigma}^2_P)$ is equal to 1/4 of the heritability, hence $h^2 = 4\hat{\sigma}^2_S / (\hat{\sigma}^2_S + \hat{\sigma}^2_P) = 4[0.1825 / (0.1825 + 1.075)] = 0.58$.

► [correlation](#), ► [heritability](#), ► [variance](#), ► [variance analysis](#). (Heritability is denoted by h^2 for historical reasons but it is not the second power of an entity). (See Hill WG, Nicholas FW 1974 *Biometrics* 30[3]:447).

Table 15. Procedure for calculating heritability based on intraclass correlation. The mean scores of the offspring are represented in the body of the table. (Y stands for individual or group measurements)

| Mean Square (MS) is SS/df | | | | | | | | |

(The lower index S stands for "sires"; the lower index P is for progenies)

Intracytoplasmic Sperm Injection: ►ICSI

Intradiabody: This is an intrabody with dual specificity, i.e., targeting two receptors within a pathway such the VEGF receptor and the Tie-2 receptor, and it leads to increased anti-tumor effect (Jendreyko N et al 2005 Proc Natl Acad Sci USA 102:829). ►intrabody, ►VEGF

Intrafallopian Transfer: This transfer of gametes (GIFT) or zygotes (ZIFT) is involved in infertility treatment procedures whereby the spermatozoa and the mature oocytes or in vitro generated zygotes, respectively are surgically inserted into the fallopian tube of the female where fertilization and/or segmentation may proceed. These procedures have a higher rate of success for conception than in vitro fertilization but they often lead to twinning if more than a single egg or zygote is used. ►ART, ►in vitro fertilization, ►TET, ►PROST; Klonoff-Cohen H et al 2001 Fertil Steril 76:675.

Intragenic Recombination: This is rare because alleles of a locus are very close to each other. Intragenic reciprocal recombination is expected to yield wild type and double mutant recombinants that can be verified only if flanking non-allelic markers are available. These outside markers — ideally — should not be more than 5–10 map units at both sides of the locus. The mutant alleles are m^1 , m^2 and m^3 , respectively, p, t and an are outside markers. The + sign indicates non-mutant (see Fig. 147). The following crosses are required to determine the linear order of the m alleles in a simple case:

Among the recombinants, the m phenotype indicates double recessive alleles in the same strand whereas the m^+ phenotype is an indication of recombination between two recessive alleles present in the heterozygous parent, which is testcrossed. According to these results the order of the mutant alleles and the markers must be $p - \underline{m^3} - m^1 - m^2 - t - a$ and none of the recombinant classes are supposed to be contaminants because the markers are consistent with the recombination events suggested. The double

| Test crosses | Reciprocal recombinant phenotypes |
|--|-----------------------------------|
| $\frac{p m^1 t^+ a}{p^+ m^2 t a^+} \times \frac{p m t a}{p m t a}$ | $p m t a^+$ and $p^+ m^+ t^+ a$ |
| $\frac{p^+ m^2 t a^+}{p^+ m^3 t^+ a} \times \frac{p m t a}{p m t a}$ | $p^+ m^+ t^+ a$ and $p m t a^+$ |
| $\frac{p m^1 t^+ a}{p^+ m^3 t a^+} \times \frac{p m t a}{p m t a}$ | $p m^+ t a^+$ and $p^+ m t^+ a$ |

Figure 147. Intragenic recombination test

mutant recombinants may be further tested by recombination to yield the two mutant classes. Intragenic recombination is a rare event (~ 0.02 to 0.000001 or less), close to the range of mutation frequency. Intragenic recombination is more likely to preserve protein function than random mutation (Drummond DA et al 2005 Proc Natl Acad Sci USA 102:5380). (See Whittinghill M 1950 Science 111:377).

Intragenic Suppressor: ▶suppressor gene

Intrasteric Regulation: The internal sequences of protein, resembling substrate tracts (pseudosubstrate) act directly at the active site in contrast to the allosteric effects when the allosteric molecule bears no similarity to the substrate and attaches to the protein at a site different from the active site. Intrasteric control is a means of autoregulation. ▶allosteric control, ▶autoregulation; Kobe B et al 1997 Adv Second Messenger Phosphoprotein Res 31:29.

Intrauterine Fertilization (IUI): In this process the sperm is deposited directly into the uterus, bypassing the cervix (the anterior part of the uterus, which may form a barrier to the passage of the sperm). This type of medical intervention may be undertaken to treat infertility in humans. ▶ART

Intravasation: Refers to the entrance of an extraneous substance into the blood vessels. Metalloproteinases, receptor urokinase plasminogen activator (uPA) and their inhibitors may affect the process. Metastasis of cancer cells may depend on intravasation. ▶extravasation, ▶metastasis, ▶metalloproteinases, ▶urokinase

Intrinsic: This adjective defines the basic, essential attribute of a phenomenon. ▶extrinsic

Intrinsic Disorder: Proteins have multiple conformations. They may play a regulatory role by optimizing allosteric couplings with different ligands (Hilser VJ, Thompson EB 2007 Proc Natl Acad Sci USA 104:8311). ▶allostery

Intrinsic Rate of Natural Increase: ▶age-specific birth and death rates

Intrinsic Terminators: These terminators of transcription in prokaryotes do not require co-factors (are rho-independent) for the termination of transcription. ▶transcription termination in prokaryotes

Introgression: Refers to the transfer of genes from one group of species to another. The two populations may inhabit the same area (sympatric) or they may have only occasional contact because of being in different areas (allopatric). After the initial crossing the mating continues largely within the group and therefore only a few of the “borrowed” genes are maintained. *Marker-assisted introgression* uses molecular tools to monitor the transfer/presence of the desired genetic regions, especially for quantitative trait loci. In human populations mitochondrial DNA analysis and Y chromosomal haplotyping are especially useful for tracing the ethnic origins. ▶QTL, ▶marker-assisted selection, ▶speciation, ▶co-evolution; Anderson E 1949 Introgressive Hybridization, Wiley, New York, Saetre GP et al 2001 Mol Ecol 10:737.

Introgressive Hybridization: This accomplishes introgression. ▶introgression

Intron Homing (retrohoming): Refers to the process of insertion of an intron at a particular site within an intron-less cognate sequence. Accordingly, some introns of yeast mitochondria serve as mobile genetic elements besides performing a ribozyme function. The homing introns, mitochondrial or nuclear, are endonucleases with similarities to restriction enzymes but their recognition sequence is much longer. Intron homing may utilize either (i) the double-strand-break repair pathway common in genetic recombination and yielding reciprocal crossover and non-crossover products, or (ii) a synthesis-dependent strand annealing process that does not produce flanking crossing over. ▶introns, ▶ribozyme, ▶homing endonuclease, ▶mtDNA; Mohr G et al 2000 Genes, Development 14:559; Belfort M et al 2002 in Mobile DNA II, ASM Press, Washington, DC p. 761.

Intron Retention: Refers to a failure of splicing out an intron. ▶introns, ▶splicing, ▶alternative splicing

Intron Sliding: This is an alternative type of splicing used by cryptic splice sites generally caused by the presence of SINE elements. ▶splicing, ▶alternative splicing, ▶SINE, ▶introns; Rogozin IB et al 2000 Trends Genet 16(10):430.

Intron Slippage (intron sliding): The position of introns (intron—exon boundary) may vary among homologous genes of evolutionarily related species by one or a dozen or more nucleotides. ▶ [introns](#), ▶ [alternative splicing](#); Wistow GJ, Piatigorsky J 1990 Gene 96:263.

Intronless Paralog: These are genes inserted into the genome by retrotransposition of processed mRNA. ▶ [retrotransposon](#), ▶ [processed gene](#); Schimenti JC 1999 Mamm Genome 10(10):969.

Introns: These are nucleotide sequences within a gene that are not represented in the mature mRNA transcripts of that gene (intervening sequences, IV). Introns are transcribed but not translated into protein that would be part of the products of the exon-coded genes or will not be included into the final RNA encoded by the gene. Introns separate the coding sequences of the exons (see Fig. 148). Introns are seen in the majority of the eukaryotic genes, including genes of mitochondria and chloroplasts and also in viruses of eukaryotes but they are exceptional in prokaryotic genes. In land plant plastid DNA ca. 20 introns are present and their size varies from 400 to over 1000 bp. The average size of an intron in mice is around $1,800 \pm 300$ and in humans about $3,000 \pm 550$. In the X chromosome the intron size is substantially longer. In imprinted genes the intron number, and particularly its size, is smaller. The RNA maturases in mammals are actually intron sequences within protein genes and assist the splicing of the pre-mRNA transcripts. In algae the cpDNA introns are quite variable in number and size; in *Euglena* 149 introns have been detected. In the red alga *Porphyra* no introns in the cpDNA have been observed. In *Chlamydomonas* the insertion site of an intron

corresponds to an *E. coli* rRNA domain. Introns may appear as latecomers to the eukaryotic organelle genes since in multiple evolutionary lines they are non-homologous either by sequence or location. However, the thymidylate synthetase gene of T4 bacteriophage has an intron, and the archaeobacterial tRNA^{Leu} as well as the large ribosomal subunit genes have introns. One of the largest introns (64-kb) has been found in the human thyroglobulin gene which is involved in the regulation of energy metabolism and in the various forms of goiter. The overall profile of a gene can be represented as: 5'- Enhancer-promoter - transcription initiation site - leader - exon ♦ **intron** ♦ exon-termination signal - 3'.

The origin of introns is unclear. Some arguments favor their ancient evolutionary presence, preceding the divergence of eukaryotes from prokaryotes (Fedorov A et al 2003 Genome Res 13:2236). Some introns may be located at critical regions of the gene, dividing it into functional domains or separating α -helices from β -sheets. It has been suggested that increased replication rate is inversely proportional to the number of introns. Indeed, introns are rare in prokaryotes and fewer in yeast.

Introns may regulate genes controlling complex developmental pathways (Juneau K et al 2006 Genetics 174:511). The large homeotic genes of *Drosophila* seem to contain more introns than other simple genes. The greater density of introns within genes may be promoted by sexual reproduction that enables them to propagate in a selfish manner through gametes of both parents. Introns can protect against the deleterious consequences of recombination because if this occurs within introns rather than within exons, no harm can be caused to the coding capacity. Recombination frequency is negatively

Figure 148. (Photomicrograph is by Batosin, L., Laub, O. Horouritz, M. & Y. Aloni. Courtesy of Professor Aloni.)

correlated with intron length. Introns can also protect against illegitimate recombination by interrupting homologous tracts at random sites. Although these problems have not yet been resolved, the mechanics of transactions concerning introns has made substantial progress.

The number of introns varies greatly (Llopart A et al 2002 Proc Natl Acad Sci USA 99:8121). Some genes, e.g., the histone, human α and β interferon genes have no introns, whereas the γ interferon gene has several. The large (~2-Mbp) human dystrophin gene contains over 60 introns. (Dystrophin is a muscle protein, deficient in muscular dystrophy). The average size of an intron generally varies between 75 and 2,000 bp but some introns are several times as long or no more than about a dozen nucleotides. There are no introns in the 5S, 5.8S, U RNA, 7SL and 7SK RNA genes. In organisms with compact genomes like *Drosophila* and budding yeast the number of introns is usually small but fission yeast contains a large number. Introns comprise nearly 24% of the human genome. The average number of introns/gene in humans is about 7. Interestingly, the mitochondrial genes of budding yeast have relatively more introns than the nuclear genes.

Introns are removed from the primary transcripts of the genes during processing. The removal of introns is essential for the expression of genes. Group II introns have six domains; domain 1 (D1) and D5 are essential for splicing. Thus, the mRNA becomes shorter than the primary transcript. When the mRNA is hybridized to the genomic coding strand of DNA, the latter reveals loops at those positions in the mRNA from where the introns were removed. The chicken ovalbumin gene contains seven introns and loops corresponding to their location and length can be detected by electron microscopy (see map

by Dugaiczky et al Stadler Symp. 11:57, and interpretative drawing by Rédei, 1982). Alternative mRNAs can be obtained from the same DNA sequence by controlling the length, number or pattern of exons used, depending on (i) the site of initiation of transcription, or (ii) the alternative sites of polyadenylation signals, or (iii) the selective retention of particular exons in the mRNA. By using these mechanisms the products of single genes can be diversified during development or differentiation. Alternative splicing may be accomplished by using more than a single promoter, resulting in alternative long or short transcripts, depending on the site of transcription initiation. Alternative polyadenylation signals, at more than a single location downstream, may truncate the transcript at the 3' end. An example of mechanism (see Fig. 149) (i), alternative promoters the exons are bracketed, introns are in bold numbers and parenthesis. Alternative splicing occurs in various eukaryotic genes and various viruses of eukaryotes. In the small genomes of the latter systems a single transcript may permit the production of several proteins. In the determination of correct splicing both cis- and transacting proteins cooperate. When the introns are removed the exons are *spliced* together and the continuity of the mRNA is restored. There are two splice sites, the *upstream donor site* and the *downstream acceptor site*. When the invariant bases (shown in bold numbers in the example) are altered, splicing generally fails. Other neighboring bases may also affect the efficiency of splicing. In animal nuclear genes, an A residue in the vicinity of the splice site is required but its position does not have to be absolutely fixed relative to the splice site. In yeast, there is an absolute requirement for a conserved UACUAAC tract within 6 to 59 nucleotides upstream from the 3' splice signal. Some

Figure I50. Lariat formation

genes have more than one splice site pairs which facilitate alternative splicing and the assembly of different mRNAs. Although originally introns were regarded as junk DNA, it is now known that some introns are translated but have independent functions from the exons; some have a role in the processing of the transcript shared by the neighboring exons whereas others perform regulatory functions (see Figs. I50 and I51).

On the basis of structural information about the splice sites, some special introns have been classified into group I and group II (see Table I6). The principal characteristics of group I introns are (i) their splicing does not always require a protein enzyme, rather (ii) a short internal sequence facilitates their folding and splicing that is initiated by (iii) an extraneous guanosine or a phosphorylated form of it (see Fig. I52).

Group II introns do not have conserved internal sequences yet they are capable of foldback pairing and the splicing requires an intrinsic signal rather than an extraneous guanine. The spliced group II introns form a *lariat* (similar to that of a tethering rope), the 5' P end forms a phosphodiester bond with the 2'-OH group of a nucleotide within the chain at some distance. The loop itself may have three nucleotides (GpApA).

The splicing of group I introns requires *transesterification* (phosphodiester linkage ex-changes). Transesterification takes place without severing the bonds first. The self-splicing is mediated by ribozymes, RNAs that have enzyme-like catalytic functions.

Ribozymes facilitate the formation of the proper configuration of the RNA transcript and may function like endonucleases. The aI2 ribonucleoprotein of the *COX1* yeast mitochondrial gene catalyzes the cleavage of the DNA target, recognized by complementarity of the sequences within the intron RNA. After cleaving the DNA the aI2 protein reverse transcribes the intron RNA using the 3' end of the DNA as a primer. The aI2 RNA cleaves the sense strand of the DNA whereas the aI2 protein cuts the antisense strand and the latter also boosts the activity of the aI2 ribozyme. The intron assumes a complex secondary

Figure I51. Self-splicing steps. Self-splicing of a group I intron (1) a guanosine (or guanylic acid) conducts a nucleophilic attack against a phosphate group near the point of juncture, and transesterification follows later at both 5' and 3' junctions. this is accompanied by the recognition of internal sequences ↓↓↓ that guide the folding. (2) exon termini in bold and the ends of the intron is in outline letters. (3) spliced exon and intron are displayed

² Yeast mitochondrial genes for cytochrome oxidase and cytochrome b

Figure I52. The U1 and U2 snRNAs facilitate the proper configuration of the folding of the transcript and thus identify the correct splicing sites. The A-2'OH nucleotide leads the nucleophilic attack, which is followed by transesterification and ligation of the exon

structure by base pairing of some complementary sequences separated by non-pairing tracts. The extraneous guanosine launches a nucleophilic attack (an electron-rich molecule reacts with an electron poor one that is willing to accept electrons) at the exon-intron boundaries resulting in a nucleotide chain breakage at the site and an exclusion of the intron. Not all group I introns are able to self-splice without the help of *maturase* proteins encoded by introns within some yeast mitochondrial genes. The self-splicing of group II introns is somewhat similar to that of group I. In group II there is no involvement

of guanine. The 2'-OH group of an adenine within the intron initiates the nucleophilic attack. After appropriate folding to bring the 5' and 3' junctures in proximity to each other, the exon is spliced by transesterification and the intron is released as a lariat. The primary RNA transcript of nuclear pre-mRNAs is capped. Cleavage takes place at the 5' end of the intron upstream of a ↓pGU pair as indicated by the arrow. The free 3' end of the intron forms a lariat with an internal A residue and then the intron with the lariat is released and the 3' end of the first exon is ligated to the 5' end of the next exon. The outcome is

the same as discussed earlier. The splicing of the nuclear pre-mRNAs requires, however, a more complex machinery involving spliceosomes.

The spliceosomes are assembled from short U-rich RNAs, ranging in size from 65 (U7) to 217 (U3) nucleotides and a set of different proteins. The most common U RNAs in the mammalian nucleus are U1, U2, U4 and U6. The U3 RNA is involved in RNA processing in the nucleolus. The U7 RNA assists in the formation of the 3' end of the histone mRNAs that have no introns. The corresponding U RNAs are highly homologous even among taxonomically different organisms such as humans and dinoflagellates. The homologous U RNAs among vertebrates are almost identical (ca. 95% similarity). The spliceosomes contain a common set of seven proteins (generally designated by capital letters [B, A', etc.] or by molecular weight [e.g., 59K, 25K]) and may also contain a few specific proteins. About 1% or less of the introns uses AU and AC (rather than the more common GU and AG) as terminal nucleotides. In plants (crucifers) especially AU-AA introns may occur. Some of these introns also use the U12 snRNA for processing. The intron-encoded U22 small nucleolar RNA facilitates the processing of the 18S ribosomal RNA in *Xenopus* oocytes. The U1 snRNA specifically binds to the 5' splice site of the intron and protects this region from RNase attack but it does not cleave at the splice site. The U2 snRNA complex performs the same function near the 3' end of the intron around the adenosine residue whose 2'-OH is involved in the formation of the lariat. The spliceosomes are ellipsoid complexes (about $25 \times 50\text{-}\mu\text{m}$ in size) that actually bring together the splicing sites to make the *cut and paste* process possible. These bindings generally require some degree of complementarity but that is not complete. Besides these two spliceosomes, others (U2, U4, U6) and a number of binding proteins may be involved in facilitating and stabilizing the binding.

The position of *introns* in *tRNA* genes is located next to the third (3') base of the anticodon triplet, with a single base in between. Yeast has about 40

nuclear-coded tRNAs and 10% of them have a single intron containing between 14 and 46 bases. This regular location is somewhat enigmatic because tRNA^{Tyr} genes of yeast with deleted intron sequences are still transcribed, processed normally and function. In the primary transcript, the intron has a triplet that is complementary to the anticodon. For correct splicing, the various loops and arms of the tRNA cloverleaf are important. The first step in splicing of tRNA transcripts is a cleavage by an endonuclease at the ends of the intron. In yeast the 5' terminus of the exon is then represented by an OH group and the 3' terminus by a 2',3'-cyclic phosphate. The cyclic phosphodiesterase then breaks the ring and generates a 3'-OH and a 2'-O-(PO₃) terminus. The 5'-OH end is phosphorylated by a kinase, requiring ATP. Thus, the termini are ready for joining by an *RNA ligase* enzyme. Essentially similar reactions are observed in splicing nuclear tRNAs in mammals and plants.

The splicing mechanisms shown and discussed earlier involve splicing exons within the same primary RNA transcripts. In some instances exons originally located in different transcripts, even in different chromosomes, may be spliced by *transsplicing* (see Fig. 153). Transsplicing can generate.

mRNAs from leader sequences remote to the exons. Transsplicing is common in the protozoa, *Trypanosomes* where different exons can be joined to a single 35-bp leader sequence. (The exons are scattered among approximately 100 chromosomes). The 3' end of the leader and the 5' end of the coding exons can be joined. Since the 5' end of the intron carries the generally conserved 5'-GU sequence, the remote other intron, preceding the remotely transcribed coding exon, terminates at 3' with the conserved AG bases and also has an adenosine nucleophile somewhere in the vicinity of its 5' terminus. The two originally remote introns can be brought together by a 5' to 2' bond as a branched molecule, and subsequently both introns are eliminated and the leader is joined to the coding exon as outlined in the Fig. 153. Transsplicing also occurs in other eukaryotes, e.g., in the nematode *Caenorhabditis*

Figure 153. Transsplicing

elegans and in the chloroplast genes of plants. The open reading frames of class II introns have sequences reminding to reverse transcriptases of the type of retroposons. There is no evidence, however, that these would function as reverse transcriptases. Introns and spliceosome sites show evolutionary variations and are suitable for tracing phylogenetic relationships (Roy SW, Gilbert W 2006 *Nature Rev Genet* 7:211). The map position of introns in animals, plants and fungi shows considerable alignment and indicates that the ancestral introns predate the evolutionary divergence of these taxonomic categories (Fedorov A et al 2002 *Proc Natl Acad Sci USA* 99:16128). Among 10,020 intron positions in human–mouse comparisons, five cases of intron loss were detected in the mouse evolutionary lineage but not in humans; moreover no gain was observed in either lineage (Roy SW et al 2003 *Proc Natl Acad Sci USA* 100:7158). Intron loss is attributed to recombination of reverse transcriptase products of spliced mRNA, processed genes (Roy SW, Gilbert W 2005 *Proc Natl Acad Sci USA* 102: 713). In seven diverse eukaryotic groups intron loss varied from $\sim 2 \times 10^{-9}$ to 2×10^{-10} per year during evolution and the rates of gain were between 6×10^{-13} and 4×10^{-12} . These figures indicate that the early ancestors of eukaryotes were intron-rich rather than introns being of more recent origin because the gain was much less frequent than the loss (Roy SW, Gilbert W 2005 *Proc Natl Acad Sci USA* 102:5773). Single introns in the majority of species tend toward the 5' end; *Arabidopsis* is an exception (Sakurai A et al 2002 *Gene* 300:89). Group II introns can be targeted for insertion into a ~ 14 -nucleotide region of target DNA of prokaryotes. Introns inserted in the antisense orientation cannot splice and disrupt the gene. Introns inserted in the sense orientation may serve for selective regulation of gene expression when linked to inducible promoters.

A comparison with the orthologous regions in the mouse and the chimpanzee reveals that human introns with the most similar boundaries are younger. Human introns are alternatively spliced with exceptionally high frequency. Genomic duplication has been an important mode of intron gain in mammals. The alternative splicing of transcripts containing these intron-breeding repeats may provide the plasticity required for the rapid evolution of new human proteins (Zhuo D et al 2007 *Proc Natl Acad Sci USA* 104:882).

Introns Group I: These self-splicing introns in some ribosomal genes use mechanisms different from the pre-mRNA or the majority of tRNA genes. ►introns for characterization, ►mitochondrial genetics for introns as mobile elements and plasmids, ►spliceosomal introns, structure: Adams PL et al 2004 *Nature [Lond]* 430:45.

Introns Group II: These introns are large ribozymes in a few mitochondrial, chloroplast, fungal and bacterial genes and differ in structure and splicing mechanisms from the common introns (Type I) of eukaryotes. Mobile group II introns are retroelements with reverse transcriptase activity. They are also self-splicing and are capable of intron homing. Group II introns can cause insertional mutations. Both group I and group II introns require deadbox proteins as RNA chaperones (Huang H-R et al 2005 *Proc Natl Acad Sci USA* 102:163). ►introns, ►intron homing, ►mitochondrial genetics, ►spliceosomal introns, ►deadbox proteins, ►chaperone, ►intron group III, Lambowitz AM, Zimmerly S 2004 *Annu Rev Genet* 38:1.

Introns Group III (twintron): These are relatively short, group III introns inserted within the boundary of group II introns in the cpDNA of *Euglena*. Some bacteria also have twintrons in intergenic regions. ►ctDNA

Intussusception: Refers to the insertion of interstitial tissue into the lumen of existing vessels.

Inulin (fructan): This denotes one of the many types of polymers of (~ 30 –40) fructose units in plants (see Fig. 154).

Invader: This refers to a molecular procedure for DNA and RNA quantification. It is suitable for highly sensitive discrimination between mutant and wild type forms and SNPs. The modified invader assay is suitable for the detection of microRNA precursor and microRNA in unfractionated detergent lysate using fluorescence analysis on microtiter plates (Allawi HT et al 2004 *RNA* 10:1153). (See Kwiatkowski RW et al 1999 *Mol Diagn* 4:353; Olivier M et al *Nucleic Acids Res* 30[12] e53)

Figure I54. Inulin

Invagination: Refers to folding inward (see Fig. I55).

Figure I55. Invagination

Invariance: This is the reciprocal value of the variance.
▶variance

Invasin: This is the integrin-binding protein of *Yersinia* bacteria assisting infection. ▶integrins, ▶*Yersinia*

Invasion of DNA Strands: ▶branch migration, ▶Holliday model

Invasive: Refers to the penetration of cells commonly leading to their destruction. Can also indicate migration of cancer cells. ▶metastasis, ▶RAGE

Invasive Growth: Yeast cells do not stay on the surface of the culture medium but penetrate it in search of nutrients.

Inverse PCR: ▶inverse polymerase chain reaction

Inverse Polymerase Chain Reaction: This process can be used for molecular analysis of flanking regions of a target (see Figs. I56 and I57).

Figure I56. Restriction fragment including flanks and target

Figure I57. Head to tail association of the flanks in inverse polymerase chain

The fragment shown here is circularized by its cohesive ends and cut with a restriction enzyme within the target. As a consequence a head-to-tail association of the flanks is produced:

This head-to-tail sequence of the flanks is amplified by PCR for nucleotide sequencing. The two flanks may be separated if an appropriate restriction endonuclease site is known at or near their boundary.
▶PCR, ▶target, ▶tail-PCR, ▶capture PCR [CPCR]

Inversion: A chromosomal segment is turned around by 180°(•); centromere (see Fig. I58).

Such chromosomal rearrangements require two breaks, both of them in one chromosome arm in the case of *paracentric inversions*, and one in each arm across the centromere in the case of *pericentric inversions*. Pericentric inversion may alter the arm ratio of the affected chromosome as discussed earlier. Within a single chromosome there may be more than one inversion. These multiple inversions may be independent or may be overlapping or a shorter inversion may be included within a longer one.

If the chromosomes are well suited for cytological analysis, the various types can be identified using a light microscope (see Fig. I59).

Inversions as such may not have much phenotypic consequence, unless they cause “position effect”, influence the expression of the gene because they interrupt either the coding or the non-translated regulatory sequences. These effects may be serious in the relatively rare inversion homozygotes. During

Thus if the **NORMAL ARRANGEMENT** of the genes is: A B C D E • F G H
after **PARACENTRIC INVERSION** the order becomes: A D C B E • F G H
after **PERICENTRIC INVERSION** the sequence is: A B G F • E D C H

Figure I58. Paracentric and pericentric inversion

Figure I59. Two-strand paracentric inversion heterozygote displays double chromatid bridge and two chromatid fragments because of the chromatid tie keeps the crossover chromatids in the middle of the cell, they fail to be incorporated into the egg and thus prevent female sterility. (Courtesy of A.H. Sparrow)

the early years of genetics, inversions were thought to be “C factors”, crossing over inhibitors. Inversions inhibit crossing over in inversion heterozygotes only in the vicinity of the breakage points where the rearrangement prevents intimate pairing of the chromatids. Crossovers are not observed primarily because the strands involved in recombination are usually not transmitted through the paracentric inversion females thus they do not produce defective gametes (see Fig. I60). The consequences for the sperms are not the same for paracentric inversion heterozygotes because the microspore tetrad is not linear and the crossover chromatids are not tied by the inversion-bridge in such a way that they would not be included in any microspore. Therefore in males all four products of meiosis could potentially be transmitted, however 50% of the gametes are still defective. In pericentric inversion heterozygotes duplication-deficiency gametes are formed (without a bridge) in both females and males if crossing over takes place within the inverted segments during meiosis. Thus, crossing over may occur but the crossover gametes or zygotes may not be viable. In animals the consequence of duplication-deficiencies may be different from that in plants. In plants the defective gametes are usually prevented from fertilization because of inviability, whereas in animals the defective sperm may be capable of fertilization but the offspring resulting from such a mating may not survive. The cytological consequences of crossing over within inverted chromosome segments are diagrammed and shown by a photomicrograph. Crossing over within pericentric inversions has the same

genetic consequence as that seen in paracentric inversions, namely 50% of the gametes formed by meiocytes, which have suffered recombination are duplication-deficient. In other words, some of the genes are present in the same strand twice and others are entirely absent, and are therefore generally inviable. Inviability may be gametic or zygotic. In the gametophytes of plants the former is seen whereas in animals the latter is prevalent. Crossing over in pericentric inversion heterozygotes cytologically differs from that in paracentric inversions (see Fig. I61).

In the former, dicentric chromosomes and acentric fragments are not generated by recombination. Double crossing over within the same inverted paracentric segment, involving two homologous chromatids does not produce defective gametes (see Fig. I62). Three-strand double crossing overs yield both acentric fragments and dicentric chromosomes besides the two parental ones. Four-strand double crossing over results in the formation of two acentric fragments and two dicentric chromosomes and generally all gametes become defective. Paracentric inversions may play an important role in speciation because they may cause hybrid male sterility and hence partial sexual isolation. W.S. Stone has estimated that during the evolution of approximately 2,000 species of *Drosophila*, about 350 million paracentric inversions might have occurred, and from these tens of thousands have been permanently fixed, and the fate of another similar number is still undecided. Pericentric inversion may also play a role in speciation because of the complete sexual isolation, and the preservation of the inverted segment as supergenes, refractory to recombination. The descendance of inverted chromosomes in natural populations can be determined on the basis of banded chromosomes or restriction fragment patterns (RFLP). It was found that in *Drosophila subobscura* populations global climate warming increased the frequency of inversions (Balayá J et al 2006 Science 313:1773).

The frequency of inversions in human populations is less than 1% per birth. The actual rate of occurrence may be much higher because many of the afflicted fetuses are spontaneously aborted. Inversions have been added to various mutation tester strains of *Drosophila* so that new mutations could be identified within a particular chromosome without confounding the results by recombination because inversions eliminate the crossovers. Short inverted nucleotide repeats are found at the termini of insertion/transposable elements. Inverted duplication of nucleotide sequences form palindromes and facilitate the formation of double-stranded sequences in single-stranded nucleic acid chains and have determining

Figure 160. Consequences of recombination. Paracentric inversion heterozygotes produce 50% defective gametes when crossing over takes place within the inverted chromosomal segment. since the frequency of crossing over depends on the length of the segment inverted frequency of the defective gametes varies from 0 to 50%. At the top, an inverted and a normal chromosome are shown. such chromosomes can pair only if the inverted strands form a loop and thus gene-by-gene alignment becomes possible. The configuration of one inverted and one normal strand is shown on the second line at left. in the center of that line the pairing and crossing over (\rightleftharpoons) are diagrammed. As a result of recombination, one of the crossover strands becomes dicentric and deficient for marker (*D*) and duplicated for marker (*A/a*). The other crossover strand becomes acentric and deficient for *A/a* and duplicated for *D/d*. At meiotic anaphase I, the crossing over results in a chromatid bridge because the chromatids are tied together even when anaphase separation proceeds. The tie may either hold together the crossover chromatids and they cannot reach either pole, rather they remain in the middle of the metaphase plane or if the tie breaks, depending on the site of the breakage, additional duplication and simultaneous deficiency may occur. In animals and plants, after recombination of paracentric inversion heterozygotes only a viable (normal or inverted) chromosome enters the egg and thus female sterility is usually not observed. In males (where polarity does not occur during gametogenesis), if recombination takes place within the inversion, 25% of the gametes contain only normal chromosomes, 25% carry inverted chromosomes containing complete chromatin. In the remaining 50% duplication-deficiency or deficiency of the genes is observed, and such gametes are generally sterile or result in embryo lethality. Recombination in pericentric inversion heterozygotes does not result in dicentric bridge but half of both male and female gametes may become defective.

roles in conformation of the molecules, such as in tRNAs. Evidence obtained from *Drosophila buzzatii* indicated that inversions may arise by recombination either within the target site duplications or between two copies of the *hobo* transposable element. Chromosomal (DNA) inversions would be expected to produce “retro-proteins” with an altered three-dimensional structure. The stability of these

retro-proteins may or may not differ from the natural sequence and may or may not affect the function of the proteins. In case a *foldback-like* transposon *Kepler* is inserted at inversion break points in *Drosophila buzzatii* it leads to a substantial reduction in gene expression supposedly due to the antisense RNA effect (Puig M et al 2004 Proc Natl Acad Sci USA 101:913).

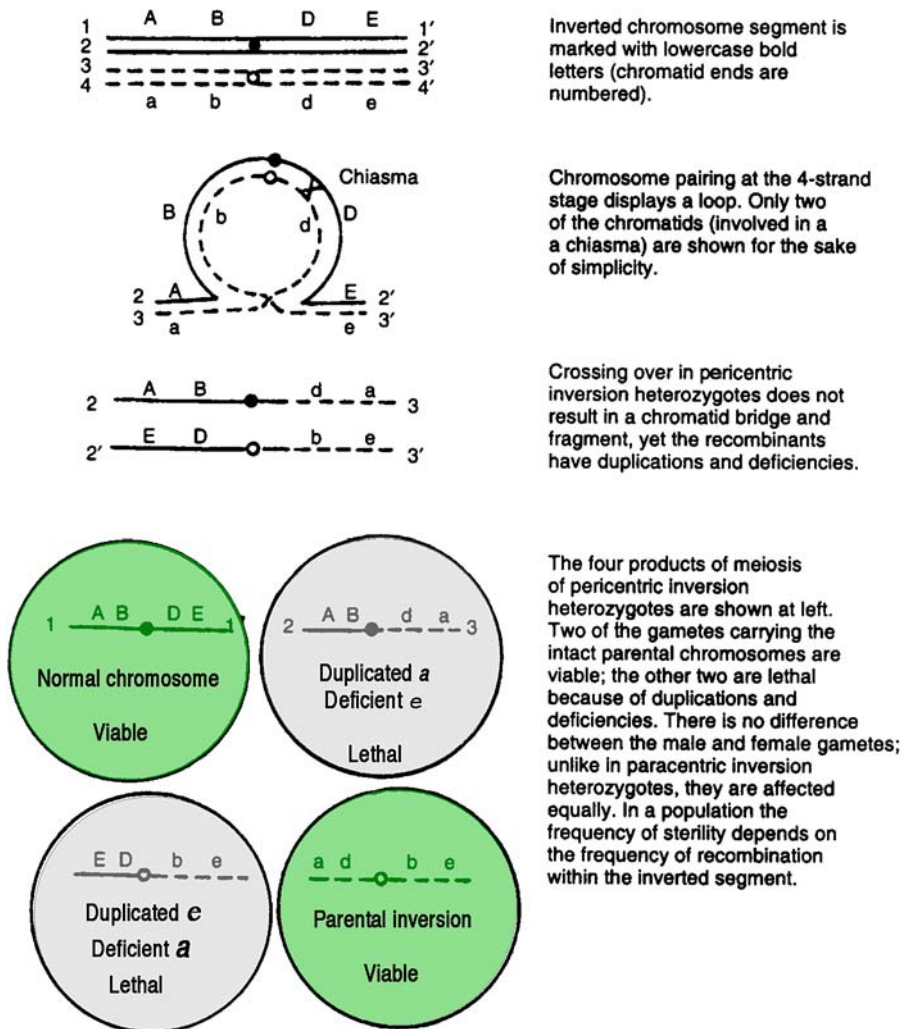

Figure I61. Pericentric inversion heterozygotes and crossing over

A 900 bp inversion in human chromosome 17q121.31 displays two main variations, H1 and H2. The H2 variant is very rare in Africa or East Asia but its frequency in Europe is 20%. In the Icelandic population it undergoes positive selection because both female and male carriers have more children than non-carriers and the recombination frequency is higher in females (Stefansson H et al 2005 Nature Genet 37:129). ▶recessive lethal tests in *Drosophila*, ▶speciation, ▶mutation chromosomal, ▶unbalanced chromosomal constitution, ▶palindrome, ▶conformation, ▶hybrid dysgenesis, ▶antisense RNA, ▶transposon; Ranz JM et al 2001 Genome Res 11:230.

Inversion Loop: ▶inversion

Inversion of Oligonucleotides: The linkages are 3'/5' or 5'/5' and have inverted polarity within the normal

nucleotide tract. They are extremely resistant to exonucleases and have a longer half-life than normal oligonucleotides yet they may not disturb the Watson-Crick structure. These may be used for oligonucleotide therapy.

Inversion, Paracentric: This involves only one arm of a chromosome. ▶inversion

Inversion, Pericentric: The inversion spans across the centromere. ▶inversion

Inversions in Phages and Bacteria: One group of enzymes is invertases (transposases) mediating inversions between the inverted terminal repeats of transposable elements. The other group comprises integrases. The inversion may affect an invertible promoter or the entire gene. The invertase of phage MU (*gin*) is positioned outside the invertible 3000-bp G region flanked by 34-bp inverted repeats. In one

Figure 162. Double crossing over within paracentric inversions. Only 2-strand double crossing over results in two complete chromosomes. Pericentric inversion heterozygotes do not yield dicentric strands yet the overall genetic consequences of double recombination are the same as in pericentric inversion heterozygotes

orientation the host specificity genes *Sv* and *U* (→) permit the attachment of *Mu* to *E. coli* and when inversion (←) takes place the phage can be adsorbed to other host bacteria. A similar system has been observed in the phase variation of *Salmonella*. ▶ *phase variation*, ▶ *transposase*, ▶ *resolvase*; Roth JR, Schmid MB 1981 Stadler Symp 13:53; Johnson RC 2002 In: Craig NL et al (eds) *Mobile DNA II*. Amer Soc. Microbiol. Press, Washington, DC pp 230.

Invertases: These are proteins (*Cin*, *Hin*, *Gin*) involved in viral transposition and bear extensive homology with the N-terminal domains of the resolvases of transposons. In biochemistry the enzyme sucrase which hydrolyzes sucrose to fructose and glucose is also called invertase. ▶ *Cin*, ▶ *Tn*, ▶ *resolvase*

Invertebrates: These are animals without a spinal column. ▶ *genome size*: <http://www.genomesize.com/statistics.php?stats=inverts>.

Inverted Repeat: ▶ *repeat inverted*, ▶ *direct repeat*

Invertrons: These are linear mobile elements in plasmids and mitochondrial DNA. It seems that

5'-linked proteins encode DNA and RNA replication and integration functions. ▶ *Agrobacterium*, ▶ *transformation genetic*, Hermanns J, Osiewacz H D 1992 *Curr Genet* 22(6)491.

Involucre: Refers to a whorl of bracts around an inflorescence. ▶ *bract*

Involution: Denotes a degenerative type of development that is marked by a return to a more primitive or inactive state.

Iodine Stain: For coloring starch (amylose) blue-black is used, while amylopectin (dextrin) is colored reddish-brown (iodine 120 mg and potassium iodide 400 mg in 100 mL water).

lojap(ij): Refers to nuclear mutations in maize located in chromosomes 3L-90 (*ij1*) and 1L (*ij2*), respectively, causing leaf striping because of defects in the development of plastids. The *ij* gene appears to be a specific mutator of extranuclear DNA and displays normal Mendelian inheritance whereas the striping itself is maternally transmitted. Defects in plastid RNA polymerase have been implicated in this

variegation. (See Silhavy D, Maliga P 1998 *Curr Genet* 33[5]340)

Ion: This is a positively (cation) or negatively (anion) charged atom or radical. ►[electrolyte](#)

Ion Channels: Refers to pores with special passage specificity, e.g., a membrane protein when bound to acetylcholine permits the influx of sodium (sodium channel); a variety of ion channels exist (mechanically gated, voltage-gated, ligand-gated, cAMP-gated, etc.). The ion channels may have two or more subunits like the staves of a barrel. The pores may be open or closed and different loops may be associated with them (see Figs. 163 and 164). The pore loop, which is a common component of many types of ion channels, determines which ion can penetrate the pore. The anion-gated ion channels appear to be structurally different from most of the cationic channels inasmuch as they may have different subunit associations creating double or triple pores. Cis–trans isomerization at a proline opens the pore of a neurotransmitter-gated ion channel (Lummis SCR et al 2005 *Nature [Lond]* 438:248). Thousands of different odors activate in the nose the trimeric G protein, G_{olf} , which in turn activates adenylate cyclase and the cAMP-gated cation channels open and transmit the signal to the brain. Some olfactory receptors utilize the IP_3 -gated ion channels. Cyclic guanosine monophosphate (cGMP)-gated channels mediate visual perception. Light rapidly induces the formation of guanylate cyclase, generating cGMP and it is degraded by cGMP phosphodiesterase. The photoreceptors (rhodopsin pigment) are in the retina of the eye. Voltage-gated Ca^{2+} ion channels regulate the influx of calcium through the plasma membrane. The mechanosensitive ion channels sense forces from the lipid bilayer without proteins (Kung C 2005 *Nature [Lond]* 436:647). Mechanical stimuli may affect Ca^{2+} and other ion channels. The L-type ion channels of the neurons may be shut off when the intracellular level of calcium increases beyond a point. The Ca^{2+} ions then serve as widespread intracellular messengers and regulate many diverse cellular functions, particularly the secretion of neurotransmitters. Their modulation is due to the $\beta\gamma$ subunits of the trimeric G protein. The glutamate receptors, permeable to Na^+ , K^+ , and Ca^{2+} , are gated by glutamate in eukaryotes and prokaryotes. The autosomal dominant human disease, *periodic paralysis*, appears to be caused by an amino acid substitution in the α subunit of a sodium channel transmembrane protein. Mutation in sodium channel SCN5A may slow down myocardial conduction and may lead to life-threatening cardiac arrhythmias. Cystic fibrosis is due to a defect in the transmembrane conductance regulator protein kinase A and

ATP-regulated chloride ion channel. In pancreatic β cells ATP-dependent K^+ channels are important for glucose-induced insulin secretion and are targets of sulfonylureas which is used for oral treatment of non-insulin-dependent diabetes (NIDDM). Truncation of the sulfonylurea receptor (SUR) causes persistent hyperinsulinemic hypoglycemia of infancy and unregulation of insulin secretion in severe hypoglycemia. Nearly 60 human diseases are channelopathies, i.e., diseases due to defects in ion channels. The human genome contains 340 putative ion channel genes. Over 400 genes in the human genome are involved with ion channels. Channels can be inward or outward rectifying, depending on the predominant direction of the flow of the ions. The rectification is not always an intrinsic property of the channel protein but may be controlled by accessory substances, spermidine, spermine and other polyamines. Glucocorticoid stress hormones may also regulate the K channels. Ion channels regulate the expression of many genes. ►[signal transduction](#), ►[SOC](#), ►[TRP](#), ►[G proteins](#), ►[neurotransmitters](#), ►[calmodulin](#), ►[rhodopsin](#), ►[periodic paralysis](#), ►[cystic fibrosis](#), ►[IP₃](#), ►[dihydropyridine receptor](#), ►[ryanodine](#), ►[diabetes](#), ►[hypoglycemia](#), ►[sulfonylurea](#), ►[pyrethrin](#), ►[LQT](#), ►[HERG](#), ►[Andersen syndrome](#), ►[Jervell and Lange-Nielson syndrome](#), ►[Ward-Romano syndrome](#), ►[myokymia](#), ►[periodic paralysis](#), ►[hyperkalemic periodic paralysis](#), ►[hypokalemia](#), ►[convulsions](#), ►[epilepsy](#), ►[migraine](#), ►[color blindness](#), ►[glucocorticoid](#), ►[Bartter syndrome](#), ►[ataxia](#), ►[myotonia](#), ►[paramyotonia](#), ►[hyperthermia](#), ►[salt-tolerance](#), ►[patch clamp](#); Doyle JL, Stubbs L 1998 *Trends Genet* 14:92; Apse MP et al 1999 *Science* 285:1256; Hübner CA, Jentsch TJ 2002 *Hum Mol Genet* 11:2435; K^+ channel structure: Jiang X et al 2003 *Nature [Lond]* 423:33, K^+ ion selectivity: Yu S et al 2004 *Nature [Lond]* 431: 830; review of diseases: Gargus JJ 2003 *Am J Hum Genet* 72:785; channelopathy mechanisms – channel functions:

Figure I64. Open and closed ion channels

Ion-Exchange Resins: These can be cation or anion exchangers, their cross linkage determines their use for the separation of molecules of different sizes. There is a variety of ion exchange resins; they are produced by the copolymerization of styrene and divinylbenzene and various other substances and are combined to produce phosphocelluloses, diethylaminoethyl-cellulose (DEAE), carboxymethylcellulose (CMC), etc. They can be used for the separation and purification of monovalent ions or polyelectrolytes of high molecular weight.

Ion Exchangers, Cell Membrane: ► [ion channels](#)

Ion Pumps: These mediate ion transport through membranes by the use of energy (ATP). They ensure osmotic balance and convert ATP energy into electrochemical gradients that are utilized by metabolic pathways. ► [proton pump](#), ► [ion channels](#), ► [uptake selective](#); Dunbar LA, Caplan MJ 2001 *J Biol Chem* 276:29617; Gouaux E, MacKinnon R 2005 *Science* 310:1461.

Ion Trap Mass Analyzer (IT): This is used in connection with mass spectrometry. It analyzes trapped and accumulated ions in high throughput equipment. IT is fast and sensitive but may not be very accurate. ► [linear ion trap](#), ► [mass spectrum](#), ► [proteomics](#)

Ionic Bond: Refers to a non-covalent attachment between a positively and a negatively charged atom.

Ionization: This is a process for the separation of molecules into ions. ► [ion](#)

Ionization Chamber: This equipment measures the radioactivity of gases by the ionizations generated through molecular collisions. Electrodes collect the ions and the current (amplified and registered) is

proportional to the radioactivity. ► [scintillation counter](#), ► [Geiger counter](#), ► [radiation measurement](#)

Ionizing Radiation: Refers to high energy electromagnetic radiation causing intramolecular alterations (ion pairs) in organic material, thereby capable of inducing mutation and cancerous transformation in living cells. Low energy (<2eV) radiation can also cause damage to the DNA and guanine residues absorb more electrons than the other bases, especially in single-stranded DNA (Ray SG et al 2005 *Proc Natl Acad Sci USA* 102:15).

The maximum legal permissible occupational limits for human exposure during a lifetime should not exceed 0.5 mSv per year; the legal limit actually should be 0.2 mSv. 1 Sv (Sievert) = 100 rem (röntgen equivalent man); 1 rem = 1 rad of 250 kVp X-rays.

► [radiation effects](#), ► [radiation measurement](#), ► [radiation hazard assessment](#), ► [cosmic radiation](#), ► [physical mutagens](#), ► [Gray units](#), ► [radiation protection](#), ► [electromagnetic radiation](#)

Ionophores: These hydrophobic molecules are involved in ion transport through cell membranes.

Ionotropic Receptors: These receptors mediate the control of ion channels after binding the appropriate ligand. Together with metabotropic receptors they play an important role in nerve synapses. ► [metabotropic receptor](#), ► [synapse](#)

IP₃ (inositol 1,4,5-trisphosphate): This is derived from inositol phospholipid PIP₂. In response to external signals it releases Ca²⁺ from the endoplasmic reticulum. IP₃R2 and IP₃R3 receptors mediate exocrine secretion, energy metabolism and animal growth (Futatsugi A et al 2005 *Science* 309:2232). ► [phosphoinositides](#), ► [InsP](#), ► [olfactogenetics](#), ► [exocrine](#), ► [Ipk1](#), ► [Ipk2](#), ► [BCL](#)

IP₅, IP₆: These are IP₃-derived signaling molecules; IP₆ along with other phosphoinositides and nuclear pore associated proteins are required for mRNA export from the nucleus. ► [RNA export](#), ► [InsP](#), ► [nuclear pore](#), ► [Ipk1](#), ► [Ipk2](#), ► [ADAR](#)

IPCR: ► [inverse polymerase chain reaction](#)

IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked): This is caused by mutation in the region of human chromosome Xp21-Xq13.3 and encodes the FOXP3 protein involved in the regulation of transcription or RNA splicing. ► [FKH](#), ► [autoimmune disease](#); Sakaguchi S 2004 *Annu Rev Immunol* 22:531.

IPI (integrated protein index): This is an inventory of all the revealed proteins encoded by a genome. ► [IGI](#)

Ipl1: Denotes a yeast mitotic histone kinase

Ipk1 (inositol polyphosphate kinase): This converts inositol-1,3,4,5,6-pentakisphosphate (IP₅) into hexakisphosphate (IP₆). IP₆ is probably a regulator mRNA export from the nucleus and it modulates the function of synaptic vesicles by interacting with synaptogamin. ►phosphoinositides, ►Ipk2, ►RNA export, ►synaptogamins

Ipk2 (inositol polyphosphate kinase): This converts inositol 1,4,5-trisphosphate (IP₃) into inositol-1,4,5,6-tetrakisphosphate (IP₄) and inositol-1,3,4,5,6-pentakisphosphate (IP₅). It is likely that Ipk2 is the same yeast enzyme that was earlier known as Arg82, a pleiotropic kinase regulating sporulation, mating, stress, arginine metabolism and transcription. IP₄ and IP₅ may be effectors for the processes. Ipk2p may also stabilize MCM1p that is probably required for Ipk2 function. ►phosphoinositides, ►Ipk1, ►MCM

IPMDH (isopropylmalate dehydrogenase): α -isopropylmalate is a precursor of leucine and it is derived from α -ketoisobutyrate.

Ipomoea (morning glory): This is an ornamental plant with a relatively short life cycle (4 months); it has many genetic variations. (See Clegg MT, Durbin ML 2003 Nature Rev Genet 4:206)

Ipsilateral: Denotes affecting only one side. ►contralateral

IPTG: Isopropyl- β -D-thiogalactoside is a gratuitous inducer analog of the *Lac* operon. β -galactosidase; ►Lac operon, ►gratuitous inducer

IQ: ►human intelligence

I - R: ►hybrid dysgenesis

Ir: HLA genes were previously known as the immune-response genes that encode the MHC complex. ►HLA

IRA1, IRA2: These are negative regulators of RAS in yeast, antagonistic to CDC25; they are structurally related to GAP. ►RAS, ►GAP; Mitts MR et al 1991 Mol Cell Biol 11:4591.

IRAK (IL-1 activated serine/threonine kinase): A Pelle-like interleukin receptor-associated serine/threonine kinase and adaptor of the MyD88 signaling pathway. IRAK-4 protein deficiency results in lack of activation of NF- κ B and MAPK and susceptibility to infection by pyogenic bacteria. IRAK-4 is involved in the crosstalk between the innate and adaptive immune systems (Suzuki N et al 2006 Science 311:1927). ►NK- κ B, ►MAPK, ►interleukins, ►pyogenic, ►MyD88, ►Pelle, ►Toll, ►IL-1; Jensen LE, Whitehead AS 2001 J Biol Chem

276:29037; Kobayashi K et al 2002 Cell 110:191; Picard C et al 2003 Science 299:2076.

IRB (institutional review board): The board oversees professional and research activities involving primarily human objects.

IRE (iron responsive element): This is a 28-nucleotide 5'-UTR sequence in the ferritin mRNA, it is necessary for iron regulation. IRE sequences in the 3'UTR of the transferrin receptor mRNA protect the mRNA from degradation if the iron level is low. Iron is an essential element for many biological functions but beyond a certain level it may be very toxic because it reacts with oxygen to form hydroxyl radicals and damages the macromolecules. In iron deficiency the cellular metabolism is reprogrammed and some mRNAs are destroyed in order to cope with the deficient Fe level (Puig S et al 2005 Cell 120:99). The quantitative effect of *Ireb-2* iron-regulatory protein on brain degeneration has been debated (Galy B et al 2006 Nature Genet 38:967). ►ferritin, ►transferrin, ►aconitase, ►UTR, ►ROS, ►hemochromatosis, ►anemia; Andrews NC 2000 Annu Rev Genomics Hum Genet 1:175, dual structure of IRE as mRNA complex and aconitase: Walden WE et al Science 2006 314:1903.

Ire: This yeast protein kinase and endoribonuclease is functionally homologous to mammalian JNK and SAPK. Ire1 is a transmembrane protein bound in the cytoplasm to TRAF2, an adaptor protein in signal transduction. Ire signals the stress in the endoplasmic reticulum (ER) when the proteins inside are not folded properly and activation of the chaperones is needed. ER stress is monitored by PERK. ►ribonuclease L, ►JNK, ►SAPK, ►chaperone, ►PERK

IRES (internal ribosome entry site, also called RLP): This may be present in circular viral RNAs (picornaviruses) and can be translated on eukaryotic ribosomes. These viral RNAs (300–450 nucleotides) are not capped at the 5'-untranslated region and carry several AUG codons, and show specific sequences serving as ribosome landing pads. IRES alone can initiate translation and can replace the 1000-kD initiation factor complex. The 5S ribosomal protein interacts with the IRES. By contacting the ribosomes it changes the structure of both the 40S and 60S subunits. The crystal structure of one single viral IRES has been revealed (Pfingsten JS et al 2006 Science 314:1450). The interaction with ribosomes requires the cellular eIF-4F eukaryotic translation initiation factor. Recently, IRES-type elements have been found in other viruses and in eukaryotes. Many of the IRES-mediated translation products of eukaryotes are involved in important cellular processes (development, cell cycle, apoptosis). The IRES

Figure I65. Positive feedback vector. It contains two cistrons; the first with an enhanced green fluorescent reporter and the second is the GA14 enhancer with viral protein V16. In between the two cistrons (ICS) are IRES elements. (Modified of Zhou, W. et al. 2005 Proc. Natl. Acad. Sci. USA 102:6273)

containing non-coding regions (5'NCR) is generally longer than the regular 5'-UTRs. The presence of IRES elements (9 or double of 9 nucleotides) permits the dicistronic transcription of genes and facilitates gene targeting, homologous recombination and modification of gene expression. The use of promoterless vector constructs positions the IRES carrying sequences within the transcribed regions rather than into the non-translated regions of the genome. The IRES elements are frequently borrowed from the encephalomyocarditis virus (EMCV) family. The advantage of this system is that it does not interfere with the regular Cap-mediated ribosome scanning. In hepatitis C virus, the IRES mediates the assembly of the translation initiation complex (Otto GA, Puglisi JD 2004 Cell 119:369). In dicistronic vectors, genes placed downstream of the IRES are transcribed more efficiently than those positioned in front of it.

The IRES elements can enhance translation and therefore their identification may help modify gene expression. The vector outlined here assists in the identification of the IRES elements (see Fig. I65). The first cistron reveals their presence by the reporter and the second cistron binds to the Gal4 upstream activating sequences and with the aid of VP16 herpes virus activator facilitates the screening and identification of the IRES elements. The *Drosophila* insulin-like receptor (dINR) pathway incorporates 4E-BP resistant cellular internal ribosome entry site (IRES) containing mRNAs, to functionally couple transcriptional activation with differential translational control in a cell that is otherwise translationally repressed by eIF-4E binding protein (4E-BP). Integrated transcriptional and translational response mechanism specifically dependent on cellular IRES coordinates an essential physiological signal responsible for monitoring nutrient and cell growth conditions (Marr MT et al 2007 Genes, Dev 21:175). ▶ [ribosome scanning](#), ▶ [dicistronic transcription](#), ▶ [targeting genes](#), ▶ [gene fusion](#), ▶ [eIF4F](#), ▶ [eIF4G](#), ▶ [picornaviruses](#), ▶ [translation initiation](#), ▶ [RLP](#), ▶ [apoptosis](#), ▶ [capping enzymes](#), ▶ [GFP](#), ▶ [GAL4](#), ▶ [VP16](#), ▶ [shunting](#); Holcik M et al 2000 Trends Genet 16:469; Pinkstaff JK et al 2001 Proc Natl Acad Sci USA 98:2770; Fukushi S et al 2001 J Biol Chem 276:20824; Hellen CU, Sarnow P 2001 Genes, Dev 15:1593; Zhou W et al 2003 Proc Natl Acad Sci USA 100:4457;

Iressa (Gefitinib): This is a potential inhibitor of EGFR and an anti-cancer drug. On the basis of a large-scale study in 2004 it was concluded that this drug did not provide any survival benefits for non-small cell lung cancer and it was subsequently withdrawn from the market. However, it may be beneficial for certain genetic constitutions. Humanized anti-hEGFR antibody (Cetuximab) and small molecule inhibitors of EGFR (Erlotinib or HKI-272) can lead to dramatic regression of lung tumorigenesis (Ji H et al 2006 Cancer Cell 9:485). ▶ [EGFR](#)

IRF: This is an interferon-regulatory transcription factor, a homolog of c25 rat factor. ▶ [c25](#), ▶ [p53](#), ▶ [interferon](#)

IRF4: ▶ [LSIRF](#)

IRIS: This is the circular pigmented membrane in front of the lens of the eye with the pupil in its center. The retina lines the inner surface of the eyeball (see Fig. I66). It contains capillary veins and it is connected to the optical nerve bundle (not shown in the Fig. I66). The black spot of the retina (not the actual color) may be impaired in macular degeneration. ▶ [macular degeneration](#)

Figure I66. Retina with macula

IRIS: This is the monocot genus of perennial flowers (see Fig. I67) ($2n = 44$, *Iris germanica*).

Figure I67. *Iris germanica* flower

Iris Pattern: The iris of the eye with potentially 266 distinguishable physical features provides a pattern suitable for individual identification when a computer analyzes the image recorded by a video camera (see Fig. I68). According to some scholars, this procedure is superior to any other personal identification method, including fingerprinting and DNA fingerprinting. Retinal scans can also determine identity to some degree by the pattern of the vasculature; it has been used in forensics mainly as a post-mortem test to ascertain the cause of death, such as strangulation, shaking, and some poisonous substances. ▶fingerprints, ▶fingerprinting of macromolecules; Daugman J, Downing C 2001 Proc R Soc Lond B Biol Sci 268:1737.

Figure I68. Iris pattern

IRM (interference-reflection microscopy): This is used to study the cell membrane and protein associations (e.g., in immunological synapse). ▶immunological synapse

IRMA (immunoradiometric assay): This uses radiolabeled antibody to quantitate a particular antigen. In the *two-site IRMA* two antibodies are used that bind different epitopes. ▶epitope, ▶ELISA, ▶radioimmunoassay; Frystyk J et al 2001 Growth Horm IGF Res 11(2):117.

Iron Age: This is a prehistoric period dating to the third or fourth millennium; it marks the beginning of recorded history.

Iron Metabolism: Several human diseases involve anomalies in iron metabolism. ▶IRE, ▶hemochromatosis, ▶transferrin, ▶Friedreich ataxia, ▶sideroblastic anemia, ▶aceruloplasminemia, ▶Hallervorden-Spatz disease, ▶ferritin, ▶porphyria, ▶anemia, Roy CN, Andrews NC 2001 Hum Mol Genet 10:2181.

Irradiation: ▶radiation

IRS: Refers to the interferon-response factor. ▶interferon

IRS: ▶insulin receptor substrate

IRS-PCR: (interspersed repetitive sequence—polymerase chain reaction): This is used with radiation hybrids as a rapid test for identifying the nature of the putative hybrid cells and also the PCR product is hybridized as a probe to a normal chromosomal complement and compare it to the previously established map. The IRS-PCR can also be used to screen cosmid and artificial chromosome libraries. ▶radiation hybrid, ▶PCR; Himmelbauer H et al 2000 Nucleic Acids Res 28[2]:e7.

IS: ▶insertion elements

Isadora: This is an 8.3 kb transposable element of *Drosophila*, generally present in 8 copies.

Ischemia: This condition is characterized by restriction of the blood vessels. It may be a major cause of stroke. For gene therapy, the introduction of anti-apoptotic genes, interleukin-1 receptor antagonists, angiogenesis activating vascular endothelial growth factor, superoxide dismutase, etc. have been considered. Among the genetic vectors, injecting adenovirus and herpes virus into the brain or into spinal artery has yielded promising results. ▶stroke, ▶apoptosis, ▶interleukin, ▶VEGF, ▶adenovirus, ▶herpes, ▶superoxide dismutase, ▶alcohol, ▶cardiac diseases

I-Sce1: This is an unusual restriction endonuclease, encoded by yeast mitochondrial introns. It recognizes 18 bp sequences, in the mouse genome it cuts only once per 7×10^{10} bp, i.e., less than once in ten times the size of the total mouse genome. In a modified form it is useful for studying the consequences of double-strand breaks and the mechanism of homologous recombination. ▶restriction endonuclease, ▶double-strand break, ▶homologous recombination; Rouet P et al 1994 Proc Natl Acad Sci USA 91:6064.

ISCNT: Refers to the interspecies somatic cell nuclear transfer technique. ▶nuclear transplantation

ISGF-3: ▶APRF

Isgylation (interferon modulated gene): This plays a ubiquitin-like role in various cellular processes.

►ubiquitin, ►interferon; Malakhova OA et al 2003 *Genes, Development* 17:455.

ISIS (isotype-specific inhibitory sequence): Various types of antisense constructs are effective in reducing or eliminating gene translation. ►antisense technologies, ►isotype

Island Model of Populations: A group of subdivided populations exchanges m alleles with each other regularly and also has a chance to receive alleles at a constant $m - 1$ rate from an earlier population. The situation resembles that of a drift in a single population under migration pressure. The model assumes that each subpopulation has the same size and is equidistant from each other. The continuous model version considers equal density at any point and the discontinuous version assumes that the subpopulations are clustered at nodal points of a lattice. Each of these distributions may be one- or two-dimensional. The discontinuous model is also known as the stepping-stone model and it may be three-dimensional. All variations of the basic model have been criticized because most of the basic stipulations may not be met under natural conditions. (See the theoretical details in Cavalli-Sforza LL, Bodmer WF 1971 *The Genetics of Human Populations*, pp 423 ff.)

Isoacceptor tRNAs: This group of different tRNAs accepts the same amino acid. The identity of a specific isoaccepting tRNA is determined by particular nucleotide sites within the group. The anticodon may serve as an identity site, however the six serine tRNAs do not share a common anticodon base. The nucleotide 73 is a discriminator base and the first base pairs within the acceptor stem. The long variable arm of the tRNA^{Ser}, the extra G1:C73 bp in tRNA^{His}, and the G3:U70 bp in tRNA^{Ala} can characterize *E. coli* tRNAs. In other species identity may be differently determined. The anticodon-flanking nucleosides may play an important discriminating role. ►tRNA, ►aminoacyl-tRNA synthetase, ►wobble, ►protein synthesis, ►transcript; Heyman T et al 1994 *FEBS Lett* 347[2–3]:143; Chaley MB et al 1999 *J Mol Evol* 48[2]:168; Crain PF et al 2002 *RNA* 8:752; Agris P 2004 *Nucleic Acids Res.* 32:223.

Isoalleles: These are wild type alleles which can be distinguished only by special techniques. ►allele, Harris MJ, Juriloff DM 1989 *J Hered* 80[2]:127; King JL 1974 *Genetics* 76:607.

Isoallotype: Refers to variable antigens of one immunoglobulin (IgG) molecule subclass which are invariant on the molecules of another subclass or subclasses. ►allotype; Delacroix DL et al 1986 *Mol Immunol* 23[4]:367.

Isoantigen: This is an allelic variant of an antigen within the species. ►alloantigen

Isobrachial: This means that the two arms of a chromosome are identical (see Fig. 169). ►isochromosome, ►chromosome arm, ►chromosome morphology

Figure 169. Isobrachial chromosome

Isochores: Refers to segments (generally larger than 200 kb) of the DNA of higher eukaryotes having rather homogeneous GC or AT content. Usually one light and two or three different heavy components can be separated by buoyant density centrifugation in the presence of certain ligands, e.g., silver ions (Ag^+). In the mammalian genome the GC-poor isochores represent about 62% and the GC-rich and GC-very rich isochores constitute 22% and 3–4% of the genome. Genes within isochores have base content characteristic of isochores. In high GC isochores the gene concentration is much higher than in the AT-rich areas. Isochores may affect codon usage and replication pattern. The cytologically identifiable Giemsa-stained bands are low in GC, the T bands are high and the R bands occupy a position in between. Because of the high GC content of the T bands, their codon usage is biased. R bands and G/R borders are characterized by a higher frequency of chromosomal exchanges (breakage and chiasmata). Viral and transposon integration sites are correlated with the base composition of the elements; sequences similar to their own are the preferred targets. The origin of isochores has been attributed to natural selection or variation in mutational bias. Recent evidence supports the latter view. ►CpG islands, ►chromosome banding, ►codon usage, ►transposons; Bernardi G 2000 *Gene* 241:3; Galtier N et al 2001 *Genetics* 159:907; Vinogradov AS 2005 *Nucleic Acids Res* 33:559.

Isochromatid Breaks: Refers to damage simultaneously inflicted to both chromatids of a single chromosome (see Fig. 170). ►radiation effects

Figure 170. (Courtesy of B.R. Brinkley)

Isochromosome: This has two identical arms and is normally produced by a misdivision of a telocentric

chromosome. ▶ **misdivision**, ▶ **trisomic secondary**, ▶ **isobrachial**

Isodiametric: Its diameters (lines passing through it center) are the same in all directions.

Isodisomy: ▶ **uniparental disomy**

Isoelectric Focusing: This is an electrophoretic separation technique based on the isoelectric point of the molecules to be separated. The isoelectric point is at a pH where a solute has no electric charge and thus does not move in the electric field. For example, when, denatured protein mixture is placed in an electrophoretic gel that contains a pH gradient established by different buffers, the polypeptides migrate to their isoelectric zones. ▶ **electrophoresis**, ▶ **two-dimensional electrophoresis**

Isoelectric Point (pI): This is a point when a charged molecule in a solution—because of the pH—shows no net electric potential and consequently does not move in an electric field. ▶ **isoelectric focusing**

Isoenzymes (isozyme): These are multiple, distinguishable forms (by primary structure [electrophoretic mobility], substrate affinity, reaction velocity and/or regulation) of enzymes that catalyze the same reaction. *Sorting isozymes* are targeted to specific subcellular compartments, e.g., mitochondria, chloroplast or to different organs (see Fig. 171). ▶ **isozyme**

Figure 171. Lactate dehydrogenase isoenzyme profile in the heart muscles in the mouse shows dramatic changes during development. Nine days before birth, isozyme LDH-5 is predominant, and LDH-1, LDH-2 OR LDH-3 are not detectable. In the adult animal almost the opposite is true. LDH is a key enzyme in the pathway of converting sugars into amino acids, lipids, etc. The numbers at the bottom indicate days before (-) or after (+) birth. (From Markerts CL., Ursprung U 1971 Developmental Genetics. Prentice-Hall, Englewood Cliffs, NJ.)

Isorefemale: Refers to a line descended from the same female ancestor which was originally infected by a

cytoplasmically infected bacterium, e.g., in *Drosophila* by *Wolbachia*. ▶ **Wolbachia**

Isoflavones: ▶ **phytoestrogens**

Isoform: Due to differences in amino acid composition, caused by mutation or alternative splicing of the RNA transcript, RNA editing, use of alternative promoters and post-transcriptional or post-translational processing essentially the same protein is somewhat altered. Polypeptides in the cellular organelles may basically have a similar catalytic function as those residing in the cytosol or organ- or tissue-specific forms of enzymes. The human WT1 (Wilms tumor) has 24 isoforms and they all share four C-terminal C₂H₂ Zinc fingers and an N-terminal Pro/Gln-rich regulatory domain. ▶ **alternative splicing**, ▶ **splicing**, ▶ **Wilms tumor**; Hastie ND 2001 Cell 106:391.

Isogamy: Similar gametes are involved in a sexual union, e.g., in protozoa. ▶ **anisogamy**, ▶ **heterogametic**, ▶ **homogametic**

Isogenic Stocks: Their genes are represented by the same alleles at all loci. For practical purposes, isogenicity in rodents is tested by skin grafts. Grafts within inbred lines are believed to be successful but not those in between different inbred lines. Grafts from parents to F₁ are supposed to be successful but not in the opposite direction. ▶ **congenic**

Isograft: In this the genotype of the donor and recipient tissues matches. ▶ **allograft**, ▶ **heterograft**, ▶ **grafting in medicine**

Isoguanine (guanopterin, oxyadenine): This purine analog can pair with thymidine and can cause infidelity of PCR (see Fig. 172). Using 2-thiothymidine triphosphate most of the problems can be prevented because thymidine does not pair well with this purine analog although it can form three hydrogen bonds with isoguanine. Isoguanine can also form three hydrogen bonds with isocytidine. In expanding the bases to 6 – in addition to A, T, G, C – fidelity per round of PCR amplification was about 98%. Such a 6-letter alphabet although not entirely palatable to DNA polymerases, is a system capable of Darwinian evolution (Sismour AM, Benner SA 2005 Nucleic Acids Res 33:5640). ▶ **thiouracil**, ▶ **PCR**, ▶ **base analogs**

Figure 172. Isoguanine

Isolabeling: Refers to ^3H label (or other) in both daughter chromatids after one replication in ^3H -thymidine medium (or other labeling medium) at a certain tract(s) as a consequence of sister chromatid exchange (see Fig. I73). ▶ [sister chromatid exchange](#)

Figure I73. Isolabeling

Isolation Genetic: This may be determined by the presence of inversions in the population that in the case of recombination yield defective gametes. Also, since recombination within inverted segments produces defective gametes, advantageous gene blocks may be preserved as “supergenes”. Genetic isolation may be the first step in speciation. ▶ [incompatibility](#)

Isoleucine-Valine Biosynthetic Pathway : Steps 1 and 2 are controlled by identical enzymes in both pathways in several organisms and therefore genetic defects in either may generate nutritional requirement for valine [$\text{CH}_3\text{CH}(\text{CH}_3)\text{CH}(\text{NH}_2)\text{COOH}$] as well as isoleucine [$\text{CH}_3\text{CH}(\text{CH}_2\text{CH}_3)\text{CH}(\text{NH}_2)\text{COOH}$] or the accumulation of the intermediates (see Fig. I74). The *maple syrup urine disease* (MSUD) is manifested in different forms in humans and other mammals and it is caused by a block in the degradation, the decarboxylation (step 2) and accumulation of leucine, isoleucine and valine. The keto-methylvalerate accumulation then causes the characteristic maple syrup odor of the urine. One of the genes (MSUD II) has been assigned to human chromosome 1p31 and a pseudogene to chromosome 3q24. The more serious aspects of the disease are physical and mental retardation, potential coma and death. The disease is also controlled by non-allelic recessive genes, (BCKDHA [branched chain keto acid decarboxylase and dehydrogenase] locus is at 19q13.1-q13.2, BCKDHB is at 6p22-p21). Gene A is responsible for the biosynthesis of the α chain of the enzyme (BCKDHA) and locus B for the β chain (BCKDHB). In one form of the A type disease the administration of thiamin (10 mg/day) reduced hyperaminoacidemia without dietary limitations. The larger subunit (M_r 46,500) of the enzyme is part of a mitochondrial protein complex. The enzyme complex also contains

component E2 (M_r 52,000) that transfers the acyl group of the keto acid from the E1 component (protein A) to coenzyme A. The disease may be due to a single base pair change resulting in a tyrosine substitution at asparagine site 394 of protein A or to deletions of several nucleotides. The defect is detectable prenatally but carriers cannot be identified because of recessivity. The prevalence varies greatly from 3×10^{-5} to 6×10^{-3} in different ethnic groups. Defects in the transaminase reaction (step 3) may also be controlled by a common glutamic-branched-chain-amino acid transaminase. In humans, however, hypervalinemia (valinemia) is caused by a defect in a specific transaminase, resulting in the lack of ability to catabolize valine into keto-isovalerate without affecting the level of leucine and isoleucine in the blood.

MSUD III (7q31-q32) is caused by dihydrolipoamide dehydrogenase deficiency. Methyl-crotonyl-CoA carboxylase deficiency (3q25-q27) is a recessive defect in leucine catabolism without acidosis. Spinal defects result in muscular hypotony and atrophy. Isovaleric acid CoA dehydrogenase deficiency (15q14-q15) is a ketoacidosis with isovaleric academia and is similar to MSUD; the clinical symptoms include retarded psychomotor activity, vomiting and protein aversion. In the Mediterranean (North Africa) region, the disease is known as Fenugreek Tea disease because the odor of the urine is reminiscent of the extract of *Trigonella foenum graecum* L. A nitrosourea-induced mutation in mice blocks the mitochondrial pathway of branched-chain amino acids and can be used as an animal model (Wu J-Y et al 2004 J Clin Invest 113:434). ▶ [genetic screening](#), ▶ [hypervalinemia](#), ▶ [3-hydroxy-3-methyl-glutaryl CoA lyase deficiency](#), ▶ [leucine metabolism](#), ▶ [methylcrotonylglycinemia](#), ▶ [methylglutaconicaciduria](#), ▶ [hydroxymethylglutaricaciduria](#), ▶ [methacrylaciduria](#), ▶ [methylacetoaceticaciduria](#), ▶ [2-methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency](#); Nellis MM, Danner DJ 2001 Am J Hum Genet 68:232.

Isolocus: Refers to paralogous locus that originates from duplication of the genome. ▶ [paralogous loci](#)

Isomerase: This is an enzyme that interconverts enantiomorphs. ▶ [enantiomorph](#), ▶ [chirality](#)

Isomerism: This is a developmental anomaly displaying single organs, present normally asymmetrically in the body, in a position symmetrical on the two sides of

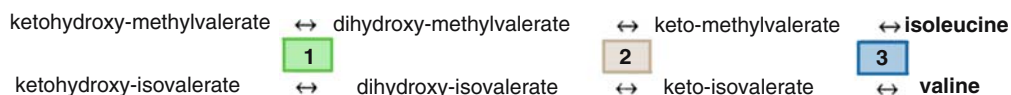

Figure I74. Isoleucine–valine biosynthetic pathway

the body axis. ▶heterotaxy, ▶situs inversus viscerum, ▶left-right asymmetry

Isomerization of Strands: One crossed over DNA strand changes into a two-strand crossover through the rotation of molecules. Isomerization occurs in a triplex formation, such as when RNA is transcribed on the DNA template (Cannon WV et al 2000 Nature Struct Biol 7:594). ▶Meselson-Radding model of recombination, ▶Hoogsteen pairing

Isomers: These are different compounds that have the same molecular formula but their structure varies. Their differences may be relatively subtle (D- and L-glucose) or may be as large as that between ethyl alcohol and methyl ether.

Isometric Phage: This is enclosed in an icosahedral or similar multifaceted globe-shape capsid. Many icosahedral viruses contain a protruding structure outside the icosahedral that serves as a packaging and injection portal (see Fig. 175). (Jiang W et al 2006 Nature [Lond] 439:612).

Figure 175. Icosahedron

Isonymy: There is a probability of kinship between individuals with the same family name. According to some scholars, the frequency of isonymous couples multiplied by a factor of 1/4 may provide information on the coefficient of inbreeding in the population. One-fourth of the married pairs have identical family names before marriage because of the inheritance of the grandfather's name through two sibs and the remaining three-quarters have different surnames. The probability of isonymy is 1/4 for first cousins, 1/16 for second cousins and 1/64 for third cousins. When multiplied by 1/4 these fractions provide the coefficient of inbreeding, i.e., $(1/4 \times 1/4) = 1/16$, $(1/16 \times 1/4) = 1/64$, and $(1/64 \times 1/4) = 1/256$ for the three types of matings, respectively. One study found that 24% of Englishmen sharing the same family name also shared the Y chromosome (King TE et al 2006 Current Biol 16:384). (See Lasker GW, Mascie-Taylor CG 2001 Ann Hum Biol 28:546)

Isopentenyladenine (6-[γ,γ -dimethylallylamino]purine): A post-transcriptionally modified base in tRNA; it is also a cytokinin plant hormone. ▶tRNA, ▶plant

hormones; Takei K et al 2001 J Biol Chem 276:26405.

Isopeptidases: These are de-ubiquitinating enzymes. ▶ubiquitin, ▶UBP

Isoprene: 2-methyl-1,3 butadiene unit of terpenoids, fragrances, rubber, etc. Isoprenylated proteins are anchored to the cell membranes (see Fig. 176). The role of the oncogene product, RAS, functions in carcinogenesis and signal transduction in isoprenylated form, attached to a farnesyl pyrophosphate. ▶RAS, ▶signal transduction, ▶membrane proteins, ▶prenylation, ▶plastoquinone; Lichtenthaler HK 1999 Annu Rev Plant Physiol Plant Mol Biol 50:47.

Figure 176. Isoprene

Isoprenoids: These include > 23,000 diverse compounds in viruses to mammals such as cholesterol, steroid hormones, bile acids, retinoids, isopentenyl-tRNA, sphingomyelins, ecdysone, gibberellic acid, abscisic acid, brassinosteroids, carotenoids, rubber, etc. They may function as regulators of transcription, developmental processes involving the hedgehog family of proteins, meiosis, apoptosis, etc. (See Niemann-Pick disease, SF-1, hedgehog, apoptosis, Edwards PA, Ericsson J 1999 Annu Rev Biochem 68:157; Sharkey TD, Yeh S 2001 Annu Rev Plant Physiol Plant Mol Biol 52:407)

Isopropyl Thiogalactoside: ▶IPTG

Isopticnic: These are molecules with equal density. ▶buoyant density

Isopticnotic Chromosome: This does not display the heterochromatic regions. ▶heterochromatin

Isoschizomers: These restriction endonucleases have very similar recognition sites; their cleaved ends being identical (cohesive) they are capable of joining each other, e.g.,

| | | |
|--------|----|--------------|
| Bgl II | 5' | A↓pGpApTpCpT |
| | 3' | TpCpTpApGp↑A |
| Bam HI | 5' | G↓pGpApTpCpC |
| | 3' | CpCpTpApGp↑G |

Their termini after ligation are:

GGATCT
CCTAGA

However, this juncture is no longer recognized by either of the two enzymes because the bases at the left and right ends are incompatible with both Bgl II or Bam HI.

Other isoschizomers are Hpa II 5' C↓CGG 3' does not cut when C is methylated

Msp I 5' C↓CGG 3' is indifferent to methylation

Isoschizomers SmaI (CCC↓GGG) and Xma I (C↓CCGGG) recognize the same sequence but cut it (↓) at different position. ▶restriction enzymes, ▶restriction-modification

Isosteres: These have a similar electron arrangement but different chemical structures and are used for substrate analog designs.

Isothermal: Denotes being at identical temperature.

Isotonic: The active salt concentration of this medium is the same as in the cell. A NaCl solution of 0.9% is isotonic with the human blood and can be used to maintain temporarily good osmotic conditions after substantial bleeding by injecting sterile *sol. natr.-chlor. isotonica* into the (blood vessels) venae. ▶hypotonic, ▶isotonic

Isotope Discrimination: The heavier atoms may be used less effectively than the lighter ones. ▶isotopes

Isotope-Coded Affinity Tags (ICAT): Two chemicals with biotin affinity and a thiol group are labeled with a heavy or light isotope, respectively. The experimental and the control proteins are reduced and derivatized with either the heavy or the light forms. The mixed samples are digested to obtain peptide fingerprints. The tagged fragments are analyzed by mass spectrometry after purification. Only the double peaks with 8 Da difference (i.e., the difference between the light and heavy labels) are further characterized (Gygi SP et al 1999 Nature Biotechnol 17:994). Non-isotopic labeling techniques have also been developed. ▶mass spectrometer [MALDI/TOF/MS], ▶non-isotopic labeling, ▶proteomics

Isotopes: Two or more nuclides having the same atomic number are the same elements but differ either in mass (stable isotopes, such as Hydrogen and Deuterium) or radioactive isotopes (atom) that disintegrate by emission of corpuscular or electromagnetic radiation (α , β γ rays). The latter ones are particularly useful in biology as radioactive tracers of minute amounts of labeled (H^3 , C^{14} , P^{32}) nucleotides or (C^{14} , S^{35} , I^{125}) proteins. Stable isotopes (N^{15} , C^{13} , H^2) can also be used as density labels for distinguishing old and newly synthesized molecules. The types of radiations and energies in million electron volts are H^3 : β , 0.017–0.019, C^{14} : β 0.155, P^{32} : β 1.71, S^{35} : β 0.167, I^{131} : β 0.605, 0.250, and γ 0.164, 0.177, 0.284, 0.364, 0.625, I^{125} : 0.0355, Y^{90} : β 2.24, K^{42} : β 3.6, 2.4 and γ 1.5, Cs^{137} : β 0.518, 1.17 and γ 0.663, Co^{60} : β 1.56, γ 2.33, U^{238} : α 4.180, γ 0.045, Ra^{226} is generally understood to be radium; it has a long half-life (1,620 years) and is quite stable.

It primarily emits α radiation (helium nuclei) 4.750 MeV and γ electromagnetic radiation (0.188 MeV). Radium is converted into a number of other isotopes. Among these radon, the commonly present gas diffusing from rocky soils, has a short half-life (3.825 days) yet it is usually replenished from the source. It emits α radiation and may pose an environmental health hazard if its concentration levels increase. Radium is no longer used for medical or to a very limited extent for industrial purposes because of the hazards involved in handling. Luminous watch dials are made now from fluorochromes. ▶Curie, ▶ μC , ▶fluorochromes, ▶biotin, ▶non-isotopic labeling, ▶half-life, ▶radiocarbon dating, ▶argon dating

Isotopic Graft: A group of cells or a piece of tissue is transplanted to the equivalent position of another animal.

Isotype: Refers to closely similar immunoglobulins with differences in the constant region. Sometimes the word is used in a broader sense to imply similar in constitution or sequence. ▶immunoglobulins, ▶allotype, ▶idiotype

Isotype Switching: Refers to a process of immunoglobulin gene rearrangement. ▶immunoglobulins

Isotypic Exclusion: Either only λ or κ light chains are used with any of the heavy chains for the formation of a particular antibody (both light chains cannot be used simultaneously). ▶antibody, ▶immunoglobulins

Isovaleric Acidemia (IVD): This disorder is controlled by a recessive gene in human chromosome 15q14-q15. It is characterized by sweaty feet-like odor (butyric and hexanoic acid) of the urine, dislike of protein, vomiting, anemia, ketoacidosis, high isovaleric acid content of the blood leading to injury of the nervous system. The biochemical lesion is in isovaleric acid CoA dehydrogenase deficiency. Several types of mRNAs of this gene have been identified on the basis of differences in transcription and different mutations or deletions. ▶amino acid metabolism, ▶isoleucine-valine biosynthetic pathway, ▶Jamaican vomiting sickness, ▶acetyl-CoA dehydrogenase deficiency

Isozyme: (see Fig. 177) ▶isoenzymes

Figure 177. Fructose-1,6-diphosphate aldolase isozymes

Isozygotic: This means homozygous for all genes.

ISP45: ►mitochondrial import

ISPCR: Denotes in situ polymerase chain reaction.
►in situ PCR

ISRE (interferon sequence response element): ►signal transduction [Jak-STAT]

ISSR (inter-simple sequence repeats): Refers to repeats between non-repeated sequences of chromosomes.

IST: Denotes interaction sequence tag.

ISTR (inverse sequence-tagged repeat): This technique is used for physical mapping of genomes. (See Rohde W J 1996 J Genet Breed 50:249)

ISWI: This is the ATPase subunit of NURF and other chromatin remodeling proteins. ►nucleosome, ►nuclear receptors, ►chromatin remodeling; Nurf, Langst G, Becker PB 2001 J Cell Sci 114:2561; Xiao H et al 2001 Mol Cell 8:531; Clapier CR et al 2002 Nucleic Acids Res 30:649.

ITAM (immune receptor tyrosine-based activation motif): ►lymphocytes, ►ZAP-70, ►T cell receptor, ►BLK, ►ITIM, ►killer cell, ►osteoclast, (see Fig. I78).

Figure I78. ITAMs are phosphorylated by Lck, Blk, Fln, Lyn and recognized by Syk. Phosphorylation and activation may be initiated by cross-linking antigen of IgM molecules

ITCH: This is E3 type ligase, its activity is promoted by phosphorylation. It plays an important role in the differentiation of lymphocytes (Gallagher E et al 2006 Proc Natl Acad Sci USA 103:1717). ►ubiquitin

ITD: ►idiopathic torsion dystonia

Iteration: This refers to repetitions; a commonly used form is the iterated integral when an individual differentiates first with respect to one of the variables while holding the other constant and then

differentiates the result with respect to the other variable. For biological experiments the distribution may be fitted to a negative binomial, requiring a similar procedure in the calculation of the maximum likelihood of values. For complex numerical iterations computer programs may be required. ►negative binomial, ►maximum likelihood

Iterative Crosses: These are used in breeding programs such as three-way and double-crosses employed for the testing or production of hybrid maize. ►heterosis

Iterative Truncation (ITCHY, incremental truncation for the creation of hybrid enzymes): This method is used to generate hybrid enzymes by fusing truncated N- or C-terminal fragment libraries. The technique of creation enhanced cross over between non-homologous proteins has been termed SCRATCHY (Kawarasaki Y et al 2003 Nucleic Acids Res 31(21):e126). The DNA coding sequences are progressively reduced with the assistance of exonuclease III before ligating the “single-crossover” hybrid library. The new coding sequence may be the same length as the “parental” ones except that parental contribution to the hybrid may vary. The components of the newly created protein may be as different as prokaryotic and eukaryotic. ►protein engineering, ►DNA shuffling; Ostermeier M et al 1999 Proc Natl Acad Sci USA 96:3562; Lutz S et al 2001 Proc Natl Acad Sci USA 98:11248; Griswold KE et al 2005 Proc Natl Acad Sci USA 102:10082., see Fig. I79)

Figure I79. Iterative truncation

Iterons: These multiple, short DNA repeats may bind to the plasmid replication protein and may either initiate or inhibit replication. (See Chatteraj DK 2000 Mol Microbiol 37[3]:467)

Iteroparity: Reproduction takes place on more than a single occasion.

ITG: ►integrin

ITIM (immunoreceptor tyrosine-based inhibitory motif): Typically, the cytoplasmic domain of these molecules contains six amino acids Ile/Val/Leu/Ser)-X-Tyr-X-X-(Leu, Val) where X can be any amino acid. A

balance between activation (ITAM) and inhibition motifs determines the development of the immune system (NK). Clustering of these receptor sites is induced by ligands and a Src type kinase phosphorylates the tyrosine residue. Such an event facilitates the recruitment of SH2 domain phosphatases such as SHP-1 and SHIP. PIR-B attenuates B cell receptor activation in cooperation with SHP-1. Other targets are Sky, BLNK, BASH, phospholipase C, FcγR, etc. ▶killer cells, ▶ITAM, ▶SH2, ▶SHP-1, ▶SHIP, ▶PIR, ▶Sky, ▶BLNK, ▶B lymphocyte receptor, ▶BASH, ▶phospholipases, ▶FcγR, ▶KIR, ▶DAP; Ravetch JV, Lanier LL 2000 Science 290:84.

ITK: This is a non-receptor tyrosine kinase of the Tec family; it signals to TCR. ▶TCR, ▶Tec

ITP: Denotes inosine triphosphate. ▶hypoxanthine, ▶inosine

ITR: Refers to inverted terminal repetition such as observed in human adenovirus DNA. ▶adenovirus

ITS: Internal transcribed spacers are short sequences within eukaryotic pre-tRNA transcription units (5' 18S - ITS - 5.8S - ITS - 28S 3'), and these clusters are separated by external tran-scribed spacers. Their analysis facilitates identification of different strains. ▶ETS, ▶tRNA; Fujita SI et al 2001 J Clin Microbiol 39:3617; ITS2 database: http://darwin.uvigo.es/software/modeltest_server.html.

IU: ▶IU

IUCD (intrauterine contraceptive device): This method prevents implantation of the egg. Although it is an effective method of birth control, it may lead to infection and may cause some discomfort.

IUGT (in utero gene transfer): Used to correct genetic defects of somatic cells by transfer of gene(s) into the unborn fetus. Its advantage is that it can be applied early during embryonic development before irreversible damage occurs, e.g., in various neurological diseases (Tay-Sachs, Niemann-Pick, Lesh-Nyhan, Sandhoff, Leigh, leukodystrophies, gangliosidoses, immunological disorders, thalassemias, osteopetrosis). It is less likely that IUGT involves vector or cell rejection. The treatment of hematopoietic stem cells may be more successful. Animal experiments have yielded encouraging results. Its drawbacks are the potential risk to the mother and the fetus. Also, the vector DNA may cause undesirable insertions or mutations in the germline. ▶ART, ▶gene therapy, Heikkila A et al 2001 Gene Ther 8:784.

IUI: ▶intrauterine fertilization, ▶ART

Ivemark Syndrome: ▶asplenia

Ivermectin: An antibiotic used to treat parasitic infections.

IVET (in vivo expression technology): This technology selects specifically induced bacterial genes that are expressed when bacteria are committed to infection or passage through a host.

IVIG (intravenous immunoglobulin gamma): Its administration provides polyclonal anti-inflammatory effectiveness against autoimmune cytopenias, Guillain-Barré syndrome, myasthenia gravis, anti-Factor VIII autoimmune disease, dermatomyositis, vasculitis (inflammation of the blood vessels) and uveitis (eye inflammation). ▶cytopenia, ▶Guillain-Barré syndrome, ▶myasthenia, ▶anti hemophilic factors, ▶polyomyositis

IVF: ▶in vitro fertilization, ▶ART

IVS: Refers to intervening sequences, they are the same as introns. ▶introns

Ixodoidea (ticks): Group of insects, that are common carriers of *Borrelia* infection, causing Lyme disease and viral infections resulting in encephalitis (see Fig. I80). The insects' saliva contains anticoagulant proteins (e.g., Salp 14) that facilitate their feeding on the host and transmission of the tick-borne pathogens. ▶*Borrelia*, Narasimhan S et al 2004 Proc Natl Acad Sci USA 101:1141.

Figure I80. Tick

Izumo: An immunoglobulin-like sperm protein that mediates sperm fusion with the oocytes.

Historical vignettes

Professor TH Morgan in *The American Naturalist* 60, p. 490 (1926)

“...except for the rare cases of plastid inheritance, the inheritance of all known characters can be sufficiently accounted for by the presence of genes in the chromosomes. In a word the cytoplasm may be ignored genetically.”

In his *A History of Genetics* (Harper & Row, New York, 1965) AH Sturtevant comments on the significance of Walter S. Sutton's papers (Biol. Bull. 4:24 [1902] and *ibid.* 231 [1903]) on the correlation between chromosomal segregation and the Mendelian laws:

“With this paper, this phase of the history is finished. The conclusions were not at once generally accepted, but they could not be disregarded and stand today as essentially correct. At last, cytology and genetics were brought into intimate relation, and results in each field began to have strong effects on the other”.

(It may be worth noting that Sutton, a student of the great EB Wilson, never completed his graduate studies at Columbia University and without a Ph.D. he went on to become a MD and a distinguished practicing surgeon. He also had special engineering talents but quit cytology and genetics where he made such a lasting impact. Sutton died at the age of 39. [See Crow EW & Crow JF 2002 *Genetics* 160:1])

J

J Base (β -D-glycosylhydroxymethyluracil): This occurs in the repetitive DNAs of protozoa and its presence is correlated with a J-binding protein and with the epigenetic silencing of telomeric surface glycoprotein genes (see Fig. J1). These surface glycoproteins mediate antigenic variations of *Trypanosomas* and other related parasites. ▶pyrimidine, ▶antigenic variation, ▶*Trypanosomas*; Sabatini R et al 2002 J Biol Chem 277:958; Yu Z et al 2007 Nucleic Acids Res 35:2107.

Figure J1. J base

J Chain: A 15-kDa polypeptide that is involved in the formation of antibody molecules. ▶immunoglobulins

J Chromosome: A J-shaped chromosome moving toward the pole (see Fig. J2).

Figure J2. J chromosome

J Gene: ▶immunoglobulins, ▶J chain

J Protein: ▶HSP

JAB (Jun activation-domain-binding protein): A co-activator of AP1 transcription factor functioning by transactivating c-Jun and JunD. It interacts with the $\beta 2$ subunit of LFA-1. It may switch off cytokine signaling. ▶AP, ▶Jun, ▶transactivator, ▶SOCS-box, ▶CIS, ▶LFA; Harding TC et al 2001 J Biol Chem 276:4531.

$$\tilde{\theta} = n\hat{\theta} - (n-1) \frac{\sum_{i=1}^n \hat{\theta}_i}{n}$$

Jackknifing: A statistical device for the estimation of bias and variance of genetic parameters without

providing essential estimates on the distribution of the estimates. The jackknife estimator of a parameter is presented here where $\hat{\theta}$ is the usual estimator using the complete set of n observations. In the jackknife procedure each sample member in turn is omitted from the data, thus generating n separate samples each of $n-1$ size. This method may be used for the estimation of the size of misclassification in conjunction with discriminant analysis. ▶discriminant function, ▶bootstrap; LaPointe FJ et al 1994 Mol Phylogenet Evol 3(3) 256.

Jackpot Mutation: This occurs early during the growth of a population and is represented by more copies than mutations, which occur late. Jackpot mutations may bias the calculations of the mutation frequency if not identified. ▶mutant frequency

Jackpot Vessel: In a series of dilutions or in a fluctuation test one vessel has more than the expected number of cells caused either by a clump of cells or a pre-existing mutation. ▶fluctuation test

Jackson Laboratory Backcross DNA Panel Map Service: This makes available DNA from the reciprocal mouse crosses (C57BL/6J x *Mus spretus*), characterized by SSLP markers, proviral loci and several other sequences. Information: Lucy Rowe or Mary Barter, Jackson Laboratory, 600 Main Str., Bar Harbor, ME 04608, USA. Phone: 207-288-3371 ext. 1687. Fax: 207-288-5079, lbr@aretha.jax.org (L. R.) or meb@aretha.jax.org (M. B.)

Jackson-Lawler Syndrome: is a keratosis of the skin and may involve teeth already at birth. It is caused by mutations at two chromosomal loci 17q12-q21 and 12q13. ▶keratosis, ▶ichthyosis

Jackson-Weiss Syndrome: ▶Crouzon syndrome, ▶Pfeiffer syndrome, ▶Apert syndrome

Jacobsen Syndrome: This dominant fragile site involves human chromosome 11q23.3 and is located at a distance of 100 kb from the CBL2 oncogene and CCG repeats. This trinucleotide repeat is also called FRA11B. The CpG repeats are liable to methylation. It involves growth and psychomotor retardation, anomalies of the face, finger and toe development. ▶fragile sites, ▶FMR1, ▶trinucleotide repeats, ▶Huntington's chorea, ▶ataxia, ▶Machado-Joseph disease, ▶Kennedy disease, ▶dentatorubral-pallidolysian atrophy

Jak Kinases (Janus tyrosine kinases): Jak3 is required for the progression of the development of B lymphocytes. Jak kinases are involved in the transmission of interleukin signals. ▶signal transduction by interferon signaling, ▶interleukins,

►**immunosuppression**; O'Brien KB et al 2002 J Biol Chem 277:8673.

Jak-STAT Pathway: Several Jak kinases, signal transducers and activators of transcription (STATs) regulate the signal transduction of interleukins and interleukin-mediated transcription. The pathway may be activated by interferons, phospholipase C (PLC), growth hormones, epidermal growth factor (EGF) and platelet-derived growth factor (PDGF). The SOCS/JAB/SSI and CIS proteins exert negative control. The Jak-STAT pathway regulates heterochromatin in the cell. Over-expression of Jak can lead to tumorigenesis in *Drosophila* and disruption of the pathway can suppress tumorigenesis (Shi S et al 2006 Nature Genet 38:1071). This pathway is missing from *Caenorhabditis*. ►**PDGF**, ►**EGF**, ►**CSF**, ►**signal transduction**, ►**SOCS**, ►**JAB**, ►**SSI**; Schindler C, Darnell JE 1995 Annu Rev Biochem 64:621; Hilton DJ 1999 Cell Mol Life Sci 55:1568; O'Shea JJ et al 2002 Cell 109:S121; Schindler CW 2002 J Clin Invest 109:1133.

Jamaican Vomiting Sickness: This is caused by the consumption of unripe ackee fruit, a common food of the people of the island. The obnoxious component of the fruit hypoglycin A may reduce blood glucose content to 10 mg/100 mL and may even cause death. The compound is a specific inhibitor of isovaleryl-CoA dehydrogenase, and isovaleric acid accumulates in the blood leading to depression of the central nervous system. The poisoning has a similar effect as human isovalericacidemia. ►**sovalericacidemia**

Jamm Domain (Jab1/MPN domain-associated metallo-peptidase): It has a functional role in the proteasome lid. ►**Jab**, ►**MPN**, ►**protease**, ►**metalloprotease**; Ambroggio XI et al 2004 PloS Biol 2:E2.

Jansky-Bielschowsky Disease: ►**ceroid lipofuscinosis**

Janus Kinases: These include Jak kinases and Tyk2; they are non-receptor tyrosine phosphorylating enzymes. ►**Jak**

Jarcho-Levin Syndrome: ►**spondylocostal dysostosis**

Jarovization (yarowization): ►**vernalization**

Jasmonic Acid ([\pm]-1 α ,2 β -[Z]-3-oxo-2-[2-pentenyl]cyclopentanecarboxylic acid): is a fatty acid derivative protease inhibitor in plants and an activator of stress response genes in case of infection or wounding. Furthermore it controls a number of developmental processes (see Fig. J3). Jasmonate regulates catabolism of amino acids in the gut of herbivores and plays a role in protection against insects (Chen H et al 2005 Proc Natl Acad Sci USA 102:19237). Around 20 jasmonates and their conjugates perform complex and far-reaching regulatory roles. Several genes have

been identified in the pathways. Jasmonate signaling appears to mediate long distance information transmission; systemic transcriptional response shares an extraordinary overlap with the local herbivory and wounding responses, indicating that jasmonates may be pivotal to an evolutionarily conserved signaling network that decodes multiple abiotic and biotic stress signals (Truman W et al 2007 Proc Natl Acad Sci USA 104:1075). JAZ proteins (jasmonate ZIM domain proteins) function as repressors of jasmonate signaling and are degraded through the SCF^{COI1}-dependent 26S proteasome pathway. Protein-protein interaction studies indicate that jasmonoyl-isoleucine (JA-Ile) specifically promotes COI1-JAZ1 interaction in the absence of other plant proteins (Thines B et al 2007 Nature [Lond] 448:661; Chini A et al 2007 Nature [Lond] 448:666). ►**plant defense**, ►**wound response**, ►**insect resistance in plants**, ►**SCF**; Seo HS et al 2001 Proc Natl Acad Sci USA 98:4788; Turner JG et al 2002 Plant Cell 14:S153; Gfeller A, Farmer EE 2004 Science 306:1515.

Jefferson, Thomas: President's paternity. ►**Y chromosome**

Jellyfish: <http://www.ucis.uci.edu/biochem/steele/default.html>.

Jervell and Lange-Nielsen Syndrome: This is 21q22.1-q22.2 and 11p15.5 recessive heart and auditory (deafness) syndrome. In the electrocardiograms the interval Q - T is prolonged. In this method the excitation of the heart atrium is denoted by the P wave, followed by the QRS complex of deflections

and excitations (depolarization) of the ventricles, and the T waves indicate the repolarization of the ventricles. Fibrillations (uncoordinated arrhythmia) of the heart atrial muscles are also observed as a consequence of deficiency of potassium and/or sodium ion channels. Sudden death may occur. ▶heart disease, ▶deafness, ▶electrocardiography, ▶LQT, ▶HERG, ▶Ward-Romano syndrome, ▶Beckwith-Wiedemann syndrome, ▶ion channels; Neyroud N et al 1997 Nature Genet 15:186.

Jesuit Model: There are more potential replicational origins than actually selected in eukaryotes. ▶replication bubble

Jews and Genetic Diseases: Common diseases among Askenazi Jews are Riley-Day syndrome, Tay-Sachs disease, Gaucher's disease, Niemann-Pick syndrome, diabetes mellitus, pentosuria, dystonia and colorectal cancer. About 1% of women carries deletions at various positions in the BRCA1 and BRCA2 breast cancer genes, Cohen syndrome, Canavan disease, pentosuria and PTA deficiency disease. Diseases that are rare in this group include juvenile form of Gaucher's disease, Glucose-6-phosphate dehydrogenase deficiency and, Bloom's syndrome. A common disease among *Sephardic Jews* is Mediterranean fever, whereas Tay-Sachs disease is uncommon. Among *Oriental Jews* of Persian origin, hypoaldosteronisms and Dubin-Johnson syndromes are relatively common. In Libyan Jewish populations, Creutzfeldt-Jakob disease is disproportionally common. There is no valid explanation for these differences in the incidence of diseases (gene frequencies). It has been suggested that genetic drift in small isolated populations may be the cause. The fact that most of these diseases are based on mutations at different sites within the respective loci is at variance with this argument. The high incidence of Tay-Sachs, Gaucher, and Niemann-Pick diseases involves lysosomes but how this could be the cause is unclear. Selective advantage of the heterozygotes, specific for these particular populations has also been considered. See diseases at separate entries, ▶Ashkenazim, ▶Sephardic, ▶human intelligence, ▶Amish, ▶founder principle, ▶evolutionary distance, ▶aspartoacylase deficiency, ▶ethnicity; Adam A 1973 Isr J Med Sci 9:1383; Ostrer H 2001 Nature Rev Genet 2:891; Risch N et al 2003 Am J Hum Genet 72:812.

JIL-1: A chromosomal kinase which may upregulate gene expression in the single Y chromosome of *Drosophila* male. ▶dosage compensation

Jimpy Mice: This is a special strain of mice with a lower rate of cerebroside synthesis resulting in neurological defects. ▶cerebroside

Jimson Weed: ▶*Datura stramonium* (see diagram of seed capsule) (see Fig. J4).

Figure J4. *Datura*

JIP: This is a JNK-interacting protein. ▶JNK

JNK (Jun amino terminal kinase): This kinase acts on the amino terminal of Jun oncogenes and other transcription factors. It is the same as SAPK. It belongs to the MAK family of protein kinases that are activated by stress (environmental stress, heat shock, tumor necrosis factor, etc.). SAPK appears to be inhibited by p21, a transforming protein. The activated JNK stimulates the transcriptional activity of AP1. The JNK interacting protein-1 (JIP-1) causes the retention of JNK in the cytoplasm and thus inhibits JNK-regulated gene expression. JNK signaling activates CD4 helper T cells (T_H), which during clonal proliferation release interleukins and become T_{H1} and T_{H2} effector cells and mediate inflammatory responses. JNK is also involved in the mitochondrial release of cytochrome c and the apoptotic path. Obesity increases JNK activity and JNK1 deficiency results in reduced adiposity and improves sensitivity to insulin (Tuncman G et al 2006 Proc Natl Acad Sci USA 103:10741). ▶aging, ▶SAPK, ▶MAPK, ▶p21, ▶p38, ▶T cell, ▶interleukins, ▶AP1, ▶Pyk, ▶JUN, ▶ATF2, ▶ELK, ▶NFAT, ▶MLK, ▶TRAF, ▶ASK1, ▶aspirin, ▶Ire, ▶apoptosis, ▶transdetermination, ▶insulin, ▶obesity; Davis RJ 2000 Cell 103:239; Bagowski CP, Ferrell JE Jr 2001 Curr Biol 11:1176; Weston CR, Davis RJ 2002 Curr Opin Genet Dev 12:14; Sabapathy K et al 2004 Mol Cell 15:713.

Jockey: ▶non-viral retrotransposable elements

Johanson-Blizzard Syndrome (JBS, 15q14-q21.1): This is a recessive pancreatic (UBR1) insufficiency disease characterized by nasal wing defect (aplasia), facultative scalp defects, imperforated (closed) anus,

deafness, hypothyroidism, dental defects, genitourinary malformation and generally mental retardation. In the absence of the UBR1 function intrauterine pancreatitis arises. The rate of prevalence is ~1/250,000. The UBR1 gene encodes at least four overlapping E3 ubiquitin ligases at the N-end rule pathway. ►ubiquitin, ►N-end rule, ►pancreatitis; Zenker M et al 2005 Nature Genet 37:1345.

Joining of DNA: ►ligase, ►blunt-end ligation, ►cohesive ends

Joint Probability: When two events are independent from each other, the probability of their joint occurrence can be obtained by multiplying the independent probabilities. The same rule also applies to more than two independent frequencies. Independence means that the occurrence of one has no bearing on the occurrence of the other(s). ►probability

Josephine Domain: This is a part of the ataxin-3 protein responsible for the neurodegenerative Machado-Joseph syndrome. Ataxin-3 functions as a polyubiquitin chain-editing enzyme as the Josephine domain is followed by an ubiquitin-interacting motif in spinocerebellar ataxia 3 (Mao Y et al 2005 Proc Natl Acad Sci USA 102:12700). ►Machado-Joseph syndrome; Nicastro G et al 2005 Proc Natl Acad Sci USA 103:10493.

Jost Factor: ►Müllerian inhibitory substance

Joubert Syndrome: Heterogeneous, autosomal recessive developmental defect of the human brain (cerebelloparenchymal disorder, cerebellar vermis agenesis) has been traced to human chromosome 9q34.3. The syndrome with oculo-renal defects was located to chromosome 11p12-q13.3 (Keeler LC et al 2003 Am J Hum Genet 73:656). Joubert and Meckel syndromes are associated with cilium dysfunction (Delous M et al 2007 Nature Genet 39:875). ►Meckel syndrome, ►cilia

Joule: 1 joule = 10^7 ergs, the energy expended per 1 second by an electric current of 1 ampere in a resistance of 1 ohm; approximately 0.24 calorie.

Juberg-Marsidi Syndrome: Xq12-q21 mental retardation, growth and developmental anomaly are based on mutation in a helicase. The same protein appears to be involved in X-linked α -thalassemia and mental retardation. ►thalassemia, ►mental retardation, ►ATRX

Judassohn-Lewandowsky Syndrome (pachyonychia congenita, PC1, 17q12-q21, 12q13): This is a hereditary recessive keratosis of the nails (onychogryposis), palm, sole and mouth. It is due to mutation in keratin 16. ►keratosis, ►ichthyosis

Judgment (iudicium): Denotes the power to arrive at a valid decision regarding facts that may not be fully understood. It is related to intuition, which means arriving at an understanding without conscious reasoning. Subjective expert judgment is the most important human quality in many areas of human activity. An important aspect of subjective judgment is its truth that can be assessed by Bayesian methods. ►Bayes' theorem; Prelec D 2004 Science 306:462.

Jukes-Cantor Estimate of Evolutionary Divergence: This is based on the number of nucleotide substitutions since the separation of two DNA sequences during evolution. $D = 2\alpha t$ where D = distance, α = the probability (p) that one nucleotide is replaced in time t . The separation in time $t = D/2\alpha$. ►evolutionary distance; Chen FC et al 2001 J Hered 92:481.

Jump Stations: A collection of links for genetic and biological information regarding databases, journals, news groups, etc. ►databases [general directories].

Jumonji: This is a catalytic domain of histone H3 demethylation. ►histone demethylation

Jumping Frenchman of Maine: This rare and obscure apparently autosomal recessive anomaly is characterized by very rapid emotional reactions.

Jumping Genes: These genes move in the genome because they are within transposons. ►transposable elements

Jumping Library: This is generated by circularizing large eukaryotic DNA fragments and cloning the junctions of the circle. The large fragments are obtained by using restriction enzymes that very rarely cut the DNA. ►chromosome jumping, ►linking library, ►slalom library, ►DNA library; Zabarovsky ER et al 1991 Genomics 11:1030.

Jumping Translocations: These involve one (donor) chromosome and multiple recipient chromosomes. Such unstable phenomena are common in cancers, mainly involving human chromosome 1. The break points are generally in regions of repetitions such as centromeric, telomeric and rRNA sequences. (See Levy B et al 2000 Cytogenet Cell Genet 88:25; Padilla-Nash HM et al 2001 Genes Chromosomes Cancer 30:349).

JUN (*jun*): The avian fibrosarcoma oncogene homolog JUN-A is in human chromosome 1p32-p31 and in mouse chromosome 4. Its homologs are present in other vertebrate species too and may be identical to a subunit of transcription factor AP-1. Along with the product of oncogene FOS, they activate several genes. The products of JUN and FOS are bound together with a leucine zipper and at their carboxyl

end they have a DNA-binding domain (5'-TGAGTCA-3'). They apparently form the C/EBP protein. JUN-B and JUN-D oncogenes are closely linked in mouse chromosome 8. JUN-B human homolog is in human chromosome 19p13.2. UV-irradiated mammalian cells may exit from the p-53 imposed block of the cell cycle by the induction of JUN. ▶AP1, ▶C/EBP, ▶oncogenes, ▶FOS oncogene, ▶JNK, ▶bZIP, ▶signal transduction, ▶de-etiolation, ▶UV, ▶psoriasis; Barr RK, Bogoyewitch MA 2001 Int J Biochem Cell Biol 33:1047.

Junction Complex: Refers to the assembly of various types of junctions (tight junctions, adhesion belt, desmosome) within cells. ▶gap junctions, ▶desmosome

Junction of Cellular Networks: These are integrators of molecular signals coming from different sources, and regulated by the interconnections. cAMP may represent such a *junction* because it is affected in a positive or negative manner by a variety of signals. Phosphokinase A as a *node* may then split the signals and directs them to multiple targets such as the cytoskeleton and cellular traffic, gene expression and cell growth, metabolism, ion channels, G protein-coupled receptors of signal transduction, and neuronal synapsis. Another example of a node is Cdc42, which receives signals through receptor tyrosine kinases (RTK) and G protein-linked receptors (GPCR) and then sorts them into serum response factor (SRF) and p21 activated kinase (PAK), S6 kinase affecting transcription, translation and cellular traffic. ▶signal transduction, ▶Cdc42, ▶RTK, ▶G proteins, ▶PAK, ▶S6 kinase, ▶coordinate regulation; Jordan JD et al 2000 Cell 103:193; McCarty DR, Chory J 2000 Cell 103:201; Vohradsky J 2001 FASEB J 15:864.

Junction Sequence: ▶introns

Junctional Diversification: When immunoglobulin genes are recombined to generate specific antibodies a few nucleotides may be lost or added to the recombining ends. ▶immunoglobulins, ▶antibody, ▶RAG, ▶combinatorial diversification; Wang C et al 1997 J Immunol 159:757.

Junctophilins: These are junctional membrane complex proteins. Junctophilin deficiency may lead to muscle and motor defects and Huntington's chorea type anomalies. ▶Huntington's chorea; Takeshima H et al 2000 Mol Cell 6:11; Holmes SE et al 2001 Nature Genet 29:377.

Jungles: These are chromosomal regions with a high frequency of recombination (genes). ▶deserts, ▶recombination by replication, ▶gene space

Juniper (*Juniperus communis*): This is an evergreen woody species, $2n = 22$.

Junk DNA: This term was coined in the 1970s to describe DNA that appeared without any obvious function such as some introns and spacers. It is now clear that several introns have maturase and other functions. Some of the non-coding DNA is interspecifically conserved, indicating some type of biological function. In animal chromosomes nearly 97% of the DNA is non-coding and this 'junk' DNA is predominantly intron material. Nowadays the term non-coding DNA is preferred. Contrary to earlier views, most of the bases in the DNA sequences are transcribed although all their functions are not yet known ▶ENCODE, ▶selfish DNA, ▶non-coding DNA, ▶trinucleotide repeats, ▶SINE, ▶LINE, ▶C value paradox, ▶TUF, ▶non-coding RNA, ▶antisense DNA, ▶antisense RNA; Wong GK-S et al 2000 Genome Res 10:1672.

Jurassic Period: Refers to a period nearly 190,000,000 to 137,000,000 years ago. During this period dinosaurs and reptiles were dominant although the ancestral forms of most vertebrates were also present and even primitive mammals had appeared.

Jurkat Cell Lines: These are derived from human T-cell leukemia and are used to study susceptibility to anti-cancer drugs and radiation.

Juvebione: ▶juvenile hormone

Juvenile Hormone: This is secreted in the larval state and prevents precocious metamorphosis into the pupal stage of the insect (see Fig. J5). The hormone has ethyl-polyprenyl components. Similar terpenes and terpene-related substances, e.g., juvebione (in balsam fir) and gossypol (in cotton) occur in plants and also affect the feeding insects. Synthetic hormones have been produced with similar physiological effects. ▶metamorphosis, ▶molting, ▶ecdysone, ▶pupa, ▶abscisic acid, ▶allostatin; Davey KG 2000 Insect Biochem Mol Biol 30(8-9):663; Gilbert LI et al 2000 Insect Biochem Mol Biol 30(8-9):614.

Figure J5. Insect juvenile hormone

Juvenile Mortality: Often this is a function of the consanguinity of the parents. One study, for example, noted that stillbirth and neonatal death was 0.044 if the parents were unrelated and 0.111 if the parents were first cousins (consanguinity 1/16), similarly

infant and juvenile death rates were 0.089 and 0.156, respectively. ► [coancestry](#), ► [inbreeding](#), ► [mortality](#)

Juvenile Onset: A hereditary condition appearing in childhood. ► [diabetes mellitus](#)

Juxtacrine Signaling: The membrane-anchored growth factors and cell adhesion molecules are signaled through juxtacrine mediators. ► [signal transduction](#)

JX₂ DNA: ► [PX DNA](#)

Historical vignettes

Peter Brian Medawar (cited by Colucci F et al 2002 Nature Immunol 3:807)

“The intensity of the conviction that a hypothesis is true has no bearing on whether it is true or not.”

Carl Wilhelm von Nägeli made an effort to convince Mendel about the insignificance of his experiments with peas because he felt it inconceivable that segregation in plants should obey statistical rules. Similarly, he was the founder and unbending adherent of the theory of pleomorphism of bacteria. According to this idea, bacteria did not have a stable heredity, but would change from one form to another by a change in the environment. Although Mendel's theory was not understood by his contemporaries, pleomorphism was subjected to serious criticism; yet von Nägeli's obvious influence definitely hampered bacteriology. Dr. W Migula, Professor at the College of Technology in Karlsruhe, gives a vivid account of the situation in his *System der Bakterien* (Fischer Vlg., Jena, 1897, p. 215):

“When Nägeli says, p. 20, that ‘Cohn [the founder of modern bacterial systematics in 1872] had established a system of genera and species, in which each function of the Schizomycetes [bacteria] is represented by a particular species; by this he expressed the rather widespread view exclusive to physicians. So far I have not come across any factual ground that could be supported by morphological variations or by pertinent definitive experiments.’ When Nägeli still says this in 1877, one must either assume that he was unaware of the work of the preceding 5 years, or that he chose to ignore it on purpose because it did not fit to his theory.”

K

K: ►kinase

K1: Non-nucleoidal methylation sites of *E. coli* transducer proteins, each spaced seven amino acid residues apart.

κ: ►symbionts, ►hereditary

κ Chain: ►immunoglobulins

K_a: ►dissociation constant

Ka: Thousand years before present time.

K_A/K_S: The ratio of non-synonymous and synonymous mutations. The former leads to amino acid replacement in the protein. The ratio indicates an adaptive change and it has been used to measure molecular evolution. It has been claimed that *Ka/Ks* is also strongly correlated with the mutation rate as measured by *Ks*, and that this correlation appears to have a similar magnitude as the correlation between *Ka/Ks* and selective strength. Thus the probability of correlation of fixation of non-synonymous codons and mutation rate may need reassessment of the use of *Ka/Ks* as a measure of molecular evolution (Wykoff GJ et al 2005 Trends Genet 21:381). Alternative splicing relaxes the *K_A/K_S* selection pressure in some cases by seven-fold and the same time increases the selection pressure against synonymous mutations, which in turn propagates into adjacent intron and strongly correlates with the level of alternative splicing of exons. Alternative splicing can generate evolutionary hot spots for proteins (Xing Y, Lee C 2005 Proc Natl Acad Sci USA 102:13526). *K_I* is the substitution rate within introns, *K₄* is the rate of synonymous substitution in fourfold degenerate sites. ►Grantham rule, ►molecular evolution, ►degenerate code, ►mutation beneficial, ►synonymous codon, ►alternative splicing, ►McDonald-Kreitman hypothesis; Navarro A, Barton NH 2003 Science 300:321, selection server: <http://selecton.bioinfo.tau.ac.il/>.

Kabat Database: ►immunoglobulins

Kabuki Syndrome (Niikawa-Kuroki syndrome): Mental retardation, eyelid defects, low stature, broad nasal tip, large earlobes, scoliosis, defective palates and other bone anomalies. Probably autosomal mutation is the major cause; deletions in chromosome 22q11.2, duplications in chromosome 1p13–1p22 and chromosome 8p23.1 have been reported. ►scoliosis; <http://www.orpha.net>.

KAI1: A prostate cancer antimetastasis gene at 11p11.2 (Dong J-T et al 1997 Genomics 41:25).

Kainate: Acyclic analog of glutamic acid that also forms a synaptic receptor. Kainate may be a neurotoxin and it is antihelminthic. (See Bailey A et al 2001 Eur J Pharmacol 431:305; Lauri SE et al 2001 Neuron 32:697).

Kairomones (allomones): Intraspecific and interspecific attractants similar to pheromones. ►pheromone, ►dodder

Kalanchoe: A bryophyllum of several species with chromosome numbers varying from 34 to nearly 300 among them. They have been used for studies of development and differentiation and had been a favorite subject for investigations of the effects of agrobacteria on plants. ►Agrobacterium

Kalilo: ►killer plasmids; Bok JW, Griffith AJ 2000 Plasmid 43(2):176.

K-Allele Model: Interprets mutation mechanisms. Accordingly there are *K* possible allelic states (at a gene or microsatellite) and each has a constant probability ($\mu/[K - 1]$) to undergo mutation to any of the other *K* – 1 allelic forms. In IAM *K* = infinite. ►IAM, ►SMM, ►TPM, ►microsatellite, ►minisatellite; Vitalis R, Couvet D 2001 Genetics 157:9111.

Kallikrein: Serine proteinases in the pancreas, saliva, urine, and blood plasma that cleave kallidin (a kind of kinin) from globulin and have a vasodilator and possibly some type of skin-irritating effect. (See Diamandis EP et al 2000 Trends Endocrinol Metab 11:54).

Kallmann Syndrome: Rare autosomal (8p11.2-p12, KAL2) recessive malfunction of the gonads resulting in infertility, lack of ability to smell (anosmia) and cleft palate and cleft lip. It is apparently caused by defects of the olfactory receptor neurons, in the steroid hormone receptor(s) and in the gonadotropin-releasing hormone neurons. There is also an X-linked (Xp22.3, KAL1) form of the disease. The autosomal form is about 5 times more common in males than in females. It has been suggested the X-linked 14 exons code for a cell adhesion (fibronectin) molecule. The KAL2 gene may control a fibroblast growth factor receptor, whereas KAL1 encodes a FGFR1 signaling molecule. ►FGF, ►infertility, ►hypogonadism, ►adrenal hypoplasia, ►gonadotropin-releasing hormone, ►olfactogenetics, ►N-CAM; Rugarli EI 1999 Am J Hum Genet 65:943; Dodé C et al 2003 Nature Genet 33:463.

Kam: ►K-allele model

Kammerer, Paul: Twentieth century Lamarckist who from 1905 reported hereditary changes in the coloration of salamanders and mid-wife toads by exposing the animals to yellow and dark backgrounds, respectively. The much-heralded experiments could not be confirmed under appropriate scrutiny and it turned out that the dark spots on the preserved specimens were marked by India ink rather than by genetic mechanisms. When the forgery came to light, Kammerer acknowledged the truth but denied personal fraud before committing suicide in 1926. The rumors were that an assistant or a janitor in Vienna, Austria played a practical joke on him. In the Soviet Union where he was invited as a professor, the withdrawal of his reports was never acknowledged because his claims were in line with the then current political dogmas. ▶[Lamarckism](#), Meinecke G 1973 Med Welt 24[38]:1462, in German.

Kanamycin (Km, kanamycin): An aminoglycoside antibiotic—synthesized by *Streptomyces kanamyceticus*—frequently used as a selectable marker in genetic transformation. Although some similar synthetic relatives of kanamycin are available, a specific mutant strain (12–6) of the bacterium has an amplified unit DNA (AUD), which may include more than 36 copies of the *Km* gene cluster of > 5.7 Mb and increased production (Yanai K et al 2006 Proc Natl Acad Sci USA 103:9661). ▶[antibiotics](#), ▶[antibiotic resistance](#), ▶[aminoglycoside phosphotransferase](#), ▶[transformation](#), ▶[genetic](#), ▶[vector](#), ▶[geneticin](#) (see Fig. K1).

KAP: Human phosphatase with specificity for Thr¹⁶⁰ in Cdk2. ▶[Cdk2](#)

Kaplan-Meier Estimator of Survival (product limit estimator): Calculated in steps for the periods of time

of the survivor numbers of a treated experimental population. The formula at the time of the first death (t_1): $(Y_1 - d_1)/Y_1$ where Y (Y_1) stands for the residual number of animals at risk and d (or in general term d_i) = the number of death. After the second death time (t_2), the formula is $([Y_2 - d_2]/Y_2)$ and so on until t_n , when it is $([Y_i - d_i]/Y_i)$. At each step, a fraction is obtained and by multiplying these fractions we obtain the survival estimate at t_n . The cumulative hazard $H_t = -\ln \Sigma(t)$. ▶[MTD](#), ▶[LD50](#), ▶[MELD](#), ▶[genetic hazards](#); Dubin JA et al 2001 Stat Med 20:2951.

Kapok (*Ceiba*): A Southeast Asian bamboo fiber tree, 2n = 72–88 with unknown basic chromosome number.

Kaposi Sarcoma (hemangiosarcoma): Indicated by red-purple nodules and plaques that become tumorous. Occurs due to autosomal dominant genes but is also an opportunistic tumor because it is expressed mainly when some types of infections, such as *Pneumocystis* microorganisms are present as in the case in the AIDS and other immunodeficiencies.

Herpes virus KSHV/HHV8 is generally present in the tissues in a latent form as episomes. In primary effusion lymphoma (PEL) cells KSHV encodes LANA (latency associated nuclear antigen). The kaposin B protein of KSHV increases the expression of cytokines by blocking the degradation of their mRNA, which normally would be labile. Kaposin binds to mitogen-activated protein kinase (MK2), a target of the p38 mitogen-activated protein kinase signaling pathway and an inhibitor AU-rich element containing mRNAs. This is one way of activation of the latent KSHV virus (McCormick C, Ganem D 2005 Science 307:739). In PEL, the LANA and KSHV are co-localized in dots of interphase nuclei and they are in a diffuse form on mitotic chromosomes. The higher frequency and aggressiveness of Kaposi sarcoma in AIDS is explained by the synergism between the cellular basic fibroblast growth factor (FGF) and the Tat enhancer protein of the virus. A novel herpes virus (HHV8/KSHV [Kaposi sarcoma associated herpes virus]) has also been blamed for causing the disease. The HHV8 infection seems to be mediated by an interaction between the RGD peptides of the viral envelope protein and $\alpha\beta 1$ integrins. The virus transactivates the promoter of the reverse transcriptase of the telomerase. The Kaposi sarcoma virus binds to nucleosomal surface of acidic H2A-H2B folded region through the first 21 residues of the LANA antigen (Barbera AJ et al 2006 Science 311:857).

Kar1: Yeast protein regulating nuclear migration (congression) during karyogamy. ►cell cycle

Kar2: Cytoplasmic assembly protein regulating nuclear fusion. ►Hsp70, ►Sec63, ►karyogamy

Kar3: An 84-kDa motor protein of the kinesin family in yeast operating in nuclear fusion and microtubule sliding prior to anaphase. ►kinesin, ►cell cycle, ►mitosis

Karmellae: Nuclear-associated endoplasmic reticulum membrane components (Koning AJ et al 2002 Genetics 160:1335).

Kartagener Syndrome (dextrocardia, 9p21, 7p21, 5p15): A complex recessive syndrome of left-right inverted location of major visceral organs, also involving lack of ciliary movement and sperm motility, and nasal polyps. The basic defect seems to involve mutation in axonemal intermediate chain of dynein (DNAI1) or in the heavy chain (DNAH5). ►situs inversus viscerum, ►asymmetry of cell division, ►axis of asymmetry, ►left-right asymmetry, ►dynein, ►asthenozoospermia; Guichard C et al 2001 Am J Hum Genet 68:1030; Olbrich H et al 2002 Nature Genet 30:143.

Karyogamy: Nuclear fusion in fungi following fusion of the cytoplasms of two cells, plasmogamy. The word καρβον means kernel, γαμειν means to marry. ►fungal life cycles

Karyogram: Depiction of the karyotype (see Fig. K2). ►karyotype

Figure K2. Karyogram of *Crepis parviflora*

Karyokinesis: Division of the cell nucleus. ►cell cycle, ►mitosis

Karyolymph: The fluid fraction of the cell nucleus in contrast to the particulate ones, for e.g., chromosomes. It is also called paralinin.

Karyopherin/importin (α and β): Cytosolic proteins that mediate nuclear traffic in cooperation with nucleoporin, with a GTPase and RAN. Importin- α (M_r 60 K) recognizes the nuclear localization sequences and importin- β (M_r 97 K) docks the nuclear pore complex. There are more than a dozen karyopherins in yeast and even more in higher eukaryotic cells. ►RNA export, ►nuclear pore, ►nuclear membrane, ►nuclear localization sequences, ►RAN, ►GTPase, ►importin, ►transportin, ►chromosome maintenance region 1, ►CAS, ►shRNA; Yoshida K, Blobel G 2001 J Cell Biol 152:729.

Karyoplast: Nucleus surrounded by only a thin layer of cytoplasm and membrane. ►cytoplast, ►transplantation of organelles

Karyosome: The mass of chromatin of the oocytes before metaphase of animal cells.

Karyotheca: Synonymous with nuclear envelope. ►nuclear membrane

Karyotype: Characteristics of a (mitotic) metaphase chromosome set by number, morphology, arm ratio, secondary constrictions, banding pattern among others. ►chromosome morphology, ►electrophoretic karyotyping, ►FISH, ►GISH

Karyotype Evolution: Chromosome number is an important characteristic of a species although identical number of chromosomes may not indicate any relationship (see Fig. K3).

The morphology of chromosomes and arm ratio are frequently used to assess similarities but substantial differences may exist within related groups and pericentric inversions may alter the relative position of the centromere. Centromere fusion and Robertsonian translocations may convert telocentric chromosomes into bi-armed ones. Misdivision may generate telocentrics from bi-armed chromosomes and change at the same time, the chromosome numbers. Paracentric inversions may serve the purpose of speciation and the sequence of change in the pattern of chromosome bands (in polytenic chromosomes or specially banded chromosomes) may be traced by the techniques of light microscopy. Translocations and other types of chromosomal aberrations may also be followed in related species. The similarities of the karyotypes can be assessed also on the basis of chiasma frequencies, if the species are closely related enough to permit meiotic analyses. FISH and GISH

Figure K3. Karyotype evolution in *Drosophila*. The haploid chromosome set in the subgenus *sophophora* of *Drosophila*. The lowest chromosomes are the X. Note the gradual fusion of the arms and chromosomes from left to right. The X chromosome of *D. anassae* probably evolved from that of *D. melanogaster* by a pericentric inversion. In *D. willistoni*, the small dot-like chromosome seems to be incorporated into the bi-armed X chromosome. (After Sturtevant AH 1940 Genetics 25:337)

are important tools of karyotyping. Chromosomal mapping of classical genetic markers or restriction fragments, sequence-tagged sites, RAPDs may also reveal the order of genes and nucleotide sequences and their evolutionary path. Karyotic changes (chromosome number and chromosome arm number) per evolutionary lineage per MY vary a great deal from 1.395 in horses to 0.025 in whales to 0.029 in other vertebrates (lizards, teleosts). ▶[chromosomal aberrations](#), ▶[inversion](#), ▶[misdivision](#), ▶[polytenic chromosomes](#), ▶[banding techniques](#), ▶[RFLP](#), ▶[RAPDs](#), ▶[sequence-tagged sites](#), ▶[polyploidy](#), ▶[evolution of the karyotype](#), ▶[fruit fly](#), ▶[FISH](#), ▶[GISH](#); Graphodatsky AS et al 2001 Cytogenet Cell Genet 92[3-4]:243, Yu K, Ji L 2002 Cytometry 48:202; Wang T-L et al 2002 Proc Natl Acad Sci USA 99:16156.

Kelch Motif: First detected in *Drosophila*. Kelch repeats have propeller-like motor function and regulate motion through intercellular bridges (Xue F, Cooley L 1993 Cell 72:681)

Kell-Cellano Blood Group (KEL): The KEL antigen is a 93-kDa membrane glycoprotein, associated with the cytoskeleton and it is encoded in human chromosome 7q32 area. Its precursor substance (Kx) is coded in the X chromosome (McLeod syndrome). Its mutation may cause “horny” appearance of the erythrocytes (acanthocytosis) and granulous inflammations in response to infectious and other factors (see Fig. K5). The frequencies of the KEL and Kx alleles in England were found to be between 0.0457 and 0.9543, respectively. ▶blood groups, ▶erythrocyte, ▶McLeod syndrome; Lee S et al 2002 J Biol Chem 276:27281.

Figure K5. Horny erythrocyte

Kelp: Large brown algae.

Kelvin: Temperature scale is used primarily in thermodynamics; $0^{\circ}\text{C} = 273^{\circ}\text{K}$; the conversion between the $^{\circ}\text{C}$ and $^{\circ}\text{K}$ is: $^{\circ}\text{C} = ^{\circ}\text{K} - 273$, e.g., $100^{\circ}\text{C} = 373^{\circ}\text{K}$ or $0^{\circ}\text{K} = -273^{\circ}\text{C}$

Kenaf (*Hibiscus cannabinus*): Warm-climate fiber crop; $2n = 2x = 36$.

Ken-Box: An amino acid sequence (KENXXN/D) in degradative proteins in either the N or C terminus. ▶ubiquitin, ▶proteasome; Chen F et al 2002 Proc Natl Acad Sci USA 99:1990.

Kennedy Disease (SBMA): A non-lethal spinal bulbar muscular atrophy, sensory deficiency, frequently with gynecomastia and impotence expressed primarily in adults. The recessive gene was mapped to Xq12. The basic defect is a CAG repeat increase (11–33 CAG in normal → 38–66 in SBMA) within the first exon of the androgen receptor (AR) in the spinal cord, brains stem and sensory neurons. Glucocorticoid receptor (GR) localizes the repeat into the nucleus. Deletion or mutation in the C-terminal of GR suppressed aggregation and nuclear localization. Surprisingly mutation in the DNA-binding N-terminal domain increased aggregation and nuclear localization by

GR. Female heterozygotes for the repeats in AR are not affected and males with AR deletions do not show SBMA although usually are sterile and somewhat feminized. Increase in size is more common when the transmission is by an affected male than by a carrier female. Longer repeats increase the severity of the symptoms. [This syndrome is not named after President Kennedy's back ailment.]. ▶atrophy, ▶neuromuscular disease, ▶androgen receptor, ▶gynecomastia, ▶fragile sites, ▶trinucleotide repeats, ▶spinal muscular atrophy, ▶testicular feminization, ▶dihydrotestosterone, ▶glucocorticoid, ▶dynein

Kennewick Man: The ~9,200 year old skeletal remains of a person found in 1996 in Oregon, USA (see Fig. K6). It represents perhaps the first humans in North America. These old relics reveal important anthropological features among them the worn-down teeth due to eating wild grains loaded with dust. (See Chatters JC 2001 Ancient Encounters Simon & Schuster, New York).

Figure K6. Kennewick man

Keratin: A protein of the surface layer of skin, hair, nails, hoofs, wool, feather and porcupine quills among others. Keratins may be high-sulphur, acidic matrix proteins or low-sulphur, basic fibrous proteins (see Fig. K7). These two types usually appear in pairs and are controlled in humans by autosomal dominant genes. Point mutation in keratin genes in human chromosomes 12 and 17 may lead to various epithelial anomalies. ▶keratosis, ▶cathepsin, ▶hair, ▶melanocortin; Gene therapy: Lewin AF et al 2005 J Investig Dermatol Symp Proc 10:47.

Figure K7. Keratin fibril

Keratitis: Autosomal dominant inflammation of the cornea.

Keratoma (hyperkeratosis): Formation of keratoses on the palms and other parts of the body. Palmoplantar keratoderma (17q12-q21) is dominant epidermolytic condition due to mutation in the keratin 9 gene has potential carcinogenic consequences. Another

palmoplantar keratoma (12q11-q13) is frequently elicited by fungal infection and it is not causing epidermolysis. Striate palmoplantar keratoderma was located to 18q12.1-q12.2. Desmoplakin (6p24) mutation is responsible for striate II keratoderma. ▶keratosis, ▶Mal de Maleda

Keratosis: Either a wart-like flat or emerging (scaly) spot(s) that may become cancerous or soft friable (sometimes colored), non-invasive benign skin lesion. Both may have a number of different forms and are under the control of autosomal dominant genes. These skin lesions generally appear during adulthood but some start in very early childhood and develop progressively and may be the signals of more serious conditions (see Fig. K8). Sunburn may lead to keratosis and squamous cell carcinoma if mutation occurs in p53. ▶skin diseases, ▶psoriasis, ▶ichthyosis, ▶Darier-White disease, ▶Judasohn-Lewandowsky syndrome, ▶Jackson-Lawler syndrome, ▶pachyonychia, ▶intermediate filaments, ▶FGF, ▶dyskeratosis, ▶p53

Figure K8. Keratosis on forehead (a), on leg (b). (M. Rédei, unpublished)

Kerma: Kinetic energy released to the medium upon irradiation.

Kermit: *Drosophila* transposable element (4.8 kb). ▶copia

Kernel: A “seed” (grain) covered by the pericarp (fruit) and not just with the seed-coat, such as a wheat or maize kernel; in barley it may also have glume (husks) attached (see Fig. K9).

Kernels: Regulatory subcircuits conserved in several developmental batteries of genes, representing the oldest networks of differentiation.

Kernicterus: A severe form of jaundice, afflicting the brain. ▶Icterus, ▶Crigler-Najjar syndrome

Ketoacidosis: Occurs in several human diseases when ketones accumulate due to a defect in succinyl-CoA, 3-ketoacid CoA-transferase, in diabetes mellitus, in Gierke’s disease (Type I glycogen storage disease), in

Figure K9. Wheat kernel

glycinemia, in methylmalonic aciduria and in lactic aciduria. ▶individual entries

Ketogenic Amino Acids: These include tryptophan, phenylalanine, tyrosine, isoleucine, leucine, lysine, which can serve as precursors of ketone bodies (acetoacetate, D-3-hydroxybutyrate, acetone) formed primarily from acetyl coenzyme A if fats are degraded. ▶Amino acid metabolism

Ketone: Closely resembles aldehyde; both have the same unsaturated carbonyl group (see Fig. K10).

Figure K10. Keto group

Ketose: Monosaccharide with the carbonyl group being a ketone, such as fructose.

Ketosis: A condition with accumulation of ketone bodies, e.g., in diabetes mellitus.

The C = O group is generally joined to two other C atoms in the ketone bodies. ▶ketone

Ketotic: Showing ketosis. ▶ketosis

Ketothiolase: ▶methylacetoaceticaciduria

Keutel Syndrome: A human chromosome 12p12.3 area recessive defect involving lung, hearing, cartilage, and face. The gene encodes an 84-amino acid transmembrane protein MGP with a 19-amino acid signal peptide. It belongs to the family of extracellular matrix proteins. In all these proteins γ-carboxyglutamic acid is found. This residue potentiates high affinity for Ca, PO₄ and hydroxyapatite crystals and calcification of the extracellular matrix. ▶extracellular matrix, ▶Singleton-Merten syndrome

KeV (kilo electron volt): 1,000 electron volts. ▶electron volt

Keyhole Limpet Hemocyanin (KLH): A carrier protein (from *Megathura crenulata*) that can be linked to synthetic amino acid sequences with 12 to 15 hydrophobic residues through an NH₂ or COOH-terminal cysteine. The synthetic peptides can be used to raise antisera against them and these may be advantageous because their recognition is independent of the conformation of the whole protein.
 ▶antiserum, ▶monoclonal antibody, ▶hemocyanin

Key-Lock Theory: Enzymes are rigid molecules that can accommodate the substrate in the manner of jigsaw puzzles in contrast to the induced fit theory.
 ▶induced fit

KGK (keratocyte growth factor): Involved in epithelial cell development in wound repair.

KGMV (known genes with maximum variants): ▶duplication

KH Module: The K homology motif is present in the heterogeneous nuclear ribonuclear protein (RNP) K, protein, ribonuclease P, the Mer splicing modulator of yeast and the fragile X product. A common feature of these domains is the binding of single-stranded RNA.
 ▶FMR1, ▶hnRNA, ▶ribonuclease P, ▶splicing, ▶fragile X; Splicing Grishin NV 2001 Nucleic Acids Res 29:638.

KID: Kinase-inducible domain in transcription factors.
 ▶transcription factors, ▶CREB, ▶kinase

KID Syndrome: Ichthyosiformis erythroderma, deafness, and liver disease. ▶erythroderma

Kidd Blood Group (Jk): Apparently associated with human chromosome 18q11-q12. The frequency of the Jk^a allele in the world appeared to be 0.5142 and that of the Jk^b 0.4858. ▶blood groups

Kidney Diseases: Possibly caused by various environmental and genetic factors. ▶Urogenital dysplasia, ▶polycystic kidney disease, ▶renal dysplasia and retinal aplasia, ▶renal dysplasia and limb defects, ▶renal hepatic-pancreatic dysplasia, ▶renal tubular acidosis, ▶nephrosis, ▶nephrosialidosis, ▶nephritis, ▶kidney stones, ▶glomerulocystic kidney disease hypoplastic familial, ▶diabetes insipidus, ▶Bardet-Biedl syndrome, ▶Alport syndrome, ▶nephritis familial, ▶nephropathy juvenile hyperuricemic, ▶oncocytoma, ▶Addison disease, ▶glomerulonephritis, ▶renal cell carcinoma, ▶hypernephroma, ▶kidney stones, ▶glomerulonecrosis, ▶glomerulosclerosis focal and segmental familial, ▶Dent disease, ▶Fraser syndrome, ▶Goodpasture syndrome, ▶nephrolithiasis, ▶hypouricemia, ▶xanthinuria, ▶nephrotic syndrome, ▶steroid resistant, ▶Meckel syndrome

Kidney Stones (nephrolithiasis): Accumulation of primarily oxalate crystals in the kidneys caused by intestinal malabsorption of dietary salts. Polygenic and autosomal dominant control have been claimed to be responsible, although one form appears to be X-linked recessive (Xp11.22). In the X-linked form the defect is caused by various mutations in an outwardly rectifying chloride ion channel. The SLC26A6 (9p13) anion exchanger mediates Cl⁻-oxalate exchange and its defect leads to reduced intestinal oxalate secretion and increased net oxalate absorption causing bladder stones (urolithiasis). ▶kidney diseases, ▶ion channel, ▶Dent disease, ▶nephrolithiasis; Jiang Z et al 2006 Nature Genet 38:474.

KIF: A motor protein superfamily. KIF in cooperation with AP1 and other proteins facilitate vesicular transport between organelles ▶AP1, ▶kinesin, ▶midzone, ▶microtubules; Nagai M et al 2000 Int J Oncol 16:907.

Killer Cells (NK, natural killer cell): Parts of the immune system; Killer cells are large granular lymphocytes. They cooperate with other elements of the defense system to eliminate foreign organisms. The natural killer cells mount a cytotoxic reaction against invaders without prior sensitization. Similar to other lymphocytes, they kill some virus-infected cells and tumor cells. NK and CTL type T cells produce perforin, which organizes access channels on target cell membranes through which the destructive granzyme A complex is delivered. The killer cells are protected from self-destruction by means of cathepsins, which prevent perforin function on the self-membranes and thus the re-entry of granzymes (Kithiganahalli N et al 2002 J Exp Med 196:493). NK cells are controlled (inhibited) by MHC receptors, specific for Class I molecules of the major histocompatibility complex (Kim S et al 2005 Nature [Lond] 436:709). The NK cells do not express conventional receptors for antigens but their triggering is carried out by the surface molecules NKp46 (activating natural killer receptor p46, human chromosome 19), NKp30 (lymphocyte antigen 117, 6p21.3-p21.1) and NKp44 (lymphocyte antigen 95 [LY95], human chromosome 6) that are the natural cytotoxicity receptors (NCR). This system is coupled with signal transducers such as CD3ζ, FcεRIγ and KARAP/DAP12 (killer cell-activating receptor-associated protein). The MIC proteins select the targets for destruction. The MICA/B proteins in association with NKG2D protein are a part of the NK cell receptors and in association with other proteins (DAP10 [19q13.1], p85 [5q13], p110 [5q13]) activates killing by NK cells. 2B4 (1q22) and NKG2D (12p13.2-p12.3) appear to be co-receptors. NK cell may kill allogeneic cells because of the

absence of the autologous MHC molecules and cells that display different antigens because of viral infection. Human NK Class I receptors consist of an immunoglobulin domain containing lysine in the transmembrane section, whereas in mice the transmembrane portion of receptors resemble C type lectins. The lectin-like heterodimer CD94/NKG2 recognizes HLA-E molecules. The killer cell inhibitory receptors (KIR, human chromosome 19q13.4) recognize HLA-B (KIR3D) or HLA-C (KIR2D). The inhibitory receptors are characterized by ITIM (immunoreceptor tyrosine-based inhibitory motif) motifs. The ITIMs are phosphorylated but can attract and activate tyrosine phosphatases resulting in suppression of the cytotoxic function of the NK cells. Those cells, which have short receptors (without ITIM) remain phosphorylated and are killers. In case ITIMs are lacking or unavailable, proteins with ITAM (immunoreceptor tyrosine-based activation motif) can be phosphorylated by ZAP-70 and Syk kinases and thus become activated. One such ITAM protein is DAP12 ($M_r = 12$ K, 19q13.1). DAP12 also binds a killer cell activating receptor (KIR2DS2). The activity of the NK cells is increased by the secreted interferons, especially by γ interferon but IFN γ provides protection for normal cells against NKs. The NK cells secrete also chemokines MIP-1 α and RANTES. The NK cells usually cooperate with the cytotoxic T cells (CTL). They are often referred to as “non-MHC-restricted” cells because they can attack even cells that do not express MHC. The outermost layer of the human placenta lacks class I and class II MHC proteins and this is sufficient to protect the hemiallogeneic fetal cells against T cells but this would not, however, protect from NK killer cells. The trophoblast cells (extraembryonic ectodermal tissue) in contact with the placenta (the tissue connecting the maternal and fetal system) express the HLA-G class I molecules and this is sufficient to protect the pregnancy from some adverse immunological reaction. There are also mononuclear killer cells that have antibody-dependent cellular cytotoxic ability. Herpes viruses may produce MHC class I homologs that may interfere with NK-cell defense systems. ►antibody, ►immune system, ►CD1, ►lymphocytes, ►T cells, ►blood cells, ►allogeneic, ►autologous, ►lectin, ►cytotoxic T cells, ►HLA, ►MHC, ►anomalous killer cell, ►NKT cells, ►monocyte, ►ZAP-70, ►Syk, ►caspase, ►p85, ►p110, ►DAP, ►Mic-1 α , ►MICA/B proteins, ►RANTES, ►ITAM, ►ITIM, ►missing self hypothesis; Brown MG et al 1997 *Immunol Rev* 155:53; Biron CA et al 1999 *Annu Rev Immunol* 17:189; Guidotti LG, Chisari FV 2001 *Annu Rev Immunol* 19:65; Moretta A et al 2001 *Annu Rev Immunol* 19:197; Raulet DH et al 2001 *Annu Rev*

Killer Genes: A well-known example of the antimorphic *killer of prune* mutations (*awd*^K, *abnormal wing disc*; at end the long arm of chromosome 3) in *Drosophila*, which are viable as homo- or hemizygotes but exert dominant killing effects on most of the hemizygous (male) third instar recessive *prune* mutations (*pn*; 1–0.8). The *awd* gene encodes a nucleoside diphosphate kinase and displays very high homology with the human gene(s) NM23 (17q22) which encode(s) metastasis inhibitor protein(s) and is detectable at reduced levels in several malignant cancers. The *prune* alleles encode a 45-kDa protein and control a lower level of pteridine (drospterin) pigments in the eye resulting in brownish rather than reddish color of the wild type. Some mutant *prune* alleles do not respond lethally to the *awd*^K mutations, others respond only in a temperature-sensitive manner and some are lethal. The biochemical mechanism of the lethal interaction between *pn* and *awd*^K is not clear. (See *Adv Genet* 35:207, Timmons L & Sheran S 1997, ►pollen-killer, ►killer plasmids, ►drospterin, ►temperature-sensitive mutation, ►medea factor, ►dosage compensation).

Killer Plasmids: The mitochondrial *kalilo* plasmid (8.6-kb) has 1,338-bp inverted terminal repeats in *Neurospora intermedia* from Hawaii. At the 5'-end it is covalently linked to a 120-kDa protein. The plasmid has two, non-overlapping, opposite orientation open reading frames. ORF1 codes for a RNA polymerase (homologous to that of phage T7) and ORF2 is a DNA polymerase gene. Integration of this kalDNA into the mtDNA causes senescence and death because it builds up at the expense of the normal mtDNA. It is transmitted in heterokaryons. The *maranhar* plasmid is prevalent in *Neurospora crassa* from South Asia. In function, *maranhar* is similar to *kalilo* although the proteins encoded are substantially different. In prokaryotes several killer systems are known. In plasmid of R1 group at least 13 *hok/sok* genes have been identified that kill cells which do not carry the plasmid. ►hok-sok-mok, ►killer strains, ►mitochondrial genetics, ►mitochondrial plasmids, ►senescence, ►mitochondrial disease in humans, ►pollen killer, ►plasmid maintenance; Schaffrath R, Meacock PA 2001 *Yeast* 18:1239.

Killer Strains: Killer strains of *Paramecium* harbor symbionts, which release toxins lethal to sensitive strains. Bacteria harboring colicinogenic plasmids may destroy colicin-sensitive strains. In yeast the double-stranded RNA viruses, L (4.6-kb) and M (two 1.8-kb dsRNA) result in the production of a killer

toxin, affecting sensitive strains. These two viruses occur together because only the L strain encodes the capsid protein whereas the actual toxin is encoded by the M genome. L and M do not exist outside the cells and are transmitted during mating. In some insects *Wolbachia pipientis* bacterial infection of the males kills all the offspring sired by these males. ▶ *Paramecia*, ▶ *symbionts*, ▶ *hereditary*, ▶ *colicins*

Killer Toxin: Secreted by many yeast cells. The producer cells themselves are immune to the toxin, but on the sensitive strains, a pore is bored and that kills the cells. The K1 killer strains contain two double-stranded RNA viral genomes: the M₁ dsRNA is 1.8-kb encodes the toxin (42-kDa) and the immunity substance precursors and the larger L-A dsRNA (4.6-kb) replicates and maintains M₁. These virus-like particles are transmitted during cell divisions and mating. Several genes are required for the maintenance of MAK (maintenance of killer), SKI (super-killer), KEX (killer expression, endopeptidase and subtilisin-like proteins), KRE (killer resistance) affects cell wall receptors and function of the killer state. The viral killer toxin, TOK1 activates plasma membrane potassium channels. ▶ *colicins*, ▶ *Paramecium*, ▶ *subtilisin*, ▶ *killer virus of yeast*

Killer Virus of Yeast: It has double-stranded satellite RNA as genetic material. Diploid cells of a/α mating type with the M dsRNA segment produce a protein toxin, which is lethal to non-infected cells but not to the infected cells and therefore are denoted as K⁺ (killer) and R⁺ (resistant) whereas the cells without this viral segment are K⁻ and R⁻. The killer and resistance substance are produced by different processing of the same gene (*KIL-d*) product. The killer can be M1 or M2 type and the two are mutually incompatible (exclusion) and usually M1 prevails. The yeast cells generally contain also a L-A dsRNA or a somewhat different helper viral genome. The a or the α cell display defective killer variegation. After mating *KIL-d* × *KIL-d* haploids the killer phenotype seems to “heal” in the diploids but in the haploid progeny of these diploids, the variegation reappears even as the defect remains mitotically stable. The “healing” seems to be the epigenetic result of the nuclear fusion and it is evoked apparently by the viral RNA. The *KIL-d* elements have prion-like properties. ▶ *killer toxin*, ▶ *mating type determination in yeast*, ▶ *prion*; Sesti F et al 2001 Cell 105:637.

Kilobase (kb): 1,000 bases in nucleic acids.

Kin Selection: In general, natural selection favors the survival of the fittest individuals. In some instances, this principle may not be so obvious because of altruism supports individuals for the benefit of the population that share their genes. Selfless females

may sacrifice themselves to predators in attempts to rescue their multiple offspring. In social insects (bees, ants, termites) only the queens and selected males reproduce yet the workers and soldiers of the colonies protect the reproductive individuals even at the cost of their life. The fitness of these non-reproducing castes is measured by the success of their mating sibs. Actually, the survival of their genes is assured indirectly through these reproducing individuals. It is nepotism, motivated by natural selection. Kin selection may be in conflict with competition under certain environmental factors (Griffin AS et al 2004 Nature [Lond] 430:1024). Olfactory stimuli frequently play a role in kin recognition. The birds (long-tailed tits, *Aegithalos caudatus*) recognize kins by vocalization learned from adults during nesting (Sharp SP et al 2005 Nature [Lond] 434:1127). ▶ *altruistic behavior*, ▶ *selection*, ▶ *fitness*, ▶ *inclusive fitness*, ▶ *male-stuffing*, ▶ *olfactogenetics*, ▶ *green beard*; Agrawal AF 2001 Proc R Soc Lond B Biol Sci 268:1099.

KIN28: A cyclin-dependent kinase of *Saccharomyces cerevisiae*; it phosphorylates the C terminal domain of RNAP II to facilitate transcription. ▶ *CDK*, ▶ *RNAP*

KinA, KinB: *Bacillus subtilis* kinases affecting sporulation regulatory proteins SpoA and SpoF, respectively. ▶ *sporulation*

Kinase: Enzyme that joins phosphate to a molecule. Genes encoding kinases and phosphatases may represent up to 15% of the genome controlling certain developmental pathways. Phosphorylation/dephosphorylation may alter the structure/activity of proteins. Some cellular responses evoked only by multiplex inhibition of kinase function (Kung C et al 2005 Proc Natl Acad Sci USA 102:3587). In the human genome 551 genes encode protein kinases and 152 encode non-protein kinases. Of these genes, 270 were cloned and characterized (Park J et al 2005 Proc Natl Acad Sci USA 102:8114). In yeast, 122 protein kinases were assayed that phosphorylated 1,325 proteins. Some kinases acted on only one protein while others were credited by 256 phosphorylation events. Transcription factors were the largest classes of proteins subject to phosphorylation. Kinases play important role in signal transduction and may be associated with target genes (Pokholok DK et al 2006 Science 313:533). Protein chips monitored the phosphorylations and the results permitted the

construction of phosphorylation maps (Ptacek J et al 2005 Nature [Lond] 438:679). ►protein kinases; Bauman AL, Scott JD 2002 Nature Cell Biol. 4[8]: E203; Cheek S et al 2002 J Mol Biol 320:855; Kinase pathways: <http://kinasedb.ontology.ims.u-tokyo.ac.jp:8081/>; Kinases of the human genome: <http://www.itb.cnr.it/kinweb/>; Protein kinase-specific site predictor: <http://kinasephos2.mbc.nctu.edu.tw/>.

Kindler Syndrome (KIND1, 20p12.3): A rare, recessive neonatal blistering, sensitivity to sunshine, abnormal pigmentation, atrophy caused by loss of a membrane associated protein that apparently links the actin cytoskeleton to the extracellular matrix. ►cytoskeleton, ►extracellular matrix, ►skin diseases; Siegel DH et al 2003 Am J Hum Genet 73:174.

Kindred: A group of biological relatives with a determined pedigree. ►pedigree analysis

Kinectin: Membrane protein, binding intracellular vesicles to kinesin. ►kinesin

K

Kinesin: A cytoplasmic protein involved in moving vesicles and particles along the microtubule plus end; it assists segregation of chromosomes and transport of organelles (endosomes, Golgi complex, lysosomes, mitochondria, nerve axons) by using energy derived from ATP hydrolysis (see Fig. K11). The ca. 380-kDa NH₂ domain has the motor function whereas the COOH terminus probably binds to organelles or microtubules. The kinesins consist of two 120-kDa heavy chains and two 64-kDa light chains arranged in two (10-nm) globular ends, connected by linear molecule either N- or C-terminal or in the middle. Some kinesins may move in either plus or minus direction on the microtubules. The motor function may also be at different sites of the sequences with a total length of 80-nm. For each 8-nm step of movement kinesin hydrolyzes one molecule of ATP. The movement is either by the “hand-over-hand” or by the inchworm model. Movement by kinesin can also reverse direction (Carter NJ, Cross RA 2005 Nature [Lond] 435:308). Kinesins belong to the KIF family of motor associated proteins. Kinesin motors transport cargo vesicles toward the plus-end of the microtubules. The Ncd, minus-end-directed motor proteins facilitate the segregation of chromosomes. ►myosin, ►dynein, ►kinectin, ►cilia, ►centrosome, ►microtubules, ►axon, ►endocytosis [endosome], ►lysosome, ►golgi, ►dynein, ►bimC, ►monastrol, ►inchworm model, ►Hand-over-hand model; Kikkawa M et al 2000 Cell 100:241; Kikkawa M et al 2001 Nature [Lond] 411:439; crystal structure: Nitta R et al 2004 Science 305:678; Awsbury CL 2005 Current Opin Cell Biol 17:89.

Figure K11. Kinesin

Kinetic Complexity: Measured by the reassociation kinetics of denatured DNA; the increase in complexity (large number of unique diverse sequences) requires longer time for re-association. ►c₀t curve, ►kinetics

Kinetics: Analysis of reaction rates. The reactions may run to completion or may remain incomplete. *0 order* of the reaction kinetics indicates that the velocity of the process is constant and independent from the initial concentration of the substrate (see Fig. K12). *First order* kinetics indicates that only one substrate is involved (monomolecular reaction). Mutation rates and terminal chromosomal deletions below a certain dose of mutagens or clastogens also follow first order kinetics. 2nd order kinetics indicates bimolecular reactions and ionizing radiation-caused chromosomal rearrangements (inversion, transposition, translocation) may also be in this category.

Figure K12. Reaction kinetics: Dose (concentration) plotted against time. The 0, 1st, 2nd, 3rd order kinetics are marked on the curves

Multiple order kinetics may be involved with more than two reacting factors. ►radiation effects, ►LET, ►clastogen, ►DNA repair

Kinetin (6-furfurylaminopurine): A cytokinin plant hormone (see Fig. K13). ►plant hormones

Figure K13. Kinetin

Kinetochore: The structural protein part of the centromere where spindle fibers are attached. Cdc42 regulates the process. The kinetochore is an assembly of more than 50 different proteins (Hauk S, Watanabe Y 2004 Cell 119:317). A synthetic lethal and synthetic dosage lethal screen in yeast identified 211 genes controlling kinetochore function (Measday V et al 2005 Proc Natl Acad Sci USA 102:13956). Ndc80 is an essential 4-unit heteromeric component of the budding yeast kinetochore forming ~570-Å long rod with globular ends (see Fig. K14). The Ndc80 kinetochore complex is shown in a cartoon below redrawn after Wei RR et al 2005 Proc Natl Acad Sci USA 102:5363.

Figure K14. Four of the kinetochore proteins

The kinetochores associate with the microtubules that connect the chromosomes with the spindle pole. The interaction between the kinetochores and the spindle fiber microtubules requires the centromere binding factor CBF3 complex and is subject to regulation by Ipl1, the budding yeast Aurora B kinase, and the counteracting phosphatase PP1/Glc7. Besides CBF3 a complex of two chromosomal passenger proteins, Bir1/Survivin and Sli15/INCENP, connects CBF3-CEN DNA to microtubules in vitro. This connection is independent of Ipl1, and Bir1 and Sli15 control the activation and targeting of the process (Sandall S et al 2006 Cell 127:1179).

When yeast mutants *mec-1* or *rad53* (corresponding human genes are ATM/ATR and Chk-like kinase) are treated with replication inhibitors, replication integrity fails and the chromosomes are partitioned unreplicated because the checkpoint deficiency leads to deregulation of the microtubule-associated proteins Cin8 and Stu2 and cause premature separation of the chromosomes (Krishnan V et al 2004 Mol Cell 16:687). These microtubules pull then mitotic/meiotic chromatids/chromosomes to the

opposite poles. The plus end of the microtubules interact with the kinetochore and at that end with the protein Dam1 complex and forms a 16-fold symmetry ring around the microtubules. Depolymerization of the microtubules generates the force required to move the chromosome during anaphase toward the poles (see Fig. K15). Figure K15 was redrawn after the more precise electron micrographs of Westermann S et al 2006 Nature [Lond] 440:565. During meiotic anaphase the two sister chromatids are pulled to the same pole because the Mam1 subunit of the monopolin protein complex is tightly bound to the Hrr25 casein kinase and this complex is attached to one pole only. During mitosis the kinetochore attachment is bipolar and the sister chromatids are separated by the microtubules (Petronczki M et al 2006 Cell 126:1049). During interphase microtubule-kinetochore association does not exist. In *Schizosaccharomyces pombe* the formation of the spindle takes about 1.5 min at 36° C whereas its elongation takes about 6.2 min. ▶Roberts syndrome, ▶CENP, ▶SKP1, ▶MTOC, ▶SPB, ▶ATM, ▶ATR, ▶Chk1, ▶centromere, ▶neocentromere, ▶microtubules, ▶Cdc42, ▶cell cycle, ▶mitosis; Skibbogens RV, Hieter P 1998 Annu Rev Genet 32:307; Kitagawa K et al 1999 Mol Cell 4:21; He X et al 2001 Cell 106:195; Tanaka TU et al 2002 Cell 108:31; Shimoda SL, Soplomon F 2002 Cell 109:9; Kinetochore–spindle review: Kline-Smith SL et al 2005 Current Opin Cell Biol 17:35; yeast kinetochore: Westermann S et al 2007 Annu Rev Biochem 76:563.

Kinetoplast: The mitochondrial DNA in some protozoa (*Trypanosoma*) is organized into kDNA (kinetoplast DNA), concatenated circular molecules. The ca. 20–50 copies of the *maxi-circular* genome (22-kbp) resemble the mtDNA of other species; the heterogeneous 5,000 to 10,000 copies of the *minicircles* are 0.5–2.8-kbp and represent about 95% of the kDNA. The sum of kDNA constitutes 7–30% of the total cellular DNA in the different *Trypanosoma* and *Leishmania* species. The maxicircle transcripts are subject to editing by adding or (rarely) by subtracting uridine from the primary transcript. Such editing, called also pan-editing, may cause some of the edited transcripts to have more than 50% uridine. The gene,

which encodes the transcript and subject to pan editing, is called a *cryptogene* because the sequences of the original transcripts are almost concealed by this process. In the minicircles short (50–100 base) sequences (guide RNA [gRNA]) remain complementary to the edited RNA. The kDNA may have major role in the life cycle of the protozoon while it is in the insect gut but not in the mammalian blood. The edited RNA of cytochrome bc₁ is translated. In Chagas disease, the kDNA can integrate at several sites of the host DNA and then be inherited. Particularly favorite targets for integration are the β -globin locus and the LINE-1 transposons (Nitz N et al 2004 Cell 118:175).

 ▶acquired immunodeficiency, ▶retroviral recombination

Figure K16. Kissing loop

KIT Oncogene: A homolog to the viral *v-kit* gene of a feline sarcoma. It is in human chromosome 4q12 and in chromosome 5 of the mouse. This proto-oncogene codes for transmembrane tyrosine kinase with homology to CSF1R and to PDGF. The KIT gene was assumed to be responsible also for piebaldism in humans and mouse. KIT also signals to spermatogenesis and oogenesis. Gastrointestinal stromal tumors may also be caused by gain-of-function mutations in the c-KIT gene. The receptor for the KIT appeared to be encoded by the *W* (*white*

fur) and the PDGF genes of mice, located to about the same or identical chromosomal site as the KIT homolog. The KIT/stem cell factor receptor is involved in hematopoiesis, melanogenesis and gametogenesis. Stem cell factor proliferation depends on phosphatidylinositol-3'-kinase (PIK). Mutation in the PIK binding site causes male sterility but no female sterility. Another mouse locus, *Sl* (*Steel*) encodes MGF (mast cell growth factor), a ligand for the growth factor receptor. The KIT oncogene product is required also for the phasic contraction of the mammalian gut and the control of hematopoietic cells. ▶piebaldism, ▶microphthalmos, ▶CSF1R, ▶PDGF, ▶oncogenes, ▶transmembrane proteins, ▶tyrosine kinase, ▶FLT, ▶hematopoiesis, ▶mast cells, ▶gain-of-function mutation, ▶stem cell factor, ▶PIK, ▶receptor tyrosine kinase, ▶CD117; Smith MA et al 2001 *Acta Haematol* 105:143; Kitamura Y et al 2001 *Mutation Res* 477:165; Heinrich MC et al 2003 *Science* 299:708.

KIX: The CREB-binding domain of CBP. ▶CBP, ▶CREB

Kjeldahl Method: Determines total nitrogen content in organic or inorganic material after hot sulfuric acid digestion in the presence of a catalyst (Se, Hg). After titration of the distilled ammonia in the presence of phenolphthalein, 1 mL 0.1N H₂SO₄ bound by the ammonia corresponds to 0.0014 g nitrogen, and the amount of nitrogen multiplied by 6.25 estimates protein content. ▶Lowry method, ▶Bradford method [for protein].

KL: A male fertility complex in the long arm of the Y chromosome of *Drosophila melanogaster*. ▶sex determination, ▶KS, ▶*Drosophila*

Klebsiella: A gram-negative, facultative anaerobic enterobacterial genus (closely related to *E. coli*) with several species, widely present in nature (including hospitals) and capable of causing urinary and pulmonary (lung) and wound infections but it has the desirable feature of fixing atmospheric nitrogen. ▶nitrogen fixation

Kleiber's Rule: ▶size

Kleinsins: Eukaryotic and prokaryotic proteins that interact with structural maintenance proteins of the chromosomes ▶SMC; Schleiffer A et al 2003 *Mol Cell* 11:571.

Klenow Fragment: The large fragment of bacterial DNA polymerase I lacking 5'-to-3' exonuclease activity (located in the small fragment of the enzyme) but retaining the 5'→3' polymerase and the 3'→5' exonuclease functions. It is generated by cleavage with subtilisin and other proteolytic enzymes. It has

been used for nick translation and the Sanger's dideoxy method of DNA sequencing. ▶nick translation, ▶DNA sequencing, ▶DNA replication in prokaryotes, ▶DNA polymerase I; Kuchta RD et al 1988 *Biochemistry* 27:6716.

KLH: ▶keyhole limpet hemocyanin

Klinefelter Syndrome: Caused most commonly by XXY chromosomal constitution, although XYY, XXXY, and XXXXY have similar consequences as well as some mosaicisms involving more one X and Y chromosomes. The XXY condition affects about one to two boys among 1,000 births. XYY is somewhat less frequent, and the more complex types are even rarer. The XYY males may be fertile although the other symptoms are common with those of XXY. Underdeveloped testes (hypogonadism) and seminiferous ducts characterize the Klinefelter syndrome (see Fig. K17).

Figure K17. Klinefelter syndrome

The afflicted individuals are generally sterile, although effeminate yet heterosexual in behavior. Their height is usually above average and the limbs appear longer than normal. About half of them show increased breast size and they are about as likely to develop breast cancer as women. They are more likely to develop insulin-dependent diabetes and heart failure (mitral valve prolapse) than normal males. Some develop speech problems. Their intelligence is generally low, particularly in those having a higher number of sex chromosomes. Klinefelter individuals are frequently slow in development and have learning disabilities. Although they tend to be shy and immature in behavior, they were considered

to be prone to violence but this latter classification turned out to be based on false statistics. It is also true that there is higher incidence of Klinefelter syndrome in prison populations but this is due to their mental deficiency. Klinefelter symptom occurs also in various other mammals. Among the sperm of human males in their 20s, the average frequency of XY sperm is 0.00075 and it gradually increases and by age 50s it may be 0.0176, i.e., 160% higher. ▶sex chromosomes, ▶sex determination, ▶sex mosaics, ▶sex chromosomal anomalies in humans, ▶XX males, ▶gynecomastia, ▶trisomy, ▶polysomic cells; Klinefelter HF Jr et al 1942 J Clin Endocrin 2:615; Smyth CM, Bremner WJ 1998 Arch Intern Med 158:1309; Lowe X et al 2001 Am J Hum Genet 69:1046; Photo: Courtesy of Dr. K.L. Becker, and by permission of the American Fertility Society.

Klippel-Feil Syndrome: In the autosomal dominant form, it is associated with fusion of cervical (neck) vertebrae and malformation of head bones conducive to conductive and/or sensorineural hearing loss. The autosomal recessive forms did not involve hearing deficit. ▶deafness

Klippel Trenaunay Syndrome: A defect of the blood-vessels. It involves venous and lymphatic capillaries and hypertrophy of bony or soft tissues. Generally it was assumed to be sporadic. Translocation (5; 11) (q13.3; p15.1) or mutation at the terminal segments of chromosome 5 have been suspected. Other studies implicated translocations 8q22.3 and 14q13 or mutations in either of these regions. VG5Q is a major susceptibility factor interacting with angiogenic factors E133K and TWEAK. The genetic determination appears somewhat complex. ▶VG5Q, ▶TWEAK, ▶angiogenesis; Tian X-L et al 2004 Nature [Lond] 427:640.

Klotho: ▶aging

Klotz Test: Estimates the statistical variance of two populations, which display identical median values. ▶variance, ▶median; Drinkwater NR, Lotz JH 1981 Cancer Res 41:113.

Kluyveromyces lacti: A yeast species in which the first time linear plasmids were found.

Kniest Dysplasia (metatropic dwarfism): An autosomal dominant disease concerned with the locus of collagen II α -1 polypeptide (human chromosome 12q13.11-q13.2). The defect involves a deficiency of the C propeptide that is required for normal fibril formation. The urine contains increased amounts of keratan sulfate. There are general problems with the cartilage. Specifically, the afflicted individuals cannot tightly close their fist, their palm is purplish, suffer from severe myopia (nearsightedness), the retina is

detached and various types of bone defects, including dwarfism, may be evident. ▶Stickler syndrome, ▶eye diseases, ▶collagen, ▶connective tissue disorders, ▶dwarfism, ▶keratin

Knirp (*kni*, map location 3–46): Zygotic gap mutation in *Drosophila*. The first seven abdominal segments are abnormal (fused/deleted) but the head, thorax, the eighth abdominal segments and tail are normal. The locus encodes a steroid/thyroid receptor protein, which responds to various ligands such as the product of gene *Krüppel*. ▶gap genes, ▶*Krüppel*

Knob: Heterochromatic cytological landmark of a chromosome. Knobs have been used to identify the fate of particular chromosomes during meiosis and evolution. Knobs were implicated in preferential segregation in maize and as affecting the frequency of recombination of syntenic markers (see Fig. K18).

Figure K18. Chromosome knobs of the pachytene chromosomes of 13 different house crickets. The dotted lines connect homologies. (From Wenrich DH 1916 Bull Mus Comp Zool Harvard 60:58)

Knobs (altogether about 22) were observed on all chromosomes of maize. These are composed of tandem arrays of about 180-bp elements and may function as neocentromeres. Molecular evidence suggests that through inversion centromeric heterochromatin moved to the arm of the chromosome where it is composed largely of tandem repeats and retrotransposons. ▶preferential segregation, ▶neocentromere, ▶heterochromatin, ▶chromosome knob; Ananiev EV et al 1998 Genetics 149:2025; Hsu FC et al 2003 Genetics 164:1087.

Knob: The terminal part of the viral fiber on the capsid, an essential means of infection by recognizing host receptor (see Fig. K19). The knob may have targeting ligands attached (not shown on this Fig. K19). ▶retrovirus

Figure K19. Terminal part of viral fiber

Knobloch Syndrome (21q22.3): A retinal degeneration, meningocele (protrusion of the meninges [spinal cord and brain membrane], myopia (defect of focusing of the eye), etc. are caused by defects in collagen COL18A1 (Suzuki OT et al 2002 Am J Hum Genet 71:1320).

Knock-Down: Slowing down the expression of a particular gene either by transformation with mRNA digesting ribozymes or more practically by the introduction of synthetic 18–25 nucleotide antisense constructs. This procedure may be practical even when only an EST is known. Generally low levels of phosphorothioate are used to avoid toxicity and still protect against nucleases. ▶antisense technologies, ▶RNAi, ▶EST; Griffoni C et al 2000 Biochem Biophys Res Commun 276:756; Kohli M et al 2004 Nucleic Acids Res 32:e3.

Knock-In (Ki): Insertion of a functional copy or a domain into an inactive/active gene. Generally a vector cassette flanked by the *loxP* gene is employed. ▶knock-out, ▶gene replacement, ▶Cre/*loxP*; Golub R et al 2001 Eur J Immunol 31:2919.

Knock-Out (KO): Inactivation of a gene by any means (e.g., deletion, insertion, targeted gene transfer) to determine the phenotypic, metabolic, behavioral or other consequences, and to draw conclusions concerning its normal function. Removal of genes by site-specific recombination is expected to specifically knock out a discrete genic sequence. The consequence of the knockout may depend also on the neighboring genes. The general procedure involves first growing embryonic stem cell (ES) of mice. The cells are then electroporated with a gene construct carrying a selectable marker (e.g., neomycin resistance) within the coding sequence and thus it is inactivated. The disrupted gene is flanked by sequences homologous to the target to facilitate homologous double crossing over. The cells are grown out on selective media and recombinants are isolated. These recombinants will not be able to carry out the normal function of the target gene because of the insert in the coding sequence. Eventually the ES cells are injected into host blastocytes with a micromanipulator and transferred into the blastocoele. In case of success, the developing embryo becomes chimeric and some of the germline cells or the entire germline will carry the knock-out and transmit it to some of the progeny. In 17 days after the transfer knock-out, offspring may be obtained. The rate of success varies depending on the technical skills of the investigator and the mice concerned but it may be also quite high, over 50%. Huge knock-out libraries of mice are being generated now worldwide in order to understand all or as many as possible of the

vertebrate genes (Grimm D 2006 Science 312:1862). ▶site-specific mutagenesis, ▶targeting genes, ▶excision vector, ▶phenotypic knockin, RNA double-stranded Internet: <http://www.gdb.org/Dan/tbase/tbase.html>; mouse; Mak TW ed. 1998 The Gene Knockout FactsBook, Acad Press, Orlando, FL, USA; Thorneycroft D et al 2001 J Exp Bot 52:1593; Mansouri A 2001 Methods Mol Biol 175:397; KOMP Knockout Mouse Project: cryopreserved knockout mouse embryos: <http://www.knockoutmouse.org>; cryopreserved knockout mouse embryos: <http://www.informatics.jax.org/external/ko/>; Mutant Mouse Regional Research Center: <http://www.mmrrc.org>; Conditional Mouse Mutagenesis Center: <http://www.eucomm.org>, NorComm: <http://norcomm.phenogenomics.ca/index.htm>; Caenorhabditis Knockout Consortium: <http://celeganskoconsortium.omrf.org/>.

Knucklewalking: African apes do not use their palm but their knuckles (flexed fingers) to lean on in quadrupedal movement.

Knudson's Two-Mutation Theory: Postulates that in retinoblastoma, usually a germline mutation is followed by somatic mutation(s) in order to express the cancer. If a mutation is recessive, both alleles of a diploid must mutate to become detectable. The number of tumors in an individual indicates the rate of somatic mutation. Although in many different cancers one or more major genes have obvious role(s), an unknown number of additional genes control predisposition to cancer, i.e., the cancer risk is polygenically determined. A large-scale study of coding sequences (13,023 genes) of human breast and colorectal cancers revealed on average 90 mutant genes in these tumors but on average of about 11 of them affected the neoplastic process (Sjöblom T et al 2006 Science 314:268). Chronic myeloid leukemia (CML) is associated with the Philadelphia chromosome, which arises by a reciprocal translocation

between chromosomes 9 and 22 and harbors the BCR-ABL fusion oncogene. It is unknown whether any other mutations are needed for the chronic phase of the disease. The CML incidence increases as a function of age with an exponent of 3. A slope of 3 could indicate that there are two mutations, in addition to the Philadelphia translocation, that has not yet been discovered. An alternative hypothesis is that cancer initiation may require only a single mutation. A mutated cell has a net reproductive advantage over normal cells and, therefore, might give rise to clonal expansion. The cancer is detected with a probability that is proportional to the size of the mutated cell clone. This model has three waiting times: (i) the time until a mutated cell is produced, (ii) the time of clonal expansion, and (iii) the time until the clone is detected. Surprisingly, this simple process can give rise to cancer incidence curves with exponents up to 3. Therefore, the CML incidence data are consistent with the hypothesis that the Philadelphia translocation alone is sufficient to cause chronic phase CML (Michor F et al 2006 Proc Natl Acad Sci USA 103:14931). ▶cancer, ▶retinoblastoma, ▶genetic tumors, ▶Armitage-Doll model, ▶Moolgavkar-Venzon model, ▶Philadelphia chromosome, ▶leukemia; Hethcote HW, Knudson AG Jr 1978 Proc Natl Acad Sci USA 75:2493; Knudson AG 2000 Annu Rev Genet 34:1; Frank SA 2005 Proc Natl Acad Sci USA 102:1071.

KO: ▶knock-out

Koala: *Phascolarctos cinereus*, 2n = 16. A tree-dweller marsupial found in Australia. (see Fig. K21).

Kohara Map: In *E. coli* it is a restriction fragment map, based on partial digests of 3400 phage lambda clones with eight restriction endonucleases. ▶*E. coli*, ▶RFLP, ▶vectors, ▶cosmids; Rudd KE 1998 Microbiol Mol Biol Rev 62:985.

Kolmogorov-Smirnov Test: A non-parametric statistical procedure for the analysis of frequency distributions. It may be used in genetics for different problems, e.g., analysis of gene or physical marker frequency distributions in different populations. The method is usually applied to expected and observed cumulative

distributions. The differences are expressed as differences between relative cumulative frequencies and usually statistical tables are used to ascertain the maximum difference between observed and expected cumulative frequency at certain level of significance. The largest absolute vertical deviation (D) = maximum $|F_s(x) - T_T(x)|$ where $F_s(x)$ is the sample cumulative distribution frequency (CDF) and $T_T(x)$ = the theoretical CDF. The procedure is simple to carry out and computer programs are also available. Details can be found in Hays WL, Winkler RL 1971 Statistics: Probability, Inference and Decision, Holt, Rinehart and Winston, New York or in Sokal RR, Rohlf FJ 1969 Biometry, W.H. Freeman & Co, San Francisco, California. ▶Wald-Wolfowitz test

Kondrashov's Deterministic Model of Evolution of Sex:

Asexual females produce about twice as many daughters as sexual ones yet the number of asexual females is not increasing in the populations ("two-fold cost of sex"). In addition, sexual recombination breaks up co-adapted gene blocks. Despite these facts sexual reproduction is widespread among animals and even in plants. The cause of this is that sexual reproduction and selection has the potential of generating adaptation to the variable environment. ▶Red Queen hypothesis, ▶sex evolutionary significance; West SA et al 1999 J Evol Biol 12:1003.

KORF (known open reading frame): Its function is well understood. ▶ORF

Kosambi's Function: In the function, $x = 0.25 \ln[(1 + 2y)/(1 - 2y)]$, where x is the recombination frequency corrected by the mapping function and y is the observed recombination fraction. Kosambi's formula considers "average" interference, and it has been used in different species although interference may vary in different situations. ▶Haldane's mapping function, ▶coefficient of coincidence, ▶mapping genetic, ▶recombination frequency, ▶mapping function; Kosambi DD 1944 Ann Eugen 12:172.

Kosmotrope: ▶chaotrope

Kozak Rule: In eukaryotes, the most efficiently translated mRNAs start with AUGxG sequence. Commonly optimal translation occurs with AC-CAUGG. ▶ribosome binding, ▶ribosome scanning; Kozak M 1999 Gene 234(2):187.

k-RNA (kinetoplast RNA): Mitochondrial RNA in *Trypanosomas*. ▶*Trypanosoma*, ▶RNA editing

KRAB (Krüppel-associated box Zn-finger proteins, ZFB/ZNF/ZFP): Mostly transcriptional repressors. ▶Krüppel, ▶DNA binding protein domains; Looman C et al 2004 Mamm Genome 15:35.

Krabbe's Leukodystrophy (globoid cell leukodystrophy): A rare chromosome 14q31 recessive disease, called also galactosyl ceramide lipidosis. The enzymatic basis of the condition is the deficiency of galactocerebroside β -galactosidase/galactosylceramidase. The onset of the disease is expected within the first half year of life and it is generally fatal by around age 2. Exceptionally its onset may be delayed to late childhood. The early symptoms are irritability, hyperactivity that is followed by lethargy, degeneration of the nervous system resulting in blindness and deafness. Cerebrospinal fluid (CSF) proteins accumulate. In the white matter of the brain, myelin is reduced and infiltrated with globoid cells that are rich in galactosyl ceramides. When umbilical cord blood was transplanted into 12–44 days old asymptomatic and 142–352 days old symptomatic infants in the former group normal blood galactocerebroside level appeared, progressive myelination followed and apparently normal cognitive function was reached in the majority of the patients. Symptomatic babies however failed to show substantial improvement (Escolar ML et al 2005 New England J Med 352:2069). This procedure provides good evidence for the success of stem cell therapy. The *twitcher* mouse is an enzymatically appropriate animal model of this disease. [▶galactosidase](#), [▶sphingolipidoses](#), [▶sphingolipids](#), [▶saposin](#), [▶metachromatic leukodystrophy](#), [▶stem cells](#), [▶Addison disease](#), [▶metachromatic leukodystrophy](#); Matsuda J et al 2001 Hum Mol Genet 10:1191.

KRAS: [▶RAS oncogene](#)

Krebs-Szentgyörgyi Cycle: (1) Oxaloacetate \rightarrow (2) Citrate \rightleftharpoons cis-Aconitate (3) cis-Aconitate \rightleftharpoons Isocitrate (4) Isocitrate \rightleftharpoons α -Ketoglutarate (5) α -Ketoglutarate \rightleftharpoons Succinyl Co-enzyme A (6) Succinyl CoA \rightleftharpoons Succinate (7) Succinate \rightleftharpoons Fumarate (8) Fumarate \rightleftharpoons Malate (9) Malate \rightleftharpoons **Oxaloacetate**. This simplified outline does not show the energy donors and cofactors. This cycle is the most efficient path to generate energy. It is also called tricarboxylic acid cycle and citric acid cycle. A modified form is the glyoxylate cycle where isocitrate lyase converts isocitrate to glyoxylate and succinate. Glyoxylate then reacts with Co-A to form malate.

Krev-1: Probably the same as Rap1. [▶Rap](#)

Kringle: A disulphide-linked, triple-looped protein domain present in some plasma proteins, apolipoproteins, plasminogens, serine proteases, phosphoglycerate kinase, thrombin, hepatocyte growth factors. Some of the kringle proteins regulate angiogenesis,

cancer and metastasis. (See Ozhogina OA et al 2001 Protein Sci 10:2114)

KROX20: A serum inducible primary-response gene with Zn-finger, originally from *Drosophila*. It controls the myelination of the peripheral neurons. Krox20 promotes adipogenesis in a hormone-dependent manner (Chen Z et al 2005 Cell Metabolism 1:93). [▶serum response element](#), [▶zinc finger](#), [▶myelin](#), [▶neuron](#), [▶Egr](#), [▶C/EBP](#), [▶PPAR](#); Turman JE Jr et al 2001 Dev Neurosci 23[2]:113.

Krüppel (Kr, 2–107.6): The maternal effect gap gene of *Drosophila*, encoding a protein with regulatory Zn-finger domain interacting with Kni (knirps) and Hb (hunchback) proteins. Its monomers activate transcription in its vicinity by TFIIB and its dimer may repress transcription by interacting with the TFIIE β subunit. Kr-like factor controls also G₁-S progression. In the human genome there are an estimated 600–700 Krüppel-like (KLF) regulatory proteins. All of them bind a very similar GT-box (CACCC element). [▶transcription factors](#), [▶EKL](#), [▶kni](#), [▶gap genes](#), [▶morphogenesis in Drosophila](#), [▶Gli oncogenes](#), [▶cell cycle](#), [▶ \$\alpha\beta\$ T cell](#); Shields JM et al 1996 J Biol Chem 271:20009; Chen X et al 2001 J Biol Chem 276:30423; Bieker JJ 2001 J Biol Chem 276:34355.

Kruskal-Wallis Test: A non-parametric method of 'analysis of variance' by ranks. Each observation regarding groups of treatment, genotypes or phenotypes to be compared are ranked as shown in parenthesis (see Table K1).

Table K1. Kruskal-Wallis test

| Group 1 | Group 2 | Group 3 | |
|-----------------------|----------|-----------|--|
| 4 (1.5) | 11 (7) | 18 (11) | Total of N = 15 observations |
| 7 (4) | 12 (8.5) | 30 (15) | T _j = sum of ranks of group j |
| 10 (5.5) | 12 (8.5) | 24 (12.5) | T = total ranks of the groups |
| 4 (1.5) | 10 (5.5) | 24 (12.5) | |
| 6 (3) | 13 (10) | 25 (14) | |
| T _j (15.5) | (39.5) | (65) | |

T = 120, i.e.,

$$T = \frac{N(N+1)}{2} = \frac{(15)(16)}{2} = 120$$

if the ranking is correct.

$$\begin{aligned}
 H &= \frac{12}{(n(N+1))} \left(\sum_j \frac{T_j^2}{n_j} \right) - 3(N+1) \\
 &= \frac{12}{15(16)} \left(\frac{15.5^2 + 39.5^2 + 65^2}{5} \right) - 3(16) \\
 &= 12.25
 \end{aligned}$$

(in the example above [note 12 is a constant]).

$$1 - \left(\frac{\sum_i t_i^3 - t_i}{N^3 - N} \right)$$

If there are ties in the ranking the H value should be corrected by dividing H by the formula shown in the box. $1G$ = number of sets of tied observation, t_i = numbers of tied in any set of i . This correction may not make much difference if N is very small or the number of ties is very large. From the chi square table (see under chi square table) we can determine for $J-1 = 2$ degrees of freedom in the example shown above that the probability is less than 0.005 that these three sets would be identical. Generally much larger samples than shown are required to get meaningful results. It is considered to be a very powerful non-parametric test. ▶Mann-Whitney test, ▶non-parametric tests

KS A male fertility complex in the short arm of the Y chromosome of *Drosophila melanogaster*. ▶sex determination, ▶KL, ▶Drosophila

KSHV: (Kaposi sarcoma associated herpes virus): ▶Kaposi sarcoma, ▶HHV8

KSR (kinase suppressor of RAS): Structurally related to RAF and has similar role in cell proliferation and development of *Drosophila*. ▶RAF, ▶RAS, ▶CNK

KSS1: A protein kinase of the MAPK family. Along with Fus3, it causes arrest of yeast cells in G1 prior to mating. ▶signal transduction, ▶MAPK, ▶Ste, ▶Fus3

Ku: Heterodimeric (Ku70 [22q13] and Ku86 [2q35], kDa) serine/threonine protein kinases that bind to DNA in cooperation with transcription factors. Ku also interacts with the termini of DNA double strand breaks and is the binding domain of DNA protein kinase (DNA-PK), whereas the catalytic subunit of DNA-PK is encoded at 8q1. During telomere replication Ku is bound to a guanine-rich overhang in yeast. Ku has a role in DNA repair and recombination, including immunoglobulin V(D)J rearrangements. The deficiency of Ku70 leads to defect in B cell maturation and development of T cell lymphoma. The XRCC5 human gene is also encoded

at 2q35. Ku70 apparently mediates non-homologous chromosomal end-joining in somatic cells and though essential, appears to be absent during the meiotic prophase. Ku70 is involved in the internalization of *Rickettsia* bacteria (pathogen of the Mediterranean spotted fever) into mammalian cells (Martinez JJ et al 2005 Cell 123:1013). ▶transcription factors, ▶p350, ▶immunoglobulins, ▶RAG, ▶DNA-PK silencer, ▶XRCC, ▶lymphoma, ▶DNA-PK, ▶ligase DNA, ▶DNA repair, ▶PIK, ▶non-homologous end-joining, ▶chromosomal rearrangements, ▶NHEJ, ▶Mre11, ▶terminal deoxynucleotidyl transferase, ▶Bloom syndrome; Featherstone C, Jackson SP 1999 Mutation Res 434:3; Woodard RL et al 2001 J Biol Chem 276:15423; Walker JR et al 2001 Nature [Lond] 412:607; Li G et al 2002 Proc Natl Acad Sci USA 99:832.

Kufor-Rakeb Syndrome (KRS, 1p36): A rare recessive Parkinson disease involving defect in the ATPase of the pyramidal excitatory neurons. ▶Parkinson disease

Kugelberg-Welander Syndrome: A muscular atrophy expressed at infancy determined either by a dominant or recessive factor in human chromosome 5q11.2-q13.3. ▶neuromuscular disease, ▶atrophy

Kunkel Mutagenesis: Template DNA is generated in a bacterial strain of *dut ung* constitution. Such are defective in dUTPase (*dut*) and uracil-N-glycosylase (*ung*). Consequently several uracil residues are incorporated into the single-stranded M13mp19 phage DNA and these cannot be removed by DNA repair because of the defective glycosylase. To this DNA a mutagenic nucleotide primer is added and then in the presence of all four deoxyribonucleotides, a new strand is synthesized using the U-containing single-strand DNA template of M13. After the new M13 DNA synthesis is completed, the molecule is transfected into wild type *E. coli* which gets rid of the U-containing strand and synthesizes DNA containing the mutant nucleotide and the resulting phage plaques contain the localized, directed mutation. ▶homolog-scanning mutagenesis, ▶localized mutagenesis, ▶site-specific mutagenesis, ▶bacteriophages, ▶glycosylases; Kunkel TA 1985 Proc Natl Acad Sci USA 82:488.

Kupffer Cell: A large phagocytotic type cell with large nucleus and nucleolus in the liver similar to macrophages. Malaria infection apparently disables these cells to succeed (Frevert U et al 2005 PLoS Biol 3:e192). Kupffer cells can play a role also in atherogenesis by removal of low-density lipoproteins through the activity paraoxonase 1 (Bradshaw G et al 2005 Proc Natl Acad Sci USA 102:11029). ▶macro-phage, ▶IL-18, ▶LDL, ▶paraoxonase

Kurtosis: A departure from the symmetrical (normal curve) frequency distribution by displaying excess or deficiency at the shoulders compared to the tails and the highest point of the curve (peakedness) (see Fig. K22). At normal distribution $(x - \mu)^4 / \sigma^4 \cong 3$. A higher ratio indicates kurtosis. A *leptokurtic* distribution is characterized by higher number of observations or measurements at the mean and at the tails. *Platykurtic* distribution displays the opposite, i.e., less at the mean and tails than expected by normal distribution. ▶normal distribution, ▶skewness, ▶moments, diagrams redrawn after Hyperstat.

Figure K22. Kurtosis

Kuru: Infectious human chronic degenerative disease characterized by tremors, ataxia (lack of muscular coordination), strabismus (contorted visual axis in the two eyes), dysarthria (stemmering and stuttering), dysphagia (difficulties in swallowing), fasciculation (bundling of nerve and muscle tissues) among others. In general, death results within a year after onset. It affects about 1% of women of the Fore tribe of Papua New Guinea, and their daughters and sons. Kuru shows vertical transmission because in the Fore tribe populations, the females and their youngsters consume some flesh of dead relatives as a cannibalistic, religious ritual. It occurs sporadically also in neighboring tribes due to stenosis, LEOPARD syndrome, or it may be viral or it is due to prions. ▶prion, ▶Creutzfeldt-Jakob disease, ▶LEOPARD syndrome, ▶stenosis, ▶encephalopathies; Collins S et al 2001 J Clin Neurosci 8(5):384; Mead S et al 2003 Science 300: 640.

KUZ (Kuzbanian): ▶ADAM

kV: kilovolt, 1,000 V. ▶volt

KVLQT1: ▶Beckwith-Wiedemann syndrome

kW: kilowatt, 1,000 Watt. ▶watt

Kwashiorkor: A condition caused by malnutrition of humans on diets low in essential amino acids, particularly lysine, tryptophan and methionine. The

symptoms are emaciation with altered pigmentation in patches on the hair and skin. On dark spots of the limbs and back the epithelial layer may be shed showing raw flesh as pink blotches. If it is coupled also with a deficiency in caloric intake, the condition is further aggravated by losing both flesh and fats and generally coupled with dehydration as well (marasmic kwashiorkor). It is a widespread anathema particularly in the tropical and subtropical areas of the world with underdeveloped agriculture and political turmoil. The term's origin is an African Gold Coast (Ghanaian) language meaning pink boys, descriptive of the syndrome. This severe malnutrition primarily affects children. The condition is aggravated by infectious diseases (e.g., AIDS) and poisons in the food (e.g., aflatoxin). The therapy is a gradual return to balanced, nutritious diet. ▶essential amino acids, ▶high-lysine corn, ▶AIDS, ▶aflatoxin

Kwok: Polymorphism (SNIPs, duplications, deletions, rearrangements) in ESTs, named after P-Y. Kwok who first called to their usefulness for studying genomic variations. ▶SNIP, ▶EST; Kwok P-Y 2002 Hum Mut 19:315.

KYA: (kiloyears ago): 1 ky = 1,000 years. ▶MY

Kynurenine: An intermediate in tryptophan metabolism. In humans an autosomal recessive deficiency of the enzyme kynurinase results in excessive amounts in xanthurenic acid in the urine (see Fig. K23). Xanthurenic acid is a tryptophan metabolite that accumulates also in case of pyridoxal phosphate (vitamin B₆) shortage in the diet. The urine of the reproductively mature female masu salmon (*Oncorhynchus masou*) contains kynurenine as a male-attracting pheromone and it active at picomolar concentrations (Yambe H et al 2006 Proc Natl Acad USA 103:15370). ▶tryptophan, ▶Huntington chorea

Historical vignette

W Haacke assumed in 1893 (*Biol. Zbl.* 13:525) that the waltzing - walking traits of mice are located in cytoplasmic elements (centrosome) whereas coat color (white-gray) segregation is assured by the reductional division of the chromosomes. ("I do not know whether the number of chromosomes present in mice had been recorded, but this number would enable us to establish the possible combinations".) The fact that he was able to obtain experimentally all 16 combinations of these 4 traits seemed to indicate to him the validity of this interpretation. Although C Correns and independently E Baur (*Zeitschr. Ind. Abst. Vererb.-Lehre* 1:291 and 330, respectively) reported genuine cytoplasmic inheritance in 1909, and their findings were abundantly confirmed, John R Preer, Jr., an eminent contributor to the field remarked: "Cytoplasmic inheritance is a little bit like politics and religion from several aspects. First of all, you have to have faith in it. Second, one is called upon occasionally to give his opinion of cytoplasmic inheritance and to tell how he feels about the subject". (P. 374 in *Methodology in Basic Genetics*, WJ Burdette, ed., Holden-Day, San Francisco, 1963.)

Laboratory Management Software: <http://www.cato.com/biotech/bio-software.html> - LIMS.

Laboratory Safety: In laboratory safety, the most important prerequisite is to know the potential hazards of equipment and the biological and chemical materials to be employed. Develop plans how to cope with possible accidents and how to dispose of spillage, fumes, fire, and other laboratory waste etc. Most of the commercial suppliers provide safety information for chemicals ordered. Use nonporous (neoprene) gloves. Sometimes using bare hands may be justified because accidental contact can be immediately sensed and proper washing can decontaminate the body. Fume hoods (with proper air exchange) must be used with chemicals that evaporate or sublime. Appropriate sterilization and the use of certified laminar flow hoods could minimize biological hazards. Laboratory waste must be segregated for solids and liquids. Do not dump any chemical (mutagens and carcinogens) into drains as that may hurt plumbers and cause problems at the level of wastewater treatment. Monitoring with radiation counters and appropriate shielding may prevent radiation hazards. Keep workbenches clean. All laboratory personnel must be properly instructed about safety and checked regularly for compliance. Remember the admonition of Paracelsus, the fifteenth-century physician and scientist, that “Poison is everything and no thing is without poison. The dosage makes it either a poison or a remedy.” ► [environmental mutagens](#), ► [chemical mutagens](#), ► [ionizing radiation](#), ► [radiation hazard assessment](#), ► [gloves](#), ► [biohazards](#); Fleming DO, Hunt DL (Eds) 2000 Biological safety, ASM Press, Washington, DC; <http://www.cdc.gov/od/ohs>; <http://www.absa.org/>.

Laboratory Tests: ► [clinical laboratory tests](#)

Labrum: An anterior-most structure (mouth) of the head of arthropods. In general, morphology edges; lips are designated as such.

Labyrinth: A communication canal or cavity such as in the labyrinthine trophoblast connecting maternal and fetal tissues of the placenta, internal part of the ear, tubules in the kidney, etc.

Lac operon: *E. coli* can utilize the milk sugar lactose by splitting it into glucose and galactose with the aid of the β-galactosidase enzyme encoded by the *Lac z* gene. This enzyme is not made unless lactose or one of its analogs is present in the culture medium (inducible enzyme) and even then not until there is glucose available. This particular metabolic response is under a very precise and complex genetic regulation in prokaryotes. When transcription begins 3 genes are, in fact, transcribed into a 3-cistronic

RNA. The *Lac y* gene encodes a galactoside permease, a membrane protein that facilitates the uptake of the substrate for the galactosidase. The *Lac a* gene is a transacetylase that acylates the galactoside with the assistance of acetyl-coenzyme-A. The nucleotide sequence of this regulatory upstream region is shown.

For the sake of brevity the map (at 8 min) is shown. When galactosidase is not synthesized, a repressor protein blocks the repressor-binding sequences, a definite tract within a section of the promoter region, a part of the operator gene. The product of the *Lac I* (1040 bp) gene is 152-kDa, a 4-subunit repressor protein. The transcription of the *Lac I* gene is separately regulated from the genes that it controls by suppression (negative control). Since the repressor-binding site is within the operator gene where the transcriptase enzyme (RNA polymerase) is attached to carry out its function, it prevents the expression (transcription) of the down-stream genes (*z*, 3510 bp; *y*, 780 bp; *a*, 825 bp) of the operon. The Lac Z protein is 125-kDa, the *Lac y* and the *Lac a* are both about 30 kDa. Because of the coordinated operation of iuxta-positioned genes, the system was named *operon*. The *Lac i* gene is transacting because its product can flow to the operator irrespective of where the gene is located within the cell; it can be in the vicinity of the operon or it can be carried by a plasmid. Furthermore, if there is an inactive i^- gene next to the operon within the bacterial chromosome the *z*, *y* and *a* genes are transcribed. Introduction of a i^+ (wild type) suppressor gene in a plasmid, the transcription is blocked from this in trans position. Also it shows that the active form of *i* is dominant. The tetrameric repressor protein is normally a homotetramer, i.e., the four subunits are identical. If the cell has two different *i* genes that code differently-altered repressor monomers, the aggregate becomes a heterotetramer and may show *allelic complementation*. The i^d gene product in the presence of the wild type polypeptide imposes a conformational change on the repressor tetramer and renders it inactive by “dominant negative complementation”. This phenomenon also indicates that the monomers alone are not functional but their aggregate (quaternary structure) is the functional repressor. Base substitution mutations within the *Lac i* may abolish the ability of the protein to bind to the operator thus allowing protein synthesis to go on constitutively (without a need for induction). Mutations may also reduce its binding and thus without induction a reduced level of transcription can still continue. If the mutations affect the inducer-binding sites of the repressor, it may no longer bind the inducer and becomes a super-repressor mutation, i^S . The number of repressor molecules per cell is about 5 to 10.

Similarly, mutations within the operator region may alter the binding of the wild type suppressor. If the

repressor is bound to it rather than the RNA polymerase, the transcription of the three structural genes (*z*, *y*, *a*) cannot proceed. The repressor does not prevent the binding of the RNA polymerase to the promoter, it may even enhance the binding of the polymerase but it blocks the initiation of transcription. Since the RNA polymerase is at its site before induction, transcription is initiated almost immediately, as soon as the inducer makes contact with the repressor. The operator gene is unique because it does not have any product; it merely serves as the starter site for transcription if the RNA polymerase can attach to it. Therefore, the operator must always be in cis position, in front of the structural genes. The binding sequences within the operator shown in the Fig. L1 here have inverted repeats (RED) and the inactivating mutations are shown blue (see Fig. L1) (modified after Watson JD et al 1987 Molecular Biology of the Gene. Benjamin/Cummings, Menlo Park, California).

Figure L1. LacY is organized into two six-helix bundles with twofold pseudosymmetry separated by a large interior hydrophilic cavity open only to the cytoplasmic side and containing the side chains important for sugar and H⁺ binding. The residues involved in substrate binding [Glu-126 (helix IV), Arg-144, Cys-148, and Trp-151 (helix V)] are shown as pink sticks, and those involved in H⁺ translocation [Tyr-236 (helix VII), Arg-302 (helix IX), His-322, and Glu-325 (helix X)] are shown in yellow. The dualfunction residue Glu-269 (helix VIII) is shown in green. Cys-154 is shown as van der Waals spheres (yellow). Pro-28, Pro-31, Ile-32, and His-35 on helix I (yellow surface) and Gln-241, Gln-242, Ala-244, Asn-245, and Thr-248 on helix VII (cyan surface) form a periplasmic gateway. The black color represents the back-side of the surfaces (Courtesy of Dr. Lan Guan; see also Guan, L. *et al.* 2007 Proc. Natl. Acad. Sci. USA 104:15294)

The left side of the operator is more likely to render it unresponsive to repressor binding. If the repressor cannot bind to the operator, an operator-constitutive system emerges that is functional without induction (o^C). When the cells are grown without galactoside the number of galactosidase molecules may be less than 5 pe. After supplying galactose, within a couple of minutes, the number of galactosidase molecules increases by about a thousand-fold. If the inducer is used up, the system reverts to the uninduced state very rapidly because the half-life of the mRNA is only about three minutes, although the already synthesized proteins may linger on for a little longer. Induction can take place without β -galactoside if thiogalactosides, particularly the often-used isopropyl-thiogalactoside (IPTG), are provided. These thiogalactosides induce the synthesis of the galactosidase enzyme although the enzyme cannot use these analogs as substrates (see Fig. L2). These therefore

Figure. L2. General organization of the *Lac* operon

are *gratuitous inducers* (see Fig. L5). The presence of the slight amounts of the permease protein in the noninduced cells is required to initiate the uptake that eventually jump-starts the system. When the inducer is added to the system, it combines with the repressor and a change in the conformation prevents it from attaching to the repressor-binding sites in the operator region. The repressor protein has two essential sites; one that binds the inducer and the other that binds the operator. Although the binding of the repressor is not exclusively limited to the operator, it binds to this region by about 10 million-fold more effectively than to other sequences of the genome. When the cells take up the inducer, the unspecific binding to the whole of the genome does not change but the binding to the operator is almost completely relieved (see Fig. L6).

The mechanisms discussed here (negative control) are only parts of the total regulatory system and we will have to look at the role of the CAP-cAMP site upstream in the promoter. CAP stands for catabolite activator protein. It has also been called the cyclic AMP receptor protein (CRP, encoded by gene *crp* at

map position 73 min). CAP is a 22.5-kDa dimeric protein. Its subunits contain a DNA-binding and a transcription-activating site. Thus, CAP interacts both with DNA at the evolutionarily conserved upstream site and with α -subunits of the RNA polymerase. The CAP protein becomes active upon forming a complex with cyclic adenosine monophosphate (cAMP). cAMP is formed from ATP by the enzyme adenylate cyclase (the encoding *cya* gene is at map position 84 min) and its formation is reduced by glucose. We have discussed earlier that as long as glucose is available for the cells, β -galactosidase and companion enzymes are not formed in appreciable amounts. This phenomenon is called the glucose effect or, also, catabolite repression. The basis of this repression is that there is not enough cAMP to activate transcription by the CAP-cAMP complex. If the CAP-cAMP system is defective the *lac* operon cannot function even if the repressor is not formed and the operator is constitutive. Therefore, the CAP-cAMP complex constitutes a positive regulatory element of the *lac* operon in contrast to the negative regulatory *i-o* system, as seen in Figure L3. We can

Figure L3. The binding sequences within the *Lac* operator. (Modified after Watson JD et al. 1987 Molecular Biology of the Gene, Benjamin/Cummings, Menlo Park, CA)

also conclude that this system uses great wisdom in managing cellular energies: it calls to duty the enzymes only when they are needed and turns off the synthesis as soon as they are no longer needed. One of the products of the galactosidase, glucose reduces the synthesis of the enzyme that splits it off from lactose. The *lac* gene has also been used extensively as a reporter in eukaryotic systems (see Fig. L4) (Mills AA 2001 Genes Dev 15:1461).
 ▶suppression, ▶helix-turn-helix motif, ▶transcription, ▶translation, ▶allelic complementation, ▶galactose, ▶galactose utilization, ▶galactosidase, ▶ β -galactosidase [for assay], ▶cAMP receptor protein, ▶*Lac* repressor; Müller-Hill B 1996 The *lac* operon. De Gruyter, New York.

Lac Repressor: A protein that negatively regulates the *Lac* operon in the absence of lactose in the medium. When the repressor is combined with lactose (inducer) or isopropyl- β -D-thiogalactoside (gratuitous inducer), cAMP and CAP, the transcription of the structural genes may be started. The bound

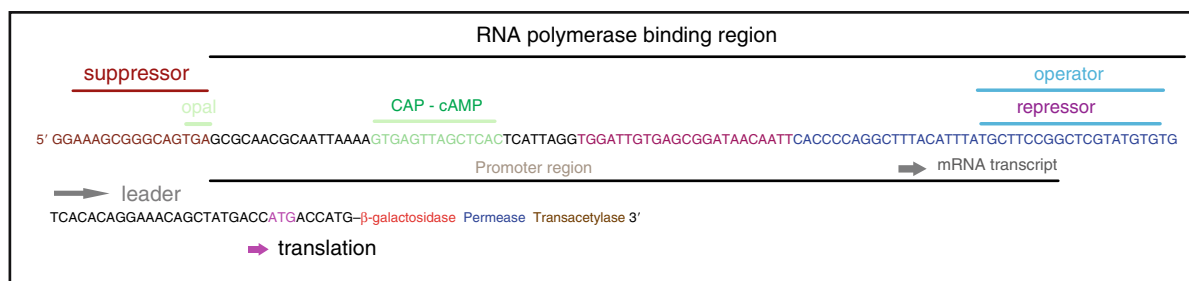

Figure L4. Base composition of some of the structural and functional elements of the *Lac* operon

Figure L5. Inducers of the *Lac* operon

repressor either inhibits the binding of the RNA polymerase or prevents elongation of the transcript. The *Lac* repressor protein (LacR/LacI) has a small headpiece (the binding domain) and a large core (regulatory domain). The intact 38-kDa repressor forms a homotetramer of 152 kDa. Each of the two LacR core dimers arranges the headpieces in such a manner that they bind maximally to the operator. Headpiece monomers bind only weakly. In the presence of an inducer (IPTG) the binding is reduced by three orders of magnitude. The LacR also mediates DNA looping to make contact at multiple sites. There are about 20 members of the family of *Lac* repressor proteins. The lactose, fructose, and raffinose repressors are tetramers while the others are dimeric. The majority of the *Lac* repressor (*LacI*) family members are most effective if no other proteins bind to them. The PurR (purine repressor), however, requires the presence of a corepressor (hypoxanthine and guanine) ligand. [▶Lac operon](#), [▶purine repressor](#), [▶cAMP receptor protein](#), [▶hypoxanthine](#), [▶looping of DNA](#); Fried MG, Daugherty MA 2001 J Biol Chem 276:11226.

Laccase: Phenoloxidases (laccase and tyrosinase) are responsible for sclerotization (hardening) and pigmentation of insect cuticles (Arakane Y et al 2005 Proc Natl Acad Sci USA 102:11337).

LacI^f: A mutant *LacI* that synthesizes about 10 times more repressor than the wild type allele.

Lactacystin (C₁₅H₂₄N₂O₇S): A *Streptomyces*-produced inhibitor of proteasome by affecting the amino-terminal threonine. It inhibits several proteases and the cell cycle, and causes neurite outgrowth in neuroblastoma cells. It may inhibit the degradation of p53. [▶ubiquitin](#), [▶neurite](#), [▶neuroblastoma](#), [▶proteasome](#), [▶p53](#); Yamada Y et al 2000 Eur J Haematol 64(5):315.

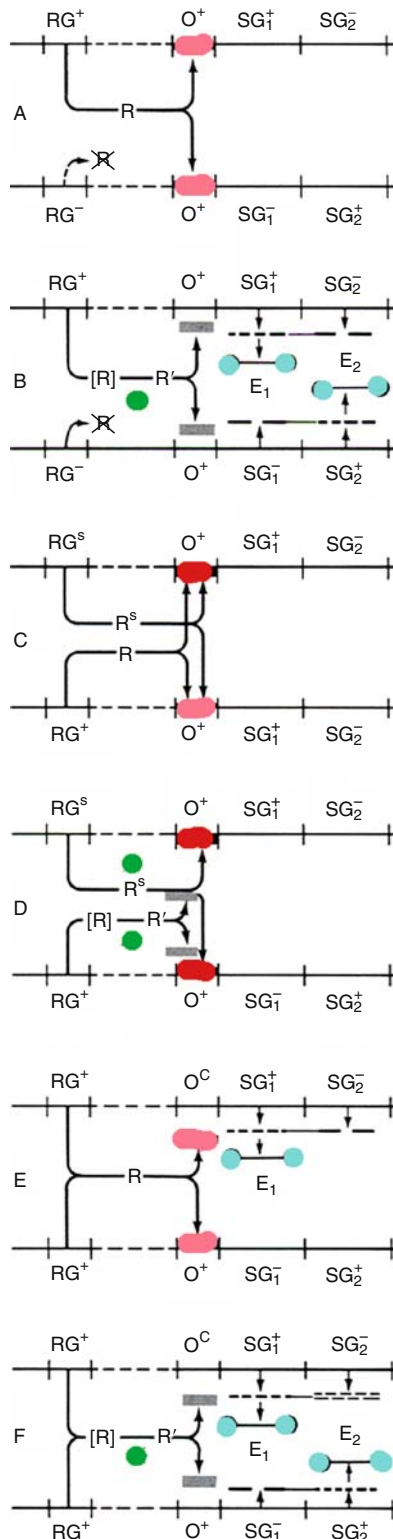

Lactam: A tautomeric form of uracil (see Fig. L7). [▶penicillin](#), [▶tautomeric shift](#), [▶pyrimidines](#)

Lactamase: [▶ \$\beta\$ -lactamase](#)

Lactase: Also known as β -galactosidase.

Lactase Deficiency: [▶disaccharide intolerance](#)

Lactate Dehydrogenase (LDH): Lactate dehydrogenase catalyzes the reaction: pyruvate + NADH + H⁺ \rightleftharpoons lactate + NAD⁺. Lactate is generally not utilized as such but it is converted back to pyruvate. The rationale of the reaction is to regenerate NADH for glycolysis in the skeletal muscles thus shifting the metabolic burden from muscle to liver. In yeast, the L-lactate dehydrogenase is also called cytochrome b₂. The mammalian enzyme is a tetramer consisting of four subunits, each with an approximate

A simplified model of the operation of negative control in an operon like lac. RG^+ : wild-type allele of regulator gene; RG^- : defective regulator gene; O^+ : wild-type operator gene; SG^+ : wild type; SG^- : mutant structural genes (responsible for enzyme proteins); (red oval) repressor.

The genetic conditions are identical to those at A, but an inducer (green dot) is provided. Now the repressor is neutralized (grey oval), and either functional (---) or defective (---) transcripts are made depending on the structural genes. The non-mutant mRNA of the SG^+ genes is translated into protein (blue circles).

A mutation from RG^+ to RG^s leads to the production of a superrepressor protein (red oval) which locks permanently into the operator. No mRNA and no protein are produced by the structural genes.

In the RG^+/RG^s heterozygotes the product of the RG^+ allele is receptive to the inducer (green dot) and is prevented from blocking the operator, but the superrepressor product (red oval) cannot be removed from the system. No mRNA and no protein are produced.

In the presence of two RG^+ genes (wild-type repressor), one of the operator alleles mutates to O^C (constitutive operator). In this case, the wild-type repressor protein is unable to bind to the O^C region even in the absence of an inducer. Consequently, transcription may proceed on one sequence of the operon.

The genetic constitution is identical to that diagrammed in E but inducer is provided for the system. Now transcription becomes possible on both sequences, and functional protein is made from the two wild-type structural alleles just as it is in the case illustrated in B.

Figure L6. *Lac* operon has been a paradigm of genetic regulation since its inception. The diagram illustrates some of the functional circuits involved by more general symbols. Of course not all genetic regulatory systems use exactly the same principles but several elements of it are valid for other regulations. (Modified after Jacob F and Monod J 1961 Cold Spring Harbor Symp. Quant. Biol. 26:193)

Figure L7. Lactam

M_r of 33,500. These subunits are encoded by two separate genes and can be combined into 5 different isozymic forms— A_4B_0 , A_3B_1 , A_2B_2 , A_1B_3 , A_0B_4 . In the skeletal muscles the A chains (synonymous with M) predominate whereas in the heart the B chains (synonymous with H) are dominant. The isozymic forms also vary during development. In cancer cells, the LDH isozymes are present in fetal rather than in the adult form. LDHA deficiency compromises the ability of cancer cells to proliferate under hypoxia, indicating the role of the enzyme in the maintenance of tumors. This fact may open an approach for controlling tumor growth (Fantin VR et al 2006 Cancer Cell 9:425).

L

In humans, the LDHA gene was assigned to chromosome 11p15.4, and LDHB to 12p12.1–12p12.2. The testes-specific LDHC protein is also encoded in the close vicinity of LDHA. The nucleotide and amino acid homology between human LDHA and LDHB varies between 68 and 75%. In mouse, LDHC displayed 72–73% homology with LDHA; in humans the similarity was just slightly higher between the two amino acid chains. In the Japanese population, LDHA and LDHB deficiencies occurred at frequencies of 0.19 and 0.16, respectively. These figures are supposed to be too high for other populations. LDHA deficiency in humans was associated with skin lesions, myoglobinuria, and fatigue. It was found that LDHA deficiency is caused by 20-bp deletions in exon 6 but nonsense mutation GAG → TAG at codon 328 was implicated at another human deficiency. LDHB deficiency was found to be due to a replacement of the highly conserved arginine 173 by a histidine. ▶isozymes, ▶code genetic, ▶dehydrogenase

Lactic Acid ($\text{CH}_3\text{CHOHCOOH}$, MW 90.08): Lactic acid is formed from pyruvate through glycolysis or by fermentation of lactose (yogurt). Lactic acid is the main end product of sugar metabolism of lactic acid bacteria. Lactic acid is formed in the skeletal muscles and oxidized in the heart for providing energy. It can also be converted again into glucose by gluconeogenesis. It is the most important preservative in silage fermented at moderate temperature. (See Gladden LB 2001 Proc Natl Acad Sci USA 98:395).

Lactic Acidosis: Lactic acidosis may be the result of deficiency of dihydrolipoamide dehydrogenase (7q31-32). It may also be due to pyruvate decarboxylase deficiency. ▶mitochondrial disease in humans, ▶Leigh encephalopathy

Lacticaciduria: Due to an autosomal recessive condition in which blood lactate and pyruvate level is increased. In the different forms of the disease, pyruvate carboxylase, pyruvate dehydrogenase, and phosphoenolpyruvate carboxykinase enzymes may be defective. Mental retardation, loss of hair, lack of muscle coordination and infant death may occur. ▶ketoacidosis

Lactobacillus acidophilus: A common, natural, non-pathogenic, useful, fermentative bacterium of the gut. The complete genome is 1,993,564 nucleotide pairs without any plasmid or prophages. Predicted open-reading frames are 1,864. (See Alterman E et al 2005 Proc Natl Acad Sci USA 102:3906).

Lactobacillus plantarum: A widely spread fermentative bacterium of 3,308,274 bp containing 3,052 predicted genes of which 70% have a putative function. The genome includes two prophages of 44 kb and 43 kb, respectively. For comparative genomics of *lactobacilli* see Makarova K et al 2006 Proc Natl Acad Sci USA 103:15611. (See Kleerebezem M et al 2003 Proc Natl Acad Sci USA 100:1990).

Lactobacillus salivarius UCC118: A sequenced, genetically studied, and prebiotic (beneficial) strain of human origin. It produces a bacteriocin in vivo that can significantly protect mice against infection with the invasive foodborne pathogen *Listeria monocytogenes*. *Lb. salivarius* UCC118 did not offer any protection when mice were infected with a strain of *L. monocytogenes* expressing the cognate immunity protein AbpIM. Thus the antimicrobial effect is a result of direct antagonism between *Lb. salivarius* and the pathogen, mediated by the bacteriocin Abp (Corr SC et al 2007 Proc Natl Acad Sci USA 104:7617). ▶bacteriocin, ▶Listeria

Lactococcus lactis: A Gram-positive bacterium of cheese making. The sequenced laboratory strain IL1403 contains 2,365,589 bp encoding 2,310 proteins. Among them 293 appear to be of prophage origin. It also contains 43 insertion elements. ▶prophage, ▶insertion element; Bolotin A et al 2001 Genome Res 11:731; <http://www.wzw.tum.de/proteomik/lactis/>.

Lactoferrin: An iron-binding glycoprotein in milk, in other secretions and in neutrophils. It defends the cells against infections and is a growth regulator. It modulates killer cells of the immune system. It is also a peptide messenger, binding to conserved DNA

sequences and activates transcription. ▶ **messenger polypeptide**, ▶ **killer cells**; Kanyshkova TG et al 2001 Biochemistry [Mosc] 66:1.

Lactose (milk sugar): A disaccharide of galactose + glucose. (See formula at ▶ **Lac operon**).

Lactose Intolerance: ▶ **disaccharide intolerance**

Lactose Permease: ▶ **Lac operon**

Lactosyl Ceramidosis: A deficiency of β -galactosyl hydrolase involving a hereditary sphingolipidosis type of disease. ▶ **galactosidase**, ▶ **sphingolipids**

Lacuna: A hole in the bacterial lawn caused by the production of bacteriocin.

LacZ: A gene for the β -galactosidase enzyme (map position 8 min). Another locus of *E. coli* (*ebgA*⁰, map position 67 min) may evolve into a β -galactosidase gene if the locus at position 8 is deleted. At least two different mutations are required to acquire this enzyme activity but it may evolve to this state through different paths. The new activity is based on an immunologically different protein from that of the *LacZ* product. ▶ **Lac operon**, ▶ **Xgal**, ▶ **galactosidase**

LacZ Δ M15: The amino terminal of the bacterial β -galactosidase gene is deleted. ▶ **Lac operon**

Ladd Syndrome (lacrimo-auriculo-dentato-digital syndrome, Levy-Hollister syndrome, 10q26): An autosomal dominant trait characterized by cup-shaped ears, insufficiency of lacrimal glands and ducts, small teeth, hearing loss, abnormal digits, etc. Fibroblast growth factor receptor (FGFR2) mutations affect the tyrosine kinase activity of the activation loop of the protein. Additional mutations involve FGFR3 and FGFR10 (Rohmann E et al 2006 Nature Genet 38:414). ▶ **FGF**

Ladder: A collection of oligonucleotides of precisely known length that can be used as standards for identifying the length of DNA fragments separated by electrophoresis. The synthetic ladders generally have a certain number of progressive base increments, e.g., 123, 246, 369. For the rainbow ladders of proteins the standards are labeled by fluorescent dyes and are detectable without staining (see Fig. L8).

Laloo: A member of the Src family of protein tyrosine kinases that activates mesoderm formation in *Xenopus* using TGF- β and FGF signaling. ▶ **Src**, ▶ **TGF**, ▶ **FGF**, ▶ **Xenopus laevis**

Lamarckism: A largely discredited evolutionary theory embodying the ideas of the French biologist J.B. de Lamarck (1774–1829). He proposed a comprehensive theory claiming that evolution proceeds by the inheritance of gradually acquired characters. He supposed that the use or lack of use of a body structure eventually leads to reinforcement or lapse of that trait by strive and direct environmental influence. The giraffes stretched their neck to reach the treetops, thus the inner drive and the circumstances contributed to their familiar shape. Contrarily, the current concepts, the neodarwinian theory believes that the longer-necked animals could feed better and thus, through continuous selection of increased neck length, their progeny had a selective advantage and facilitated the propagation of cumulative mutations that assured the survival of the best adapted genotypes. Neo-Lamarckism is basically an identical dogma to Lamarckism, except it emphasizes the use or disuse idea rather than the inner drive or autogenesis aspects. ▶ **soviet genetics**, ▶ **lysenkoism**, ▶ **Kammerer**, ▶ **transformation**, ▶ **directed mutation**; Aboitiz F 1992 Med Hypotheses 38(3):194; Lamarck's contributions: <http://www.lamarck.cnrs.fr/>.

Lambda Chain (λ chain): An immunoglobulin light chain. ▶ **immunoglobulins**

Lambda Phage (λ): A temperate bacteriophage, an obligate parasite. It belongs to the family of *lambdoid* phages, that includes phages $\phi 21$, $\phi 80$, $\phi 81$, etc. Lambdoid phages are characterized by cohesive ends, the ability to recombine, and inducibility by UV. Each λ particle contains in its icosahedral head (0.05 μm in diameter) one double-stranded DNA molecule of ca. 49,502 bp that has been completely sequenced by 1982. In its *E. coli* host it can replicate either autonomously and produce hundred progeny particles in 50 min at 37°C. Alternatively, it may insert into the host chromosome as a prophage, generally near the map position of the galactose (*gal*) operon. Phage λ usually does not kill all bacterial cells and therefore its plaques are turbid.

Gene *cI* is the principal phage gene enforcing the lysogenic state (λ being a pro-virus in the host chromosome). In addition, *cI* assures immunity to infection by other λ phages. When *cI* is inactivated, the phage may enter productive growth, i.e., it is liberated from the host chromosome (induction) and begins autonomous replication resulting in lysis of the host. Spontaneous induction occurs at a frequency of 10^{-3} per generation. Exposure to UV light may cause induction in most cells. Mutations *recA⁻* and *cI ind⁻* prevent induction by radiation as well as by spontaneous means. The *N* gene of the phage regulates both *cI* (the repressor of autonomous replication) and the morphogenetic genes involved in operations during the lytic lifestyle (see Fig. L9).

Figure L9. The major functional regions of phage lambda. The head and tail genes are essential for morphogenesis and for the packaging of foreign DNA into λ phage vectors. The region between J and N (the stuffer) can be removed and replaced by foreign genes in the replacement vectors. Just left of the DNA replication genes is the phage immunity region. Before gene *N* is the left *nin* and after gene *P* there is right *nin* region controlling transcription termination. The *ori* gene is the replicational origin and transcription may proceed left- or rightward from pL and pR, respectively. There are additional promoters for the delayed early genes (pI, internal), for the transcription of genes located in the replaceable region and pE and pM for the establishment and maintenance of *cI* repressor controlling the transition from lysogeny to morphogenesis in cooperation with other genes. The total length of the DNA in the wild type phage is about 49.5 kbp. In order to assure packaging, the total DNA in the vectors cannot be less than 78% and not more than 105% of the wild type genome. The region of the A to J genes (ca. 20 kb) and that from pR to the cos site (8 to 10 kb) must be retained for the viability of the particles

The λ genome may assume either a linear or circular form because at the ends (12 bp) of the DNA strands the complementary cohesive sites (*cos*) may open up to a linear form or circularize:

5'pGGGCGGCGACCT CCCGCCGCTGGAp 5'.

Between these ends the genes (encoding about 50 proteins) are in functional units corresponding to their temporal sequence of expression. This relatively small genome transcribes genes in both strands of the DNA double helix. Because of this, it has both left- and rightward transcriptions. The multiple promoters serve the purpose of most efficiently regulating the expression of the genes. The immunity region contains the major regulatory genes of the phage. After infection of the host cell or induction, transcription begins at either the leftward or at the rightward promoters. The leftward promoter, pL, mediates the transcription of genes involved in recombination (integration and excision) under the control of the (12.2 kDa) *N* gene product that may prevent transcription termination of genes using the pL or pR promoters. Some mutations (*ninL* and *ninR*) on both side of *N* may make the system insensitive to the *N* protein. A balance of the action of its own and some host genes determines the fate of the behavior of the phage. For lysogeny, genes *cII* and *cIII* (in opposite promoters, pR and pL, respectively) activate promoters pE (that includes the *cI*) and pL (that

includes gene *int*). The *cI*, the λ repressor, then produces a 236 amino acid protein that prevents the expression of genes involved in phage DNA synthesis and morphogenesis. It activates the synthesis of the *Int* and *Xis* proteins that in turn mediate recombination; thus the phage can integrate into the host chromosome as a prophage (see Fig. L10).

A and *cI* that exclude superinfection by other phages (immunity) and replication of phage DNA become synchronized with that of the host. Actually, the prophage appears as an integral part of the host chromosome. At this state the pM maintenance promoter regulates concentration of the *cI* repressor (see Fig. L11).

The recognition site of the lambda repressor is:

TATCACCGCCAGAGGTA
ATAGTGCGGTCTCCAT

The ability of λ to have a lysogenic state makes it a temperate phage. If, for any reason, *cI* is not functional the bacterial plate shows clear plaques, indicating that the phages are in the reproductive growth phase. The first gene turned on at the pR promoter is *cro* that is followed by *cII* that has gene *P*, the product of λ , a DNA pre-priming protein with host proteins. The expression of gene *Q* prevents transcription termination of the genes involved in lysis and morphogenesis. The products of the *S* and *R* genes mediate lysis of the host cell and this permits the liberation of the phage progeny. Under the

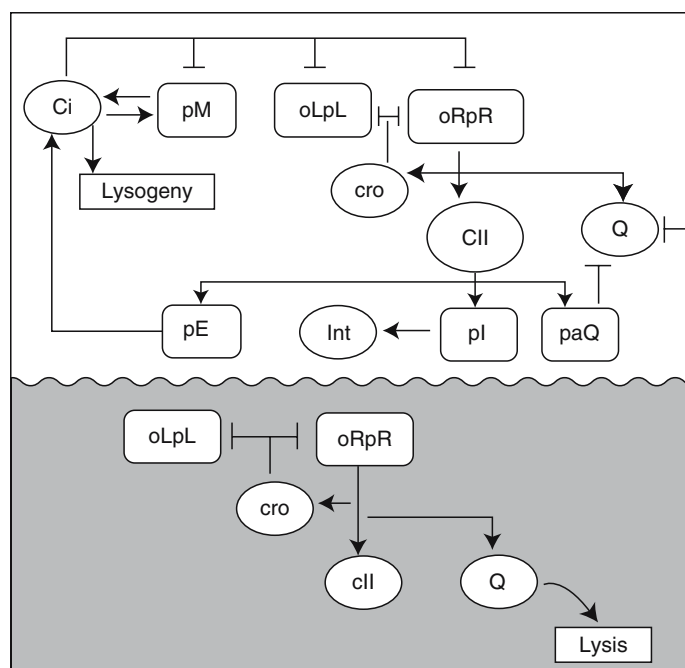

Figure L10. The network of lysogeny-lysis pathways. The ovals represent proteins and the squares stand for promoters. Arrows indicate positive actions while the bars, negative actions. (Redrawn after Kobiler O et al. 2005 Proc Natl Acad Sci USA 102:4470)

Figure L11. The structure of the lambda repressor. (From Alm E and Baker D 1999 Proc. Natl. Acad. Sci., USA 96:11305)

influence of protein Q the pR promoter assists in the transcription of all late genes and its role ends somewhere in the recombination-control region around the area of *b*. In the integrated state the prophage is replicated under the control of the host as if it would be an intrinsic part of the bacterial genome. Autonomous replication of phage DNA requires the function of the replicational origin (*ori*) where the O protein binds and replication originates. The replication is preceded by circularization of the phage DNA with the mechanical assistance of the cohesive (*cos*) ends which are then sealed by a DNA ligase. When the DNA injected into the host cell first replicates by the bidirectional theta (θ) replicational form, it generates monomeric DNA circles. When the function of the *gam* gene is turned on, replication is switched to the bacterial recBC protein-dependent rolling circle type (sigma replication, σ). This replication results in the formation of linear concatamers attached by the *cos* ends. These concatamers are then stuffed into the preformed phage heads (encapsidation) as shown by the Fig. L12.

The pR promoter mediates the transcription of the head and tail genes. The head and tail components are made and assembled separately before joining into the mature phage particle (see Fig. L12). In this process, the cooperation of host proteins (*groE*) is needed. The concatenated λ DNA molecules are then filled in into the pre-head. The DNA was synthesized in head-to-tail molecules, involving more than a single genome (concatamer). The protein products of the *NuI* and *A* genes bind to the DNA not far from the left *cos* sites and are brought to the pre-head. The *FI* gene product then reels it into the head until the terminal *cos* site is found where the NuI-A protein complex (terminase) cuts it off. The product of the *D* gene stabilizes the head shell and the FII protein completes the head that is now attached to the pre-fabricated tail assembly. The mature phage particle is equipped with injector mechanisms that facilitate the absorption of the particles to the host cell and introduction of its genome through the host cell membrane.

The phage genes under the control of the pL promoter are called early genes, those under pR are called delayed early and those regulated through pR are referred to as late genes. The two major promoters, pL and pR, may not necessarily stop at the termination signals represented by the arrowheads but may continue transcription and thus represent “read-through.” The regulation of the *N* gene product is accomplished by acting at the *nut* sites rather than at the terminator sequences (tL and tR). The *nutL* is located before the terminator, less than 60 bp from pL and the *nutR* is about 250 bp from pR. The *nut* regions have a dyad symmetry, including *boxA* and *boxB*. The region where the *Q* gene product binds is designated as *qut*. The activities of the N and Q proteins are frequently called antitermination function. The function of the λ N gene is also regulated by bacterial (N utilization) genes *nusA*, *nusB*, *nusE*, and *nusG*. *NusA* is a transcription factor while *nusG* encodes ribosomal protein 10. The nusB protein and S10 dimer bind to the *boxA* sequences in bacteria. The nusG assembles the other Nus proteins for binding to RNA polymerase. NusA can facilitate transcription termination by the N protein at intrinsic terminators but all Nus proteins are required for stopping transcription in rho-dependent termination. When the Nus complex and other proteins associate with RNA polymerase, it becomes modified at the *nut* site and can pass through the terminator sites without stopping transcription. The polymerase core can associate either with the σ subunit of the transcriptase or with the Nus N complex. When the N protein replaces the σ subunit of the RNA polymerase the termination signals are ignored. The *qut* sites permit a change in transcriptase to work faster and avoid stoppage at the terminator sites and proceed through the lytic phase into the vegetative growth stage.

Recombination of λ may be mediated by the closely linked genes *exo* (also called *redX*, *reda*, or *redA*) and the *bet* complex (also called β , *red β* , *redB*). These two *red* complexes are involved in general recombination and are not dependent on the function of the host *recA* function. The *exo* gene codes for a 5'-exonuclease (M_r 24,000) that can convert a branched DNA structure into an unbranched nicked duplex by the process called strand assimilation.

The *bet* gene product (subunit M_r 28,000) binds to the exonuclease and promotes reannealing with the complementary DNA strand. The *gam* gene product (M_r 16,500), in a dimeric form, binds to the bacterial host enzyme recBC and inhibits its activities. General recombination is affected by *Chi* (χ) sites near *A*, between *I* and *J*, *xis* and *exo*, within *cII*, between *Q* and *S* genes. *Chis* do not have any gene product; rather, they offer a suitable site for an enhancement of recombination (about five-fold, measured by burst size) through the RecBC pathway.

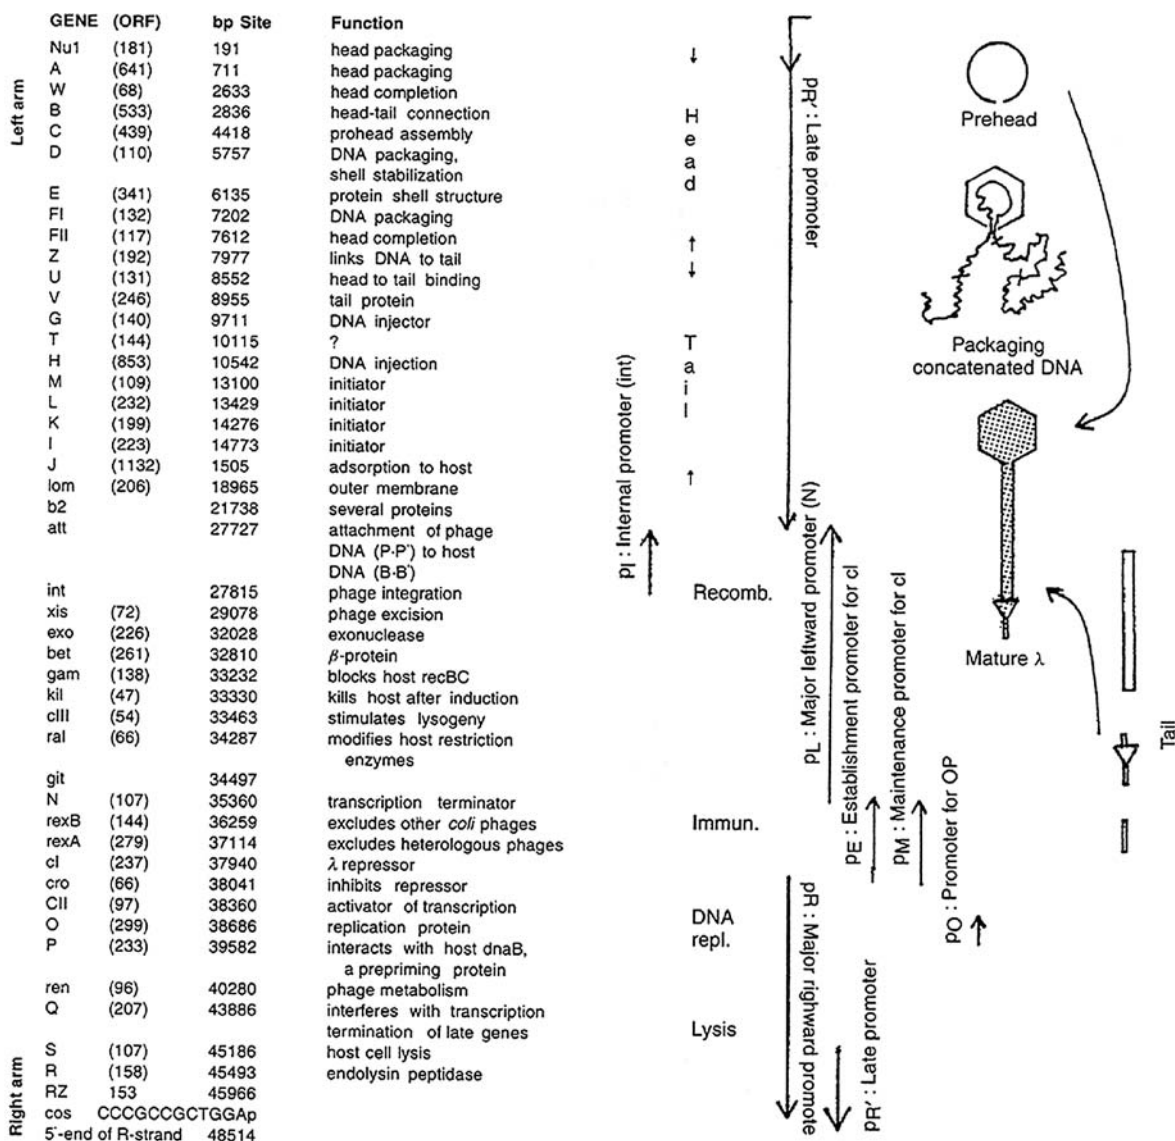

Figure L12. The map of bacteriophage lambda showing the order of the major genes. ORF indicates the size of the open-reading frames and bp site stands for the number of nucleotides starting at the left arm. The base sites may vary in different λ -phages. The morphogenetic pathway is also outlined. (Data from Hendrix RW et al. eds. 1983. *Lambda II*. Cold Spring Harbor Laboratory Press, Cold Spring Harbor, NY.)

Near the *chi* sites an octamer consensus exists: 5'-GCTGGTGG-3'. The stimulation of recombination by *chi* is not limited to its location but it is effective over a considerable distance. *Chis* act "dominant" because it is enough to be present in one of the recombining partners. When *Chi* is present in only one of the partners, recombinants without active *chi* are much more frequent than the reciprocals (non-reciprocity). Enhancement of recombination to its left is greater than to its right side (directionality).

Recombination may also be site-specific, requiring a special nucleotide sequence, the primary *att* sites of high efficiency and the much lower efficiency

secondary *att* sites. The *att* sites have common 15-bp core sequences that are 70 to 80% AT. In the phage, the primary *attP* sites are represented as - - -POP' - - - and there is a corresponding site of homology in the bacterium *attB* (~~~BOB'~~~). After recombination (insertion) at the crossing over region (O), by the means of pairing as an inversion loop, in the bacterial cell there will be:

In excision, the process is reversed. The insertion is mediated by λ protein *Int* and the excision uses the products of λ genes *Int* and *xis*. Both processes

also require the bacterial integration protein factor (IHF, M_r 20,000) and other host gene products (see also Kazmierczak RA et al 2002 *Nucleic Acids Res* 30:5193). The coding region of *int* extends 84 to 1,151 bp right from the crossing over site. The M_r of the Int protein is about 40,000 and at the amino terminus it is rich in basic residues and it works as a topoisomerase. The Xis protein shares amino acid sequences with Int. The *xis* product contains 72 amino acids with 25% Lys and Arg. Because of the site-specific recombination, λ phage can mediate specialized transduction.

Phage λ has been used for the development of a number of genetic transformation vectors. Genes not exceeding 5% of the genome can be inserted at a single target site into the λ DNA and can be propagated (insertional vectors). The nucleotide sequences between genes J and N can be deleted (representing about 25% of the genome) and replaced. The DNA can still produce nearly normal size plaques as long as the total length of the DNA remains no less than 37 kb and not more than 52 kb (replacement vectors). In cosmid vectors it is essential to retain the *cos* sites plus 4–6 kb at both termini, including also the origin of replication. The vectors so constructed can propagate foreign DNA exceeding 30 kb.

Synthetic lambda circuits have been constructed. By replacing the CI repressor with another tunable module, Tet repressor and several cis-acting sites have been generated. Tet repressor lacks several important properties of CI, including positive auto-regulation and cooperative DNA binding. Using a combinatorial approach, phage variants were isolated with behavior similar to that of wild type. These variants grew lytically and formed stable lysogens. Lysogens underwent prophage induction upon addition of a ligand that weakens binding by the Tet repressor. Strikingly, however, the addition of a ligand that weakens binding by the *Lac* repressor also induced lysogens. This finding indicates that the *Lac* repressor was present in the lysogens and was necessary for stable lysogeny. Therefore, these isolates had an altered wiring diagram from that of lambda. It was assumed to be practical to customize gene regulatory circuits that would be regulated by small molecules or protein cofactors (Atsumi S, Little JW 2006 *Proc Natl Acad Sci USA* 103:19045). ▶Charon vectors, ▶cosmid vectors, ▶theta replication, ▶rolling circle, ▶rho terminator, ▶specialized transduction, ▶burst size, ▶chi elements, ▶recombination, ▶helix-turn-helix, ▶DNA-binding protein domains, ▶O-some; Hendrix RW et al 1983 *Lambda*, Cold Spring Harbor Lab. Press; Cue D, Feiss M 2001 *J Mol Biol* 311:233; Friedman DI, Court DL 2001 *Curr Opin Microbiol* 4(2):201; details of the λ regulatory networks: Oppenheim AB et al 2005 *Annu Rev Genet* 39:409.

Lambdoid Phages: Lambdoid phages are closely related to the λ phage such as P22 of *Salmonella*. ▶P22; Clark AJ et al 2001 *J Mol Biol* 311:657.

Lambert: A unit of luminous intensity: 1 lumen per cm^2 . The lumen is the unit of luminous flux emitted in a unit solid angle (steradian) by a uniform point source of one candela. ▶candela [candle]

Lamella: A thin plate or membrane sheet.

Lamellipodium: A sheet-like cellular extension involving actin and assisting cell movement. ▶filopodium

Lamina: The lamin structural network and associated proteins. The nuclear lamina surrounding the nucleus controls nuclear pores, regulates transcription and organization of the heterochromatin. ▶lamins

Laminin: A large glycoprotein (~1-MDa) localized in the synaptic cleft between the neuronal basal lamina of the muscle cell sheath and the acetylcholine receptors. ▶synapse, ▶acetylcholine, ▶agrin, ▶epidermolysis, ▶basement membrane; Koch M et al 1999 *J Cell Biol* 145:605.

Laminopathies: Laminopathies are human diseases involving laminins of the nuclear membrane such as the Emery-Dreifuss muscular dystrophy and Lamin B receptor mutations (Pelger-Huet anomaly, hydrops-ectopic calcification-moethaten skeletal dysplasia, osteopoikilosis, idiopathic torsion dystonia, lissencephaly). Laminopathies are involved in several other diseases affecting muscles, axon myelination, lipodystrophy, progeria, etc. (See diseases listed at separate entries, for review: Burke B, Stewart CL 2006 *Annu Rev Genomics Hum Genet* 7:369; Capell BC, Collins FS 2006 *Nature Rev Genet* 7:940).

Lamins: Lamins are intermediate filament proteins (encoded at 1q21). When they are polymerized, nuclear lamina are formed; during interphase, lamins support the nuclear membrane. The A-kinase anchoring protein 149 (AKAP149) seems to recruit lamins to the nuclear envelope and protein phosphatase 1 (PP1) modulates the membrane architecture during mitosis. Lamins also help to define embryonal polarity. In *Drosophila* ~500 transcriptionally silent and late-replicating genes interact with B-type lamin. These genes lack active histone marks and are widely spaced. Lamin target genes cluster in the genome and are coordinately regulated during development and are involved in the global organization of chromatin (Pickersgill H et al 2006 *Nature Genet* 38:1005). ▶intermediate filaments, ▶lipodystrophy, ▶muscular dystrophy [Emery-Dreifuss type], ▶cardiomyopathies [CMD1A], ▶Hutchinson-Gilford syndrome, ▶aging; Wilson KL et al 2001 *Cell* 104:647.

L-Amino Acids (levorotatory amino acids): The common natural amino acids. ► [D-amino acids](#)

Lamm Equation: The Lamm equation determines sedimentation or diffusion in analytical ultracentrifugation. ► [ultracentrifuge](#)

LAMP-1, -2 (lysosome-associated membrane proteins): LAMP-1 is a 120 kDa acidic glycoprotein (13q34) and its defect may account for some neurodegeneration in mice. LAMP-2 deficiency is associated with Danon disease (Xq24) characterized by impaired degradation (autophagy) of some liver proteins and various muscle anomalies (cardiomyopathy). ► [Danon disease](#); Winchester BG 2001 Eur J Paediatr Neurol 5(Suppl A):11.

Lampbrush Chromosome: A giant chromosome in oocytes (mainly in amphibia), with conspicuous loops extending about 40 μ m on a core resembling brushes used to clean the glass chimney of kerosene lamps (see [Fig. L13](#)). These loops are highly active in RNA synthesis, and although not polytenic, they are well visible under the light microscope. The photograph is a section of a long chromosome (Courtesy of Dr. Joseph G. Gall). A set of amphibian lampbrush chromosomes may display 10,000 loops alternating with condensed chromomeres. On the surface of the DNA loops the nascent RNA transcripts may be visible. This high activity may precede meiosis and continues during it in order to secure a good supply to later meet the needs of the rapidly developing zygote. ► [giant chromosomes](#), ► [newt](#); Gall JG, Murphy C 1998 Mol Biol Cell 9:733.

Figure L13. Lampbrush Chromosome

LANA (latency-associated nuclear antigen): ► [Kaposi sarcoma](#)

Lander-Green Algorithm: A multipoint linkage test using hidden Markov principle. ► [hidden Markov model](#), ► [Elston-Stewart algorithm](#); Lander ES, Green P 1987 Proc Natl Acad Sci USA 84:2363.

Landmark Genomic Scanning: Landmark genomic scanning visualizes restriction enzyme sites in genomic DNA by direct labeling and two-dimensional electrophoresis. ► [two-dimensional electrophoresis](#), ► [mDIP](#); Hirotsume IH et al 1994 DNA Res 1:239.

Landrace: Locally adapted variety of plants or breed of animals that may include a number of different genotypes and similar phenotypes. Landraces are the

products of intuitive selection of the growers or husbandrymen, respectively.

Lange-Nielssen Syndrome (cardio-auditory syndrome): The Lange-Nielssen syndrome involves heart arrhythmia and deafness, and sudden death. The gene responsible, KVLQT1, spans the region 11p15. This area also includes the Beckwith-Wiedemann syndrome. ► [Beckwith-Wiedemann syndrome](#), ► [LQT](#), ► [deafness](#)

Langer Mesomelic Dwarfism: ► [dyschondrosteosis](#)

Langer-Giedion Syndrome (LGS, 8q24.11-q24.13): The Langer-Giedion syndrome generally involves mental retardation, small brain (microcephaly), bulbous nose, sparse hair, emergences on the bones (exostosis), etc. The autosomal dominant phenotype is based on deletions in the 8p22-8q24.13 chromosomal regions. ► [deletion](#), ► [exostosis](#), ► [trichorhinophalangeal syndrome](#), ► [mental retardation](#), ► [head/face/brain defects](#)

Langerhans Cell: A dendritic antigen-presenting cell with an indented nucleus. They are present in the epidermis and some internal organs. ► [dendritic cell](#), ► [antigen-presenting cell](#)

Langerhans Islets: Cells with dentate nucleus in the pancreas, arranged in groups. They appear to have antigen-presenting abilities. From the β cell, the islets secrete insulin, from the α cells, glucagons, and from the δ cells, somatostatin. Mice that lack phosphatidylinositol kinase (PDK1) have a reduced number of β cells and suffer from hyperglycemia (diabetes). Haploinsufficiency for the Foxo1 transcription factor resulted in increased cell number but not in cell size and yet restored glucose homeostasis (Hashimoto N et al 2006 Nature Genet 38:589). ► [diabetes mellitus](#), ► [pancreas](#), ► [insulin](#), ► [insulin-like growth factor](#), ► [Fox](#), ► [PIK](#), ► [phosphatidylinositol kinases](#), ► [glucagons](#), ► [somatostatin](#)

Language: A unique feature of the human species that has apparently been determined by the FOXP2 gene (7q31), which has evolved at about a 60-fold higher rate than the same sequence in chimpanzees. Human toddlers may learn 10 words per day and humans may acquire a vocabulary of 60,000 words by the time of high school graduation. Dogs may also learn the meaning of ~200 words although by a process different from that of humans (Kaminski J et al 2004 Science 304:1682). The origin and evolution of languages is difficult to study using the currently available means because spoken words do not have paleontological records. Comparative genomics, hereditary speech defects, and anthropology may shed some light on the development of languages but there is no generally accepted theory for interpreting

scarce facts. Comparative linguistics can reveal the relationships among existing languages or extinct languages for which written records are available. The language of human populations has some relation to the genetic structure of the populations concerned (Cavalli-Sforza LL et al 1988 Proc Natl Acad Sci USA 85:6002). There are some problems, however, because language can spread horizontally whereas genes are transmitted only vertically. Also, population admixture is common during human migrations. In addition, there may be strong pressure to preserve or spread a language and culture beyond the boundaries of genetic groups (Hunley K, Long JC 2005 Proc Natl Acad Sci USA 102:1312). On the basis of language structure (sound system and grammar) the phylogeny of several Melanesian languages could be determined (Dunn M et al 2005 Science 309:2072). ▶[speech and grammar disorder](#), ▶[aphasia](#), ▶[MASA syndrome](#), ▶[chimpanzee](#), ▶[FOX](#); Zhang J et al 2002 Genetics 162:1825; Ferrer i Cancho R, Solé RV 2003 Proc Natl Acad Sci USA 100:788; Fisher SE, Marcus GF 2006 Nature Rev Genet 7:9; neural basis of language development: Friederici AD 2006 Neuron 52:941.

L

Language, Computer: A set of representations used by a computer program.

Language Impairment, Specific (SLI): About 4% of English-speaking children of normal intelligence and average environment suffer from low language skills for their age. It is a polygenic disorder and chromosomes 13q21, 16 and 19 sites are significantly involved. ▶[speech and grammar disorder](#); SLI Consortium 2002 Am J Hum Genet 70:384.

Lanosterol: A precursor of cholesterol (see [Fig. L14](#)). ▶[geranyl pyrophosphate](#), ▶[cholesterol](#)

Figure L14. Lanosterol

Lantibiotics: Small peptide antibiotics produced primarily by *Lactococcus lactis*; other Gram-positive bacteria synthesize it too against competing bacteria. The best known among this group of antibiotics is nisin, which is used by the food industry and is useful because the body rarely develops resistance to it.

▶[nisin](#); van der Meer JR et al 1993 J Bacteriol 175:2578, nisin structure: Li B et al 2006 Science 311:1464.

Laparoscopy: The examination or treatment of the interior of the abdomen by a special device, the laparoscope, that may be equipped with a laser source.

Lapatinib: ▶[Trastuzumab](#)

Lard: An Apo-3 family TNF/NGF receptor. ▶[Apo-3](#), ▶[TNF](#), ▶[NGF](#)

Large Embryo/Offspring Syndrome: Bovine and ovine embryos, under unusual experimental conditions preceding the blastocyte stage, increase in size and involve problems of fetal loss, difficulties in parturition (birth), and developmental defects. In vitro embryo culture, nuclear transplantation, high urea diet of the mother, etc., may be responsible for the anomalies. Mice produced by nuclear transplantation tend to be large and obese but the condition is not transmitted to their offspring. ▶[nuclear transplantation](#), ▶[tetraploid complementation](#); Young LE 1998 Rev Reprod 3:155; Tamashiro KKK et al 2002 Nature Med 8:262.

Large T Antigen: ▶[SV40](#)

Lariat RNA: is formed during the splicing reaction of the primary transcript of eukaryotic genes. In the first step, the pre-mRNA is cut at the junction of exon 1 and intron resulting in a piece of RNA containing intron-exon 2. This “2/3 molecule” immediately forms a loop-like lariat (remining one of the tethering rope of cowboys). In the second step, the intron-exon 2 junction is cut and exons 1 and 2 are ligated (spliced). Afterward, the intron is released and the procedure follows for the other junctions. ▶[introns](#), ▶[splicing](#); Ooi SI et al 2001 Methods Enzymol 342:233.

Laron Type Dwarfism: ▶[pituitary dwarfism](#), ▶[dwarfism](#)

Larsen Syndrome (LRS1, 3p21.1-p14.1): Larsen syndrome is characterized by dominant knee dislocation, prominent forehead, cylindrical fingers, short digits, and a flat nasal bridge. ▶[bone diseases](#)

Larva: An insect at the developmental stage after hatching from the egg. It resembles more a worm than an adult insect (see [Fig. L15](#)). The imago emerges from it after pupation. During the larval stage the germline and the imaginal discs are laid down. ▶[Drosophila](#)

Figure L15. Larva

Lascaux Cave: The Lascaux cave is located in the caves of Dordogne, southwestern France. It reveals the remarkable art of the Cro-Magnon men, originated about 15,000 years ago. These colored paintings disclose a great deal about the types of animals present in the area in the paleolithic age and attest the intelligence and artistic abilities of the early European ancestors. More recently, even older (35,000–40,000 years) ancient artwork and artifacts have been discovered both in Europe (Grotte Chauvet) and Africa. The animal shown in [Figure L16](#) displays great similarity to a present-day longhorn bull. The success of animal breeding can be assessed by a comparison with the modern breeds of cattle. (See Guthrie RD 2006 *The Nature of Paleolithic Art* University of Chicago Press, Chicago, Illinois; Valladas H et al 2001 *Nature [Lond]* 413:479; <http://www.culture.fr/culture/arcnat/chauvet/en>).

Figure L16. Lascaux cave painting (Courtesy of the Caisse Nat. Mon. Hist. Sites, France)

Laser (light amplification by stimulated emission of radiation): Laser equipment produces electromagnetic radiation in the infrared and visible spectrum by stimulation of atoms. The laser beam does not diffuse like that of an electric light. The radiation travels in the same direction, at the same wavelength of a very narrow frequency band. Thus, it focuses all the energy to a fine point. Lasers can produce radiation at many wavelength and frequencies. Intense light source and electron currents can activate gases, semiconductors and ions in solid material to produce coherent laser light. The lasers can be pulsed or continuous. The former produces extremely high peaks of power, the latter is highly stable and gives pure emission. Laser radiation is applicable to different scientific instruments (e.g., laser scanners), photochemistry (e.g., laser photolysis), identification of fluorochrome-labeled molecules and also to surgery, etc. Laser beam exposure poses a risk for the eyes. (See entries ahead).

Laser-Capture Microdissection: This technique may be used to trace the event in cellular differentiation. Cell cultures or tissue sections are placed on a polymer

film activated by laser pulses. The shape of the cells and their DNA, RNA, and protein content is preserved. cDNA libraries can then be hybridized to thousands of genes and their expression in health and disease or patterns of DNA methylation studied and used for biological or diagnostic purposes. It may be used for isolation of pure cell types—without injury to macromolecules—from microscopic tissue sections and transferring them to laser-activated polymer films. The procedure permits molecular analysis (e.g., microarray hybridization) of tissue-, cell-specific alterations due to disease and/or therapy. ▶[microarray](#), ▶[laser](#); Emmert-Buck MR et al 1996 *Science* 274:998; Simone NL et al 1998 *Trends Genet* 14:272; Kerjean A et al 2001 *Nucleic Acids Res* 29(21):e106; Craven RA, Banks RE 2001 *Proteomics* 1:1200.

Laser Scanning Cytometry: Laser scanning cytometry analyzes DNA content of normal and cancer cells; it can be used to measure in situ hybridization by automation. ▶[multiphoton microscopy](#); Darzynkiewicz Z et al 1999 *Exp Cell Res* 249:1; LaSalle JM et al 2001 *Hum Mol Genet* 10:1729; Angenandt P et al 2004 *Anal Chem* 76:1844.

Last-Male Sperm Precedence: In many insects (e.g., *Drosophila*), the female stores the sperm in her spermatheca before fertilization. When multiple insemination takes place by different males, the sperm of the last male preferentially sires the majority of the offspring due to sperm displacement and inactivation (?). The sperm elimination is controlled by the seminal fluid produced by the accessory gland. ▶[certation](#), ▶[multipaternal litter](#), ▶[multiparental hybrid](#), ▶[sperm precedence](#); Hooper RE, Siva-Jothy MT 1996 *Mol Ecol* 5:449; Snook RR, Hosken DJ 2004 *Nature [Lond]* 428:939.

LAT: A class of herpes virus genes of mainly unclear function. They are transcribed when the virus is maintained in a quiescent state bound to the nucleosomes in the neurons. A LAT protein has an adapter function in TCR-mediated signal transduction. ▶[herpes](#), ▶[TCR](#), ▶[signal transduction](#); Aguado E et al 2002 *Science* 296:2036.

Late Genes: Late genes are transcribed only during the later life cycle of an organism. The viral genes involved in replication and in the synthesis of structural (coat) proteins (e.g., during the lytic phase of a bacteriophage). These genes use late promoters, different from the early ones. ▶[early genes](#), ▶[delayed-response genes](#)

Late Period: The late period of phage development starts with the beginning of DNA replication. ▶[development](#), ▶[lambda phage](#)

Latent Period: A latent period is when the infection has occurred but the symptoms are not yet manifested.

In phage biology, the latent period is the time between the injection of the phage DNA into the bacterium and the beginning of lysis. It is also the time from the initiation of a disease to the onset of symptoms.

►burst

Late-Replicating Chromosome: A late-replicating chromosome or chromosomal region is heterochromatic and genetically not active. ►Barr body, ►lyonization, ►heterochromatin

Lateral Plate Mesoderm: A lateral plate mesoderm is present in the neurula of vertebrates and gives rise to the nervous system, heart, blood vessels, blood, linings of the body cavities, and the mesodermal part of the limbs. ►left-right asymmetry, ►neurula

Lateral Transmission: Same as horizontal transmission. Lateral transmission is suggested generally when similar nucleotide sequences occur among species that may not be related by orthologous descent. Lateral transmission is common (1.5–14.5%) in bacteria by means of transformation by exogenous DNA, by phage-mediated transduction, and conjugational transfer of plasmids. According to a new estimate, using a different method among 57,670 prokaryotic gene families distributed across 190 sequenced genomes, at least two-thirds and probably all appeared to be affected by lateral transmission at some time in their evolutionary past (Dagan T, Martin W 2007 Proc Natl Acad Sci USA 104:870). A H-NS-like protein aids lateral transmission in bacteria (Doyle M et al 2007 Science 315:251).

Antibiotic resistance and virulence genes are commonly transmitted laterally and may become important factors of population adaptation and evolution. On the basis of the sequenced genomes of eukaryotes, the lateral transfer of genes might have occurred during evolution. The lateral acquisition of the number bacterial genes by the human genome has been estimated at 40 to over 200. A common objection to such claims is that the convergent evolution of these genes or sequences may not be ruled out with great certainty. Furthermore, many of the supposedly horizontally acquired sequences in vertebrates were already present in nonvertebrate lineages (Stanhope MJ et al 2001 Nature [Lond] 411:940). In addition, the endosymbiotic acquisition of chloroplasts and mitochondria and DNA traffic among these organelles poses additional problems in identifying the lateral transfers. ►transmission, ►transmission lateral, ►transposable elements, ►transformation, ►infectious heredity, ►orthologous genes, ►convergent evolution, ►operon selfish, ►H-NS; Garcia-Vallvé S et al 2000 Genome Res 10:1719; Andersson JO et al 2001 Science 292:1848; Brown JR 2003 Nature Rev Genet 4:121; Boucher Y et al 2003 Annu Rev Genet 37:283; Ochman H et al

Laterality Disorder: ►situs inversus viscerum, ►situs ambiguus, ►left-right asymmetry

Latexin: A mouse carboxypeptidase inhibitor with similarity to the putative human tumor suppressor TIG1; it has cysteine fold domains. ►carboxypeptidase, ►cystatine; Aagaard A et al 2005 Structure 13:309.

Lathyrism: Caused by the presence of β -cyanoalanine and its decarboxylation product, β -aminopropionitrile in the seeds of the food and forage legume, *Lathyrus sativus*. Some other contaminating weed legumes may also be major culprits in lathyrism. In some countries, the ground seed is used as a filler in bread making. As a feed its amount should be kept below 10% of the ration. Cooking reduces its adverse effect substantially. These compounds affect the cross-linking of collagen resulting in spasms, pain, paralysis of the lower extremities (paraplegia), abnormal sensitivity (hyperesthesia), burning sensation of the skin (paresthesia), curvature of the spine, rupture of the aorta, etc. ►collagen; Spencer PS et al 1993 Environ Res 62:106; Riepe M et al 1995 Nat Toxins 3:58.

Lathyrus odoratus (sweet pea): An ornamental legume ($2n = 14$), a favorite object of early studies on the gene-controlled anthocyanin synthetic pathways. The *L* dominant allele (long) and the recessive *l* allele (disc) determine the shape of the pollen (see Fig. L17). Although this is a gametophytic trait, the phenotype is determined by the genotype of the anther (sporophytic) tissue and thus is an example of delayed inheritance. ►delayed inheritance, ►sweet pea

Figure L17. Pollen grains of *Lathyrus*

Latin Square: A square array of items in parallel columns and rows in such a manner that each must occur once but only once in each row and column (see Fig. L18). Such a design lends itself for the evaluation of experiments by analysis of variance. It can be

employed in agricultural field experiments and is useful for pharmacological, microbial and other research where the partition of the data into relevant variances is very important. ► [analysis of variance](#), ► [Graeco-Latin square](#)

Latrotoxin: A large peptide neurotoxin binding to neurexins. ► [neurexin](#)

LATS: (large tumor suppressor): A negative regulator of CDC2 and cyclin A. LATS1 deficiency in mice may produce soft-tissue sarcomas, ovarian tumors, and pituitary defects. ► [CDC2](#), ► [cyclin A](#), ► [sarcoma](#), ► [pituitary](#), Hori T et al 2000 *Oncogene* 19:3101.

Lattice: A three-dimensional pattern of atoms or points.

Lauryl Sulfate: ► [dodecyl sulfate sodium salt](#)

Law: Both civil and criminal law consider genetic principles and methods. Examples are: regulating marriage, social policy, demographic factors, using dermatoglyphics (fingerprinting), serological methods, DNA fingerprinting, patents, etc. The branch of genetics involved in legal matters is called forensic genetics. ► [forensic genetics](#), ► [paternity testing](#), ► [abortion](#), ► [stem cells](#), ► [genetic discrimination](#), ► [patents](#), ► [GMO](#), ► [animal genetics](#), ► [genetic privacy](#)

Law of Large Numbers: The increase in the size of a population assures a closer fit of the observed data to a valid null hypothesis or that the experimentally observed mean represents the true mean of the population dispersed according to the normal distribution. ► [normal distribution](#), ► [mean](#), ► [null hypothesis](#)

Lawn, Bacterial: A Petri plate containing nutrient agar and growing bacterial cell colonies (see [Fig. L19](#)).

Figure L19. Bacterial lawn

Lawrence-Moon Syndrome: An autosomal recessive mental retardation involving retinal defects, underdeveloped genitalia, and partial paralysis.

Lawrence-Seip Syndrome: A lipodystrophy (loss of fat substance from under the skin); it is accompanied by enlargement of the liver, excessive bone growth, and insulin-resistant diabetes.

LB Agar: Add 1.5 to 2% agar to LB medium. ► [LB bacterial medium](#)

LB (Luria-Bertani) Bacterial Medium: H₂O, deionized, 950 mL; bactotryptone, 10 g; bacto yeast extract, 5 g; NaCl, 10 g; adjust pH to 7 with 5 N NaOH, fill up to 1 L.

LBD: Ligand binding domain. ► [ligand](#)

LC: Literature curated. ► [curated](#)

LC50: A lethal concentration 50 of a chemical is expected to cause death in 50% of the treated cells or individuals of a population. ► [LD₅₀](#), ► [LCLo](#), ► [LDLo](#)

LCA: LCA stands for last common ancestor of species compared.

LCA Oncogene: The LCA oncogene is isolated from human liver carcinomas; it was assigned to human chromosome 2q14-q21. ► [oncogenes](#)

LCK: A lymphocyte nonreceptor protein tyrosine kinase of the SRC family, located to human chromosome 1p35-p32. ► [oncogenes](#), ► [tyrosine kinase](#), ► [signal transduction](#), ► [T cell](#), ► [ITAM](#), ► [palmitoylation](#); Holdorf AD et al 2002 *Nature Immunol* 3:259.

LCLo: (lethal concentration low): The lowest concentration of a substance, in air, that causes death to mammals in acute (<24h) or subacute or chronic (>24 h) exposure. ► [LDLo](#)

LC-MS (liquid chromatography-mass spectrometry): A bioanalytical pharmaceutical tool used in conjunction with quadrupole mass spectrometers. ► [quadrupole](#), ► [proteomics](#); O'Connor D 2002 *Curr Opin Drug Discov Devel* 5:52.

LCR (locus control region): A nuclease-hypersensitive region far upstream or downstream or on other sites apart from the structural gene. Its presence is required for the expression of a particular gene locus and its role probably involves the opening of the chromatin for transcription. All the genes are in competition for the assistance of the LCR and those that are closer to it have an advantage. LCR may be at many kb distance from the locus it controls. The multiple genes appear to be transcribed alternately as the chromatin loops back and forth. In the LCR of the β -globin gene there are 5 DNase I hypersensitive sites, which synergistically activate the gene cluster (globin ϵ -G γ -A γ - δ - β) in a developmentally specific sequence. Hypersensitive site 4 is the most important for activation of transcription. Each of the hypersensitive sites bind transcriptional activators (E-box

factors, GATA-1, NF-E2, CACCC binding proteins [e.g., Sp1]) and yet they also have some specificities. For the globin cluster, the most important role of LCR is the steady maintenance of transcription. The globin gene LCR is very well conserved among the various species. The CACCC box of the β -globin genes has an important role in the transcriptional regulation of the γ - and β -gene promoters. The Sp1-related protein binds ubiquitously and the Krüppel-like proteins (EKLf) bind to this box only in the erythroid lineage. Although CACCC boxes are present in both the γ and β promoters, in the γ four repeating copies of a CCTTG sequence suppresses EKLf binding. Thus the functions appear to be controlled also by the structural/sequence context. The LCRs also include enhancer elements. At the LCR of the β -globin gene there is a (LARC) complex of a heterogeneous nuclear ribonucleoprotein (C1/C2), nucleosome remodeling complex (SWI/SNF), and nucleosome remodeling and deacetylating complex (NuRD)/MeCP1. LARC binds the hypersensitive 2 (HS2)-Maf (Maf is AP1/NF-E2, a basic leucine zipper protein) recognition element (MARE). The binding proteins assure β -globin transcription by chromatin remodeling (Mahajan MC et al 2005 Proc Natl Acad Sci USA 102:15012). ▶nuclease sensitive site, ▶regulation of gene activity, ▶heterochromatin, ▶chromatin, ▶position effect, ▶looping of DNA, ▶promoter, ▶chromatin remodeling, ▶E-box, ▶transcription factories, ▶GATA, ▶NF-E2, ▶Sp1, ▶EKLf, ▶Sp1; Fraser P, Grosveld F 1998 Curr Opin Cell Biol 10:361; Grosveld F 1999 Curr Opin Genet Dev 9:152; Johnson KD et al 2001 Mol Cell 8:465; Ho Y et al 2002 Mol Cell 9:291.

LD50: A calculated dose of a substance expected to kill 50% of the experimental population exposed to it. Rats have been used for the determination of LD₅₀. This type of test will be phased out to avoid cruelty to animals. ▶LDLo

λdash: A replacement vector for the stuffer DNA fragment which carries multiple cloning sites on both sides of *red* and *gam* genes and appropriate promoter (s) specific for T3 or Ty RNA polymerase and so the insertions can be transcribed without a need for recloning. ▶λFIX, ▶EMBL3, ▶stuffer DNA, ▶lambda phage, ▶cloning

LDB: LIMB domain binding factor. ▶Lim domain, ▶NLI

λdgal: A lambda phage deficient but carries the galactose gene. ▶specialized transduction

Ldj1, Ldj2: Ldj1 and Ldj2 are DnaJ-like farnesylated chaperones of higher plants. ▶DnaK, ▶chaperones, ▶prenylation

LDL: ▶low-density lipoproteins, ▶familial hypercholesterolemia, ▶sterol, ▶myocardial infarction

LDL Receptor: An LDL receptor mediates LDL endocytosis; it is encoded in human chromosome 19-p13.1-13.3. It is homologous with the EGF receptor. An LDL-related protein (LRP5) defect is the cause of a type of osteoporosis. ▶low-density lipoproteins, ▶EGFR, ▶lysosomes, ▶LDL, ▶osteoporosis; Gong Y et al 2001 Cell 107:513.

LDLo (lethal dose low): The lowest dose of a substance introduced by any route, except inhalation, over a period of time in one or more portions, and has caused death to mammals. ▶LClo, ▶LD50

L-DNase II: A post-translational product (from a serpin-like protease inhibitor or leukocyte elastase inhibitor) upon cytosolic acidification. It degrades DNA during apoptosis. ▶apoptosis, ▶serpins, ▶elastase

LDP (long-day plant): ▶photoperiodism

Lead Poisoning: Lead poisoning can cause kidney and growth problems as well as anemia, hearing loss, seizures, and coma. The most common source are house paint (before 1978) and old gasolines, and old plumbing.

Leader Peptide: Directs the translocation of proteins. In bacteria it consists of 16–26 amino acids involving a basic amino terminal, a polar central domain, and a non-helical carboxy domain. The latter is essential for recognition by leader peptidase to cut it off. For mitochondrial import, the leader has 10–70 residues and it is rich in positively charged and hydroxylated residues. Similar leader peptides mediate the import of proteins from the cytosol to the chloroplasts or to the nucleus. The leader sequences do not enter the target organelles. ▶signal peptide; Wang AH, Yang XJ 2001 Mol Cell Biol 21:5992.

Leader Sequence: A leader sequence is a nontranslated stretch of nucleotides at the 5'-end of the mRNA. Some mRNAs lack a leader, e.g., the lambda phage cI gene. The tobacco mosaic virus carrying the translational enhancer Ω works more efficiently in the absence of a Shine-Dalgarno sequence. ▶mRNA, ▶Shine-Dalgarno sequence; O'Donnell SM, Janssen GR 2001 J Bacteriol 183:1277.

Leading Strand: A leading strand of DNA faces the replication fork by the 3'-OH end and is extended by adding, directly, 5'-deoxynucleotidephosphates to that end after removal of the γ and β position phosphates from the nucleotide triphosphate precursors. In prokaryotes, the most essential genes (essential for viability) are transcribed from the leading strand and this bias is not a consequence of the level of expression of the genes. In *E. coli*, the DNA polymerase tends to slow down until the transcription is completed (co-oriented collision).

After the completion of transcription, replication may resume its normal rate. On the lagging strand replication stalls (head-on collision) when it encounters transcription and the RNA polymerase is displaced from the lagging strand. In eukaryotes, the principle of gene distribution is unclear because multiple DNA polymerases exist and each is somewhat different. ►lagging strand, ►replication fork, ►replication, ►DNA replication, ►gene distribution

Leadzyme: A ribozyme that can cleave itself at a specific phosphodiester site in the presence of lead ions (Pb^{2+}). The leadzyme has an asymmetric internal loop flanked by Watson-Crick hydrogen-paired nucleotides. The shaded section indicates the catalytic core (see Fig. L20). ►ribozyme, ►DNA-zyme; Doherty EA, Doudna JA 2000 Annu Rev Biochem 69:597.

Figure L20. Diagram of leadzyme LZ4 after Wedekind JR and Mckey DB 1999 Nature Struct. Biol. 6:261

Leaf Skeleton Hybridization: A procedure carried out on plant leaves infected by the cauliflower mosaic virus vector with the same purpose as colony hybridization of bacteria, i.e., to detect foreign gene sequences in the CaMV vector. ►CaMV, ►colony hybridization; Melcher U et al 1992 Arch Virol 123(3-4):379.

Leaky Mutant: A leaky mutant has an incomplete genetic block in a synthetic step. ►genetic block, ►hypomorphic

Learning Behavior: Learning behavior is partly genetically controlled and it has been found that slow-learning mice have reduced amounts of protein kinase C in the hippocampus of the brain. It thus appears that the PKC gene is a part of the polygenic system affecting this complex trait. Learning is potentiated by the regeneration ability of the central nervous system. Increased histone acetylation and inhibition of histone deacetylase induced sprouting of dendrites, increased the number of synapses, reinstated learning behavior and access to long-term memory after some neuronal degeneration (Fischer A et al 2007 Nature [Lond] 447:178). ►brain human, ►Boolean algebra; Dubnau J, Tully T 1998 Annu Rev Neurosci 21:407; Chklovskii DB et al 2004 Nature [Lond] 431:782; Abbott LF, Regehr WG 2004 Nature [Lond] 431:796.

Learning Disability: ►Tourett's syndrome, ►dyslexia

Least Significant Difference (LSD): A measure of the significance among a set of means compared. The standard error of the difference between two means can be determined on the basis of the Student's t distribution using $\sqrt{2s^2/n}$ where s^2 is the standard error, n is the size of the population. The standard error of the difference is then multiplied by the minimal t value at a particular level of significance from the Student's t table and any value that exceeds this product constitutes the LSD. ► t value, ►Student's t distribution, ►F-distribution

Least Squares: The least squares formula is the basis for the theory of regression (b) where S means sum,

$$b = \frac{S(y[X - \bar{x}])}{S(X - \bar{x})}$$

where y = one of the variates, x = other variate, \bar{x} mean of x .

Least square methods are also used for the estimation of evolutionary distance. The smallest minimum sum of squared differences computed from paired data indicates the best topology for an evolutionary tree. ►minimum evolution method, ►four-cluster analysis, ►neighbor joining method, ►correlation, ►multiple regression

Least-Trimmed Square: A computational procedure used in regression analysis (LiLM 2005 Comp Stat Data Anal 48:717).

Leaving Group: The displaced molecular group in a chemical reaction.

Leber Congenital Amaurosis: ►amaurosis

Leber Optic Atrophy: About 95% of the cases involve mutations at mtDNA nucleotides 3460, 11778 and 14484. ►mitochondrial disease in humans, ►optic atrophy, ►amaurosis congenita, ►eye diseases; Howell N et al 2003 Am J Hum Genet 72:1460.

Lecithin: A glycerol phospholipid. It is also called phosphatidyl choline.

Lecithin-Cholesterol Acyltransferase Deficiency (Norum disease, Fish-eye disease): Lecithin-cholesterol acyltransferase deficiency is either a relatively rare recessive Norum disease coded in human chromosome 16q22.1 and in mouse chromosome 8 or is, by a dominant mutation at the same locus, the fish-eye disease. This defect in lipid metabolism causes proteinuria, anemia, renal and heart defects. In Norum disease, there is a general failure in esterification of cholesterol in high-density lipoprotein whereas in the fish-eye diseases the deficiency is more specific. The name comes from the opacity of the eye resembling that of boiled fish. ►lipoprotein, ►apolipoprotein, ►cardiovascular disease, ►West syndrome, ►vascular disease

Lectins: Lectins were first identified as plant proteins associated with glycans that agglutinate erythrocytes by virtue of binding to surface sugars (Dodd RB, Drickamer K 2001 *Glycobiology* 11:71R). Lectins also occur in invertebrate and vertebrate animals and may also serve as ligands in the natural killer cells. In addition, they play a role in general cell adhesion, managing of peptides in the endoplasmic reticulum, surface recognition and protection against bacteria and viruses. Natural killer cell receptors of lectin-like C-type—although heterogeneous—were preserved during the evolution of four orders of mammals (Hao L et al 2006 *Proc Natl Acad Sci USA* 103:3192). Lectins introduced into potato by genetic engineering may have adverse effects on experimental animals if consumed. ▶concanavalin, ▶selectin, ▶cell adhesion, ▶killer cells, ▶complement, ▶endoplasmic reticulum, ▶receptin, ▶DC-SIGN, ▶NOD2, ▶SIGN-R1; Weis WI, Drickamer K. 1996 *Annu Rev Biochem* 65:441; <http://plab.ku.dk/tcbh/lectin-links.htm>.

Leech: A hirundinaceous (blood-sucking) lower animal with only ≈350 nerve cells per ganglion (see Fig. L21). ▶ganglion; Stent GS et al 1992 *Int Rev Neurobiology* 33:109.

Figure L21. Leech

LEF (lymphoid-enhancer binding factor): A transcription factor regulating lymphocyte differentiation; it is a member of the high mobility group proteins. It interacts with β -catenin and regulates signal transmission to the nucleus. It binds to the TTCAAACC sequences in the TCR α enhancer region. LEF is similar to TCF and this family of proteins also regulates axis formation with the aid of β -catenin-associated proteins. Catenin-activation plays a role in human cancers. ▶high mobility group proteins, ▶lymphocytes, ▶Gardner syndrome, ▶melanoma, ▶catenins, ▶pilomatricoma, ▶R-spondin, ▶TCF; Liu T et al 2001 *Science* 292:1718.

Left-Handedness: ▶handedness

Left-Right Asymmetry: In vertebrates, the body plan appears almost entirely symmetrical by outward appearance; however, the arrangement of the internal organs (heart, pancreas, stomach, spleen, liver gall bladder) is not symmetrical. Left-right asymmetry is widely found in several syndromes of all higher organisms (prevalence $> 1 \times 10^{-4}$). In some humans the normal pattern of the location of organs is disturbed (Kartagener syndrome, situs inversus viscerum). The pattern of differentiation is under

the control of a cascade of events, which bears some similarities and differences in the various organisms.

The processes are under the control of genes and proteins with somewhat variable homology. *N*-cadherin appears to be an early regulator for establishing the asymmetry of the body. The initial signals emanate from the organizer where activins on the right side stimulate the fibroblast growth factor (FGF-8), which in turn blocks the Cerberus (Cer)/Dan/gremlin/Caronte (CAR) family of genes/proteins. The homologous macromolecules are so named in different organisms. On the left of the organizer/primitive streak, Sonic hedgehog (SHH) acts in a direction opposite to FGF-8; it activates CAR. CAR then interferes with the bone morphogenetic protein blocking-action and NODAL (Nod)/Lefty-2/Activin is/are turned on. Nod has a central morphogenetic function. On the left side, ACTIVIN RIIIB/SMAD-2 then blocks \emptyset SnR (Snail related). NODAL depends on Notch signals, which respond to extracellular calcium (Raya Á et al 2004 *Nature [Lond]* 426:121). ACTIVIN RIIIB also turns on PitX2/ NKX3.2/ bagpipe. On the right side of the lateral plate mesoderm the mirror image of the processes go on. What is activated on the left side is more or less attenuated on the right side.

In the midline, Lefty-1, stimulated by CAR, seems to stabilize the difference between the two sides of the mesoderm. Lefty-1 is highly homologous to Lefty-2. Although this simple model (see Fig. L22) provides a generalized picture, the processes actually involve additional genes and proteins in an interacting cascade of events. The EGF (epidermal growth factor)-Cryptic protein1 (224 amino residues in humans) complex interacts with Nodal and regulates laterality. The fibroblast growth factor induces the release of the sonic hedgehog signal and retinoic acid

Figure L22. Some of the circuits in the determination of left-right asymmetries

and mediates the left–right determination (Tanaka Y et al 2005 Nature [Lond] 435:172). In the ventral node there is a leftward move of the nodal fluid propelled by cilia and the KIF3 motor complex (see Fig. L23). Conventional cilia in the trachea display

Figure L23. Abstract drawing of cilia base electron micrograph

9 + 2 microtubule arrangement whereas in a nodal form the arrangement is 9 + 0 due to a Hedgehog signaling pathway-mediated intracellular elevation of Ca^{2+} (Hirokawa N et al 2006 Cell 125:33). The normal asymmetry of the organ plan is called situs solitus whereas the reversed arrangement is situs inversus. Some other laterality differences are called isomerism. The overall normal pattern of left/right asymmetry is evolutionarily conserved in vertebrates. In *Caenorhabditis*, neuronal asymmetry is controlled by a microRNA (Johnston RJ, Hobert O 2003 Nature [Lond] 426:845). In *Drosophila*, myosin (Myo1A) and actin cytoskeleton regulate left–right asymmetry (Hozumi S et al 2006 Nature [Lond] 440:798; Spéder P et al 2006 Nature [Lond] 440:803). An intrinsically chiral structure, perhaps the centrosome, serves as a template for directing polarity in the absence of spatial cues. Such a template could help to determine left–right asymmetry and planar polarity in development (Xu J et al 2007 Proc Natl Acad Sci USA 104:9296). ▶situs inversus viscerum, ▶asymmetric cell division, ▶lateral plate mesoderm, ▶cilia, ▶chirality, ▶centrosome, ▶Kartagener syndrome, ▶organizer, ▶Rieger syndrome, ▶hedgehog, ▶FGF; diagram modified after Esteban CR et al 1999 Nature 401:243; Capdevila J et al 2000 Cell 101:9; Burdine RD, Schier AF 2000 Genes & Development 14:763; Garcia-Castro MI et al 2000 Science 288:1047; Mercola M, Levin M 2001 Annu Rev Cell Dev Biol 17:779; Hamada H et al 2002 Nature Rev Genet 3:103; Raya Á et al 2006 Nature Rev Genet 7:283; Tabin CJ 2006 Cell 127:27.

Leghemoglobin: A hemoglobin protein which is coded for by genes of leguminous plants. This protein accumulates in the root nodules formed by the presence of nitrogen fixing bacteria. The leghemoglobin transfers oxygen to the electron-transport system of the bacteria and prevents the accumulation

of toxic amounts of oxygen that would interfere with nitrogen fixation. ▶globin, ▶myoglobin, ▶hemoglobin; Kawashima K et al 2001 Plant Physiol 125:641.

Leghorn White: The poultry breeds White Plymouth Rock and White Wyandotte have plumage which is determined by recessive genes *ii cc*. The White Leghorn on the other hand has the *IICC* genotype where *I* is a dominant suppressor gene of color (*C*). Thus, when it is crossed to another white breed, e.g., White Wyandotte, in the F_2 of their hybrids the segregation is 13 white or speckled and three black. The blacks have the genotype either *iiCC* or *iiCc*. ▶chicken

Legionnaire's Disease: The airborne and potentially lethal, opportunistic infection is caused by the bacterium *Legionella pneumophila*, although over 40 different species exist. Some amoebae may be rarely responsible for similar disease. The bacterial chromosome contains 3,397,754 bp DNA, and has 45 kbp plasmid-like elements. (See Swanson MS, Hammer BK 2000 Annu Rev Microbiol 54:567; Chen J et al 2004 Science 303:1358; Chien M et al 2004 Science 305:1966).

Legit: A statistical concept worked out by R.A. Fisher (Biometrics 6:353) showing the change in allelic frequencies in a cline. If the allelic frequency is known, the legit can be read from the table published in the *Biometrics* article cited above. ▶cline, ▶diffusion genetic

Legumes: A taxonomic group of plants (e.g., pea, beans) with an ability to accumulate atmospheric nitrogen in symbiosis with some nitrogen-fixing bacteria. ▶Rhizobia, ▶nitrogen fixation, ▶Medicago, ▶Lotus, Glycine genome database: <http://www.comparative-legumes.org>.

Leigh's Encephalopathy (LS, 19q13, 11q13, 9q34): The autosomal recessive disorders occur in multiple forms and are characterized by high pyruvate and lactate concentrations in the serum and in the urine. The biochemical findings may be caused either by a defect of pyruvate carboxylase or a necessary cofactor of the enzyme, thiamin triphosphate (TTP). The latter deficiency may be brought about by the absence of thiamin pyrophosphate-adenosine triphosphate phosphoribosyl transferase. The pyruvate carboxylase gene appears to be in human chromosome 11. The nuclear-encoded (3q29 and 5p15) flavoprotein subunit of succinate dehydrogenase controls a mitochondrial enzyme complex II, including succinate dehydrogenase. Mutation in the SURF1 gene (9q34), encoding cytochrome c oxidase, is involved in some cases of the Leigh syndrome. At chromosome

2p16-p21, a mitochondrial cytochrome oxidase subunit deficiency is responsible for Leigh syndrome of the French-Canadian type (LSFC, Mootha VK 2003 Proc Natl Acad Sci USA 100:1605). A mutation in the mitochondrial NDUF complex may cause leukodystrophy and myoclonic epilepsy. Gluconeogenesis may become defective and necrotic brain lesions, heart and respiratory disorders may be present. Prenatal diagnosis is successful in some cases. A defect in the NADH-Ubiquinone Oxidoreductase Fe-S Protein (NDUFS8, 11q13) or a mutation in the 18-kDa NADH-Coenzyme Q Reductase (NDUFS4, 5q11.1), or the NADH-Coenzyme-Ubiquinone Oxidoreductase Fe-S protein 7 (NDUFS7, 19p13), or the NADH-Ubiquinone Oxidoreductase Flavoprotein 1 (DUFV1, 11q13) may also be the cause of Leigh syndrome. These proteins are all components of the mitochondrial respiratory chain that includes more than 40 subunits of which only seven are encoded in the mtDNA. ▶neuromuscular diseases, ▶gluconeogenesis, ▶mitochondrial diseases in humans, ▶encephalopathies, ▶NDUF, ▶lactic acidosis, ▶Saguenay-Lac-Saint-Jean syndrome

Leiner's Disease: Caused by deficiency of the C5 complement component resulting in low opsonization and various types of infections, primarily during childhood. ▶complement, ▶opsonin

Leiomyoma: Generally benign tumors of the smooth muscles occurring in the uterus, genitalia, kidney, gullet, etc., controlled by autosomal dominant genes and their translocations or deletions in several chromosomes (Sandberg AA 2005 Cancer Genet Cytogenet 158:1). Predisposition is coded in the long arm of human chromosome 1q42.3-q43. Up to 77% of women of reproductive age show this condition (Cramer SF, Patel A 1990 Am J Clin Path 94:435), but less than 0.1% of the cases develop into malignancy (see Fig. L24). The high-mobility group of proteins are frequently involved.

Figure L24. A. Firm skin-colored or light brown papules and nodules on the skin in leiomyoma. B. Histological image of papillary type II renal cell carcinoma. The cell cytoplasm stains by either alkalic or acidic dyes and the large nuclei display inclusion-like eosinophilic nucleoli. (From Toro JR et al 2003 Am J Hum Genet 73:95; courtesy of Dr. Jorge R. Toro)

Estrogen and progesterone receptor defects are common in leiomyomas. Renal cell cancer is frequently involved. Mutation in fumarate hydratase at 1q42.3-q43 acts as a suppressor of leiomyoma and is also responsible for neurological impairment and encephalopathy. Besides the main target, the uterus, other body parts may also be affected. ▶cancer, ▶fumarate hydratase, ▶high-mobility group of proteins; Walker CL, Stewart EA 2005 Science 308:1589.

Leishmania: The several species of a protozoon closely related to *Trypanosoma*. In mammals, including humans, it causes skin (T_H -1 response) and kalazar visceral ailments (T_H -2 response) that range from relatively mild to life-threatening depending on the species. The parasites invade neutrophils, monocytes, macrophages, dendritic cells, and fibroblasts. There are numerous minor genes that control human susceptibility; a major gene at 11q12 controls *L. donovani* susceptibility. Macrophages and monocytes spread the parasite all over the body. In mice, at least three genes control cutaneous leishmaniasis susceptibility; among them wound healing has a prominent role (Sakthianandeswaren A et al 2005 Proc Natl Acad Sci USA 102:15551). Susceptibility to the different forms and strains of the disease may be under the control of 1,000 genes. The activation of macrophages through IFN- γ may control the disease through the formation of antimicrobial substances, e.g., NO. The amastigote form occurs in mammalian blood and the promastigote form in the gut of the sandfly that spreads the infection. The virulence and transmission is controlled by lipophosphoglycan on the surface of the cells. The genome of this protozoon can now be effectively manipulated by molecular techniques. The *L. donovani* complex species are morphologically indistinguishable but have been identified by molecular methods, multifactorial genetic analysis that includes DNA sequences of protein-coding genes as well as noncoding segments, microsatellites, restriction-fragment length polymorphisms, and randomly amplified polymorphic DNAs, for a total of 18,000 characters for each of the 25 geographically representative strains. On this basis new taxonomic classification has been proposed (Lukes J et al 2007 Proc Natl Acad Sci USA 104:9375). ▶Trypanosomatids, ▶kinetoplast, ▶marker, ▶macrophage, ▶ T_H , ▶IFN- γ , ▶nitric oxide, ▶metacyclogenesis; Lipoldová M, Demanmt P 2006 Nature Rev Genet 7:294; Tamar S, Papadoupoulou B 2001 J Biol Chem 276:11662; Sacks, D, Kamhawi S 2001 Annu Rev Microbiol 55:453; genomes of three species causing different diseases: Peacock CS et al 2007 Nature Genet 39:839; http://www.sanger.ac.uk/Projects/L_major/.

Lek: A social mating group of animals.

Lemna: The upper cover bract of the grass flower, frequently bearing an awn at the tip (see Fig. L25).
▶palea

Figure L25. Lemna

Lemon (*Citrus limon*): $2n = 18$ or 36 . ▶orange, ▶grapefruit

Lemur: *Cheirogaleus major* and *C. minor*, $2n = 66$; *Hapalemur griseus griseus*, $2n = 54$; *Hapalemur griseus olivaceus*, $2n = 58$; *Lemur catta*, $2n = 56$; *Lemur coronatus*, $2n = 46$; *Lemur fulvus albifrons*, $2n = 60$; *Lemur fulvus fulvus*, $2n = 48$; *Lemur macaco*, $2n = 44$; *Lemur variegatus subcinctus*, $2n = 46$.
▶prosimii, ▶primates

Length Mutation: Length mutation is either the deletion, duplication, insertion or any other alteration of the chromosome or nucleic acid sequence affecting the size of a tract. ▶chromosomal aberrations

Lenticel: The structure on tree barks permitting passage of gaseous substances; lens-shaped glands at the base of the animal tongue.

Lentigines (singular lentigo): Lentigens are also known as freckles (see Fig. L26). ▶LEOPARD syndrome, ▶xeroderma pigmentosum

Figure L26. Lentigines

Lentil (*Lens culinaris*): A pulse, popular in the old world because of its high percentage of protein ($\approx 25\%$), $2n = 2x = 14$.

Lentiviruses (slow viruses): Cytopathic single-stranded RNA retroviruses with similar properties to HIV. They infect primates and domestic animals. The equine infectious anemia virus (EIAV) is contagious for horses. The Maedi visna virus (MVV) infects sheep; the caprine arthritis encephalitis virus (CAEV) is pathogenic for goats. The bovine immunodeficiency virus (BIV) attacks cattle. The feline immunodeficiency virus (FIV) is a threat to cats. The simian immunodeficiency virus (SIV) may be found in apes

and monkeys and may or may not affect them seriously but probably does lead to the evolution of the human immunodeficiency viruses, HIV1 and HIV2.

The HIV genome contains two identical repeats, coupled to a tRNA primer for reverse transcription. The two terminal repeats are essential for replication, transcription, polyadenylation, and integration. Besides three minimally needed genes (*gag*, *pol*, *env*) for the family, they may contain additional genes (▶acquired immunodeficiency syndrome). They are suitable for vector construction by pseudotyping and are promising in gene therapy. An advantage of these vectors is they are suitable for transformation of most nondividing cells because of their ability to pass through cell membranes and nuclear pores, using a system for nuclear localization factors. Some HIV-based vectors may, however, infect only activated cells (see Fig. L27). Some retroviral vectors can infect

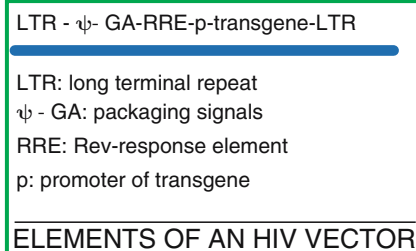

Figure L27. Elements of an HIV vector

cells only during mitosis when the nuclear membrane transiently disintegrates. Amphotropic, replication-deficient HIV vectors have been developed that retain the ψ signal as well as parts of the *gag* and the RRE domain of Rev and Tat, facilitating packaging as well transcription and cytoplasmic transfer of the vector transcripts. Their use may involve the potential danger of self-replication and activation of proto-oncogenes by insertion in their vicinity. For gene therapy the cells are transfected with three separate plasmids. One (the vector) contains the sequences required for infection and transfer of the gene selected. The packaging plasmid carries the elements (structural proteins but not the envelope protein) needed for vector production. The *env* gene must be avoided so the vector would not infect the $CD4^+$ T cells. The third plasmid carries a different envelope gene, encoding, e.g., the G glycoprotein of the vesicular stomatitis virus (see Fig. L28). This protein assures stability and can be employed at high titer. The three vectors lack overlapping sequences, as a result of which, reconstitution of a virion by recombination is prevented. Accessory proteins (Vpr, Vif, Tat) may be required for the efficient transfection of different cell types. The 5' LTR is needed as

Figure L28. Lentivirus particle

a promoter. A deletion in the 3' LTR is incorporated into the 5' LTR during reverse transcription and prevents the production of vector RNA. Such constructs prevent the formation of replication competent lentivirions (RCL). A nonintegrative lentiviral vector derived from HIV1 with a class 1 integrase (IN) mutation (replacement of the 262RRK motif by AAH) displayed episomal expression—in vitro and in vivo—with 500–1,250 times less integration and thus substantially reduced the risk of insertional mutation (Philippe S et al 2006 Proc Natl Acad Sci USA 103:17684). ▶**HIV**, ▶**pseudo-typing**, ▶**ψ**, ▶**gene therapy**, ▶**retroviral vectors**, ▶**MoMuLV**, ▶**retroviruses**, ▶**cytomegalovirus**, ▶**adeno-associated virus**, ▶**vesicular stomatitis virus**; Lever, AML, p. 61 in Meager A (Ed) 1999 Gene therapy technologies, applications and regulations, Wiley, New York; Tang H et al 1999 Annu Rev Genet 33:133; Schnell T et al 2000 Hum Gene Ther 11:439; Kafri T 2004 Methods Mol Biol 246:367.

Lentz-Hogben Test: The Lentz-Hogben test is the same as the ascertainment test.

Leopard Cat (*Felis bengalensis*): $2n = 38$.

LEOPARD Syndrome: An acronym for Lentigines, Electrocardiographic conduction abnormalities, Ocular hypertelorism, Pulmonary stenosis, Abnormalities of the genitalia, Retardation of growth, sensorineural Deafness, and autosomal dominant inheritance. The lentigines may turn neoplastic. The lesions in the PTPN11 gene are shared with the Noonan syndrome. ▶**lentigines**, ▶**hypertelorism**, ▶**stenosis**, ▶**sensorineural**, ▶**cancer**, ▶**Noonan syndrome**; Digilo MC et al 2002 Am J Hum Genet, 71:389.

Leopold of Albany: Hemophilic son of Queen Victoria, who died at age 31 of hemorrhage after a fall, and who transmitted this gene through his daughter, Alice and she transmitted it to his grandson (Rupert) Lord Trematon who also died from hemorrhage after an auto accident. ▶**hemophilia**

Leopold of Battenberg: The hemophilic grandson of Queen Victoria who died of hemorrhage after surgery at age 33. ▶**hemophilia**

Lepidotrichia: The bony structures of the fins of fishes.

Lepore: ▶**thalassemia**

Leprechaunism (Donahue syndrome): Dwarfism caused by a defect in the insulin receptor.

Leprosy (Hansen disease): A neurological disease caused by *Mycobacterium leprae* (3,268,203 bp) invading the Schwann cells and macrophages in the peripheral nervous system. It damages the host immune system and disfigures the extremities (arms and legs), head and other parts of the body. Only 49.5% of the genome codes for proteins, 27% are pseudogenes and 23.5% are noncoding but may have some regulatory functions. It appears that, during evolution, this bacterium (compared to other mycobacteria) lost significant functional parts. Gene expression profiles, e.g., that of the leukocyte immunoglobulin-like receptor family, helps in identifying the clinical stages of the disease (Blehariski JR et al 2003 Science 301:1527). Major human susceptibility loci are at 10p13 and at 6q25-q26 (Mira MT et al 2004 Nature [Lond] 427:636). A second linkage signal was detected in Vietnamese populations in the 6p21 chromosomal region (within HLA), and fine mapping placed the peak (lod score = 2.7) of the responsible lymphotoxin gene in that area (Alcaïs A et al 2007 Nature Genet 39:517). ▶**mycobacteria**, ▶**Bacillus Calmette-Guerin**, ▶**lymphotoxins**; Cole ST et al 2001 Nature [Lond] 409:1007; Young D, Robertson, B. 2001 Curr Biol 11:R381; Siddiqui MR et al 2001 Nature Genet 27:439; Cole ST et al 2001 Nature [Lond] 409:1007; Mira MT et al 2003 Nature Genet 33:412.

Leptin: Assumed to be a hormonal feedback signal (167 amino acids) produced by adipocytes. It acts on the ventromedial hypothalamus and regulates food intake and metabolic rate negatively (Dhillon H et al 2006 Neuron 49:191). Obesity may also be the result of resistance to leptin. A deficiency or resistance to leptin causes increased food intake in mice and humans whereas injection of leptin, the hormone, encoded by the *ob* gene of mice, reduces body weight by reduction of fat tissues and controls glucose and lipid metabolism.

Leptin has repressive effects on hepatic stearyl-CoA desaturase-1, an enzyme catalyzing the biosynthesis of monounsaturated fatty acids (Cohen P et al 2002 Science 297:240). Leptin also has angiogenic

activity. Glucosamine, hyperglycemia, and hyperlipidemia may stimulate leptin synthesis.

Recombinant human leptin corrects sterility caused by the *ob/ob* condition in female mice. The leptin receptor of mouse (*Ob-R*) gene encodes five alternatively spliced transcripts. Leptin-deficient humans are deficient in sexual development. Leptin signals through the STAT3 protein and modulates insulin activity (see Fig. L29). It activates ATP-sensitive K

Figure L29. A simplified outline of the melanocortinergic pathway of leptin action. POMC = pre-pro-opiomelanocortin, AGRP = agouti-related protein, MC4R = melanocortin. (After Barsh GS et al 2000 Nature 404:644)

channels and inhibits hypothalamic neurons (nucleus arcuatus hypothalami and the nucleus paraventricularis hypothalami), but the arcuate nucleus may also stimulate the lateral hypothalamic neurons and the parasympathetic and preganglionic neurons may receive mixed signals. Neuropeptide Y interacts with leptin and may promote appetite. Leptin also affects the synthesis of the α -melanocyte-stimulating hormone (α -MSH) which down-regulates appetite. The melanin-concentrating hormone (MCH) is also high in the brain of *ob* homozygous rodents. Dopamine-deficient mice do not feed even when leptin is missing. The OBR-A receptor may also affect leptin transport. The suppressor of cytokine signaling (SOCS3) also appears to be a factor in mediating resistance to leptin. The synthesis of leptin may be suppressed by CART (cocaine- and amphetamine-regulated transcript). Leptin may inhibit bone formation by acting through the central nervous system. The leptin receptor (OB-R) occurs in several isoforms because of alternative splicing of its RNA transcript. The leptin and the insulin pathways may interact at several levels. Peroxisome proliferator-activated receptor γ (PPAR) co-activator (PGC-1) is an important regulator of energy output (thermogenesis). Administration of leptin to starving mice reversed the immunosuppressing effect of starvation.

Leptin-deficient mice, however, are protected from T cell mediated hepatotoxicity because of the reduction of TNF- α and IL-18. Malnutrition and starvation appears to be a serious factor in susceptibility to infectious diseases. It is not known whether treatment with leptin under conditions of hunger would be desirable because it increases energy storage and expenditure, and may further aggravate malnutrition. Leptin deficiency in rats leads to depression-like symptoms that can be remedied by intrahippocampal infusion of leptin but not by infusion of leptin into the hypothalamus (Lu X-Y et al 2006 Proc Natl Acad Sci USA 103:1593). ▶obesity, ▶STAT, ▶insulin, ▶brain human, ▶orexin, ▶ion channels, ▶angiogenesis, ▶melanocortin, ▶CART, ▶neuropeptide Y, ▶PYY₃₋₃₆, ▶AGRP, ▶melanocyte stimulating hormone, ▶opiocortin, ▶SOCS-box, ▶TNF, ▶IL-18, ▶ciliary neurotrophic factor, ▶ghrelin, ▶muscarinic acetylcholine receptors; Sierra-Honogmann MR et al 1998 Science 281:1683; Harris RBS 2000 Annu Rev Nutr 20:45; Forbes S et al 2001 Proc Natl Acad Sci USA 98:4233.

Leptokurtic: ▶kurtosis

Leptomycin: An antibiotic and nuclear export inhibitor in meiosis.

Leptonema: ▶leptotene stage

Leptotene Stage: The leptotene stage is distinguished in meiosis when the chromosomes appear under the light microscope as single strands although they have been doubled during the preceding S stage. The chromosomes are greatly relaxed and stretched out. The threads (leptonema) are usually quite tangled and their termini cannot be distinguished by light microscopy. Bead-like structures of localized condensations, the chromomeres, are usually visible. The photograph (courtesy of Dr. A. Sparrow) shows late leptotene (see Fig. L30). ▶meiosis, ▶chromomere

***Lespedeza bicolor*:** A forage legume, $2n = 18, 20, 22$.

LESTR (leukocyte-expressed seven-transmembrane-domain receptor): LESTR is the same as fusin.

LET: LET or linear energy transfer is a measure of energy delivered by ionizing radiation in keV (kilo electron volts) per nanometer path within the target. Approximate LET values in biological material: gamma rays from ^{60}Co source (1.2 to 1.3 MeV): 0.3; hard x-rays (250 keV): 3.0; β -rays from ^3H (0.6 keV): 5.5; recoil proton from fast neutrons: 45; heavy nuclei from fission (α -particles): 5,000. ► [ionizing radiation](#), ► [kinetics](#), ► [DNA repair](#)

let-23: A gene of *Caenorhabditis* coding for a transmembrane receptor protein. ► [signal transduction](#)

Lethal Equivalent: The designation of genetic factors in an individual that, in combinations, are responsible for death. For example, if three genes each are expected to reduce life expectancy by a chance of 0.33, their combined lethal equivalent value is ≈ 1 , i.e., approximately the same as one that causes early death with 100% probability (see [Fig. L31](#)). The actual calculation must, however, be carried out by a different procedure because no information can be obtained on the number of the individual recessive sublethal genes. Thus, if it is observed that the infant mortality among the offspring of totally unrelated parents is ($F = 0$) 8%, and among the offspring of first cousins ($F = 1/16$) of the same population is 13% [F is the coefficient of inbreeding], the difference $0.08 - 0.13 = 0.05$, i.e., 5%; then, $5\% \times 16 = 0.8$, i.e., 80%. Since among diploids two recessive alleles at a locus are required for expression, the frequency of lethal equivalent recessive genes is $\sqrt{0.8} < 0.89$. Thus the number of lethal equivalent recessive genes per gamete in this particular population is ≈ 0.89 , close to 1 per gamete. The number of lethal equivalents in a population is $\sum q$ where q is the frequency of the recessives and s is the selection coefficient. ► [coefficient of inbreeding](#), ► [coefficient of coancestry](#), ► [genetic load](#), ► [incest](#), ► [selection coefficient](#); Makov E, Bittles AH 1986 *Heredity* 57 (3):377; Anderson NO et al 1992 *Plant Breed Revs* 10:93.

Figure L31. Lethal mouse embryo

Lethal Factors: Lethal factors have been extensively used for the genetic analyses of developmental pathways because they permit studies on the consequences of arrest of differentiation at particular stages. Conditional lethal mutations survive under certain temperature regimes or on supplemented nutritive media and offer particular advantages because they can be more easily analyzed by biochemical methods. The presence of lethal factors may modify segregation ratios. Dominant and recessive lethal factors may not permit the expression of syntenic genes or only at low frequency depending on the extent of recombination. Therefore, genes on the homologous strand may appear in excess. Semi-recessive lethal mutations may cause 2:1 segregation instead of 3:1 in F_2 ($1/1$ dead). ► [segregation distorter](#), ► [meiotic drive](#), ► [certation](#)

Lethal Mutation: A lethal mutation normally fails to survive. In *Caenorhabditis*, only 20–35% of the genes are mutable to an obvious visible, lethal or sterile phenotype and the majority of mutations appear like the wild type. This information resulted from the sequencing of the whole genome and has been interpreted by (partial) redundancy of the genetic material. In *Drosophila*, 24–30% of genes are estimated to be vital and apparently more than half of them are in the 2nd chromosome. ► [conditional lethal mutations](#)

Lethal Synthesis: Lethal synthesis occurs when a toxic analog of a metabolite is incorporated into a biological system and eventually exerts deleterious or lethal effects.

Lettuce (*Lactuca sativa*): A composite salad crop with chromosome numbers $n = 8, 9$ and 17.

Leucine Metabolism: Leucine $[(\text{CH}_3)_2\text{CHCH}_2\text{CH}(\text{NH}_2)\text{COOH}]$ is a nonpolar amino acid; it may be formed from isoleucine $[\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}(\text{NH}_2)\text{COOH}]$. ► [isoleucine-valine biosynthetic pathway](#), ► [3-hydroxy-3-methylglutaryl CoA lyase deficiency](#), ► [methylcrotonylglycinemia](#), ► [methylglutaconic aciduria](#), ► [hydroxymethylglutaric aciduria](#)

Leucine-Rich Repeats: 15–29 leucines assist ligand recognition in processes such as signal transduction, cell development, DNA repair and RNA processing, and resistance to pathogens. ► [leucine zipper](#), ► [ligand](#), ► [DNA repair](#), ► [introns](#)

Leucine Zipper: Dimeric regulatory proteins of two subunits; at the COOH terminus, an amino leucine occurs at every seventh position; at the amino terminal domain, positively charged amino acids are found and this region is bound to DNA in a zipper-like manner (see [Fig. L32](#)). The leucine zippers may be homo- or heterodimeric and thus increase their

specificity by a combinatorial control mechanism. The basic leucine zipper (bZIP) contains 25 conserved amino acids of these nine substitutions and disrupts function. The binding domain is usually 100-amino-acid long. ▶DNA-binding protein domains, ▶binding proteins, ▶regulation of gene activity, ▶Max, ▶induced helical fork, ▶bZip; Rieker JD, Hu JC 2000 Methods Enzymol 328:282; Palena CM et al 2001 J Mol Biol 308:39.

Leucoplasts: Plastids without carotenoids and chlorophylls.

Leucyl tRNA Synthetase (LARS): Leucyl tRNA synthetase charges tRNA^{Leu} by leucine. Its gene is in human chromosome 5. ▶aminoacyl-tRNA synthetase

Leukalexins: These are released by effector cells and slowly degrade the DNA of the target cells. ▶immune system; Joag S et al 1989 J Cell Biochem 39(3):239.

Leukemia: A cancer of the blood forming organs characterized by an increase of the number of leukocytes and accompanied by an enlargement or proliferation of the lymphoid tissues. It involves anemia and increasing general weakness and tiredness. Two main types are generally distinguished: *acute myelogenous leukemia* (AML/FPD, 21q22.1-q22.2) that primarily affects adults. AML is frequently caused by the ectopic expression (through translocational gene fusion) of the *CDX2* homeobox gene. Fusion of the *ETV6* transcription factor gene has minimal or no effect for AML development (Rawat VPS et al 2004 Proc Natl Acad Sci USA 101:817). Reduction in the level of the PU.1 transcription factor decreases the levels of c-Jun and JunB oncogenes and blocks differentiation, increasing self-renewal of hematopoietic stem cells in AML (Steidl U et al 2006 Nature Rev Genet 38:1269). In chronic lymphocytic leukemia (CLL, 11q13.3) the circulating malignant cells are differentiated B

lymphocytes. Down-regulation of Death-associated protein kinase 1 (DAPK1, 9q34.1) by methylation of its promoter is common in CLL and in such a case hereditary predisposition occurs (Raval A et al 2007 Cell 129:879). MicroRNAs miR-15a and miR-16-1 downregulate the antiapoptotic effect of the Bcl2 and may play a role in the development of the cancer (Cimmino A et al 2005 Proc Natl Acad Sci USA 102:13944). A low-grade B-cell malignancy involves chromosomal aberrations at 13q14, a site concerned with about 25–50% of CLL, the position of a tumor suppressor. MicroRNA sequences are located in this region and their deletion occurs in about 68% of the CLLs (Calin GA et al 2002 Proc Natl Acad Sci USA 99:15524). The acute myelogenous leukemia (AML) may be preceded by haploinsufficiency of the core binding factor α subunit (CBFA2, 6p21). The acute myeloid leukemia involving inversion in human chromosome 16 is a fusion of the core binding factor- β (BGF/CBFB/PEBP2B) and the smooth muscle myosin heavy chain (MYH11). It results in transcriptional repression. About half of the AML cases involve cytological anomalies. A defect in JunB may lead to AML. The acute lymphoblastic leukemia (ALL) mainly affects children. It involves, primarily, chromosomal aberrations affecting several genes genomewide (Mullighan CG et al 2007 Nature [Lond] 446:758). Thiopurine methyltransferase assay (TPMT) is successful for determining the dosage of thiopurines appropriate for an individual (Weinshilboum R 2003 New England J Med 348:529). Blood asparagine level can be decreased along with chemotherapy. Such a treatment may result in drug resistance by upregulation of glutamine-dependent asparagine synthetase (Richards NGJ, Kilberg MS 2006 Annu Rev Biochem 75:629).

The acute myeloid form frequently involves a translocation between human chromosome 8 and 21 [t(8;21)(q22;q22)]. In chromosome 21 the breakpoints are generally within the same intron of the receptor for the granulocyte-macrophage colony-stimulating factor (CSF2R). At the same chromosome-21 location a basic helix-loop-helix protein, class B1 (BHLHB1), is encoded as shown by the t(14;21)(q11.2;q22) translocations. Patients in relapse usually have activated Jak-2 protein tyrosine kinase. Tyrphostins (AG-490) effectively block leukemic cell growth in these cases by inducing apoptosis in the cancer cells without affecting normal blood-forming cells. The *chronic myeloid leukemia* (CML) is generally associated with a translocation between chromosomes 22q11.21 and 9q34.1 (▶Philadelphia chromosome). The translocation is within the BCR (breakpoint cluster region) of chromosome 22 and in chromosome 9; the ABL gene (Abelson murine leukemia virus oncogene) is affected. The

translocation causes a fusion between the 5' proximal region of one of the BCR spanned loci and the ABL gene. The fused BCR-ABL region encodes a 210-kDa tyrosine kinase protein, which causes malignant transformation of leukocytes. Transplantation experiments in mice demonstrated hematological malignancies in the recipients of this protein. At the early stages of the disease the use of the drug STI-571 specifically and effectively blocks the kinase and counteracts the malignancy. Treatment at advanced stages involves resistance in about a year. Chronic lymphocytic leukemia Type2 (BCL2) is a follicular lymphoma involving translocations between chromosome 18q21 (immunoglobulin heavy chain gene J) and gene BCL in chromosome 18 and placing BCL under the influence of the IgJ_H enhancer. It leads to a low-grade malignancy. In another step, a translocation with chromosome 8 brought in the MYC c-oncogene (myelocytomatosis v-oncogene homolog in chromosome 8q24) and the double translocation caused a high-grade malignancy. Transfection with a BCL-2 construct resulted in oncogenic potential. The BCL-2 product is an integral mitochondrial membrane protein (M_r 25,000). A human chromosome 19q13 oncogene apparently causes B cell leukemia/lymphoma (BCL3 or BCL4). It usually involves translocations. Chronic B cell leukemia (BCL5) also involves a translocation between BCL-2 and a truncated MYC resulting in high-grade expression. Chronic lymphatic leukemia (CLL or BCL1) is clearly a familial disease involving translocations (11;14)(q13;q32). Again, the translocation involves the joining segments 3 and 4 of the heavy chain Ig in chromosome 14. As a consequence, the immune system is weakened and the leukemia is often associated with other disturbances of the immune system (hyperthyroidism, pernicious anemia, rheumatoid arthritis, autoimmune disease). Acute T cell leukemia (ATL/TAL/SCL) is due to the activation of the α -chain of the T cell receptor (TCRA, chromosome 11p13) by translocations t (11;14)(p13;q11). The 14q11 band contains the variable region of TCRA and the 11p15.5 is the location of the HRAS (Harvey rat sarcoma) oncogene. Lymphoid leukemia, LYL1, involves translocations between chromosome 7 at the T cell receptor β -chain gene (TCRB, 7q35) and the LYL1 gene, chromosome 19p13.

Myeloid/lymphoid mixed lineage leukemia (MLL/ALL/HRX) involves translocations of 11q23 to AF10 (at human chromosome 10p12 encoding a 1,27 amino acid protein) and displays lymphoid myeloid phenotypes. It is present in infancy. DOT1L (DOT1-like, homolog of yeast) encodes at human chromosome 19p13.3, a histone 3 methyltransferase that interacts with MLL; histone H3 is hypermethylated at lysine 79 and subsequently HOXA9 and other

leukemia-related genes are upregulated (Okada Y et al 2005 Cell 121:167). The sequences of 11q23 involve a postulated transcription factor and it is also frequently included in about 30 different translocations. Cleavage of the MLL gene (translocations) may be caused by inhibition of topoisomerase II by bioflavonoids (flavone, rutine, kaempferol, etc.). The MLL gene is an apparent regulator of a homeobox, shared by other animals. Taspase I (threonine aspartase) is an asparaginase enzyme processing MLL (Khan JA et al 2005 Structure 13:443). The very common B-cell precursor (BCP) leukemia responds favorably to the CD19-associated tyrosine kinase inhibitor, genistein. CD19 is a B cell-specific TK receptor and its destruction leads to apoptosis of 99.9 percent of leukemia cells. The stem cell leukemia (SCL) gene is normally involved in the differentiation of the hematopoietic cells but it may form a complex with the oncogene product LMO-2 and GATA proteins. The tetramer may act in the development of acute T cell leukemia. In the acute promyelocytic leukemia (APL) the translocation involves 15q21 (PML [promyelocytic leukemia inducer])-17q11.2 (RARA [retinoic acid receptor α]). A translocation between 11q23 (PLZF [promyelocytic leukemia Zn-fingers])-17q12 (RARA) is another cancerous gene fusion transactivating the p21 transforming protein. PLZF normally is a transcriptional repressor and it regulates limb and axial skeletal patterning. PML is also a tumor suppressor and it inhibits translation of hypoxia-inducible factor (HIF-1 α) by repressing TOR and neoangiogenesis supportive of tumor growth. Mutation in these proteins promotes cancer growth (Bernardi R et al 2006 Nature 442:779). PML bodies oppose nuclear AKT oncogene (Trotman LC et al 2006 Nature [Lond] 441:523). PML and PLZF heterodimerize and thus form nuclear bodies. The oncogenic domain of PML is involved in the degradation of ubiquitinated proteins. PML-RARA is retinoic acid responsive whereas PLZF-RARA is a retinoic acid resistant leukemia. The juvenile myelomonocytic leukemia is a complex disease encoded at 17q11.2, 12q24.1, and 5q31. It is frequently associated with neurofibromatosis and cases of the Noonan syndrome due to somatic or germline mutations of protein tyrosine phosphatase (PTPN11) (Tartaglia M et al 2003 Nature Genet 34:148).

In animal models, *N*-methylnitrosourea (MNU), 3-methylcolanthrene (MCA), ionizing radiation, Moloney mouse leukemia virus, etc., may induce leukemia. ►interferon, ►T cell, ►TCR, ►RAS, ►immunoglobulins, ►ABL, ►Abelson murine leukemia virus, ►FMS, ►ELL, ►Philadelphia chromosome, ►BCR, ►Myb oncogene, ►MYC, ►Mylotarg, ►colony stimulating factor, ►apoptosis,

Leukemia Inhibitory Factor (LIF): The human cytokine (241 amino acids, encoded in chromosome 22q12.1-q12.2) is involved in negative and positive regulation of myeloid leukemia cell lines, in the development of motor neurons, and in a wide variety of other functions. LIF causes the dimerization of LIFR (LIF receptor) and glycoprotein gp130. LIF activates transcription factors STAT3 and BMP2 induces SMAD1. The STAT and Smad family of proteins bind p300 and are involved in the differentiation of astrocytes. BMP causes the tetramerization of the bone morphogenetic protein receptors (BMPR1 and BMPR2) and the heterodimer phosphorylates SMAD1. In all probability, p300 could be involved with the acetylation of histones and thereby the facilitation of transcription. Its receptor, encoded at 5p12-p13, is shared with other cytokines. An inactive LIF does not affect embryonic development in mice but it may be important for implantation of the egg. LIF^{-/-} males are normal but the females are sterile. ▶ neurons, ▶ cytokines, ▶ STAT, ▶ bone morphogenetic protein, ▶ Smad, ▶ p300, ▶ gp130, ▶ astrocyte, ▶ GFAP, ▶ TGF, ▶ histone acetyl transferase, ▶ APRF, ▶ Abelson murine leukemia virus, ▶ retroviral restriction factors; Stewart, CL et al 1992 Nature [Lond] 359:17; Cheng J-G et al 2001 Proc Natl Acad Sci USA 98:8680, structure of LIF-LIF Receptor binding: Huyton T et al 2007 Proc Natl Acad Sci USA 104:12737.

Leukocyte (leucocyte): A white blood cell. Their average numbers under normal conditions per mL of blood in humans is ~6,000. It is ~28,000 in chickens, ~15,000 in pigs, ~9,000 in dogs, and ~8,000 in horses and cattle. ▶ blood, ▶ erythrocyte

Leukocyte Adhesion Deficiency (LAD): LAD2 is a deficiency of CD15-fucose cell surface glycoprotein, ligand of selectins E and P. ▶ selectins, ▶ fucosyltransferase

Leukocyte Adhesion Deficiency (ITBG2, LAD): A human chromosome 21q22.3 dominant/recessive immunodefect that involves common infections, lack of pus formation, and impairment of granulocytes, monocytes and lymphocytes. ▶ selectins, ▶ fucosyltransferase

Leukocyte Antigen: ▶ HLA

Leukocyte Common Antigen: ▶ CD45

Leukocytosis: Activation of the leukocyte producing system. It is mediated by the leukocyte mobilization factor (LMF) formed from the α chain of the C3 complement component by enzymatic fragmentation. ▶ leukocytes, ▶ complement

Leukodystrophy: ▶ metachromatic leukodystrophy, ▶ Addison disease, ▶ Krabbe's leukodystrophy, ▶ Gaucher's disease, ▶ Pelizaeus-Merzbacher disease, ▶ Charcot-Marie-Tooth disease, ▶ cytotoxic T cell. Adult onset dominant leukodystrophy (chromosome 5q) is due to duplication of lamin B1; the homologous gene in *Drosophila* involves developmental eye anomaly (Padaiah QS et al 2006 Nature Genet 38:1114, see correction in Nature Genet. 39:276). The duplication causes progressive demyelination of the central nervous system with symptoms resembling multiple sclerosis. ▶ lamins, ▶ laminopathies, ▶ multiple sclerosis

Leukoencephalopathy: A group of neurological disorders. A dominant dementia, CADASIL, was located at 19p13.2-p13.1. Leukoencephalopathy with vanishing white matter and neurological deterioration is at the region 3q27 encoding the ϵ and β subunits of the translation initiation factor eIF2B. Swelling and cysts in the brain characterize a third type. The disease is caused by the human polyomavirus, JC, which infects in early childhood and is prevalent in immunocompromised adults. It enters the cells by a ligand-induced clathrin-dependent pathway (Elphic GF et al 2004 Science 306:1380). Recessive leukoencephalopathy with brain stem and spinal cord involvement and lactate elevation is encoded in human chromosome 1. Sequencing of this region uncovered mutations in *DARS2*, which encodes mitochondrial aspartyl-tRNA synthetase (Scheper GC et al 2007 Nature Genet 39:534). ▶ CADASIL, ▶ eIF2B; Leegwater PAJ et al 2001 Nature Genet 29:383.

Leukopenia: A condition with reduced numbers of leukocytes and neutrophils in the blood.

Leukosis: The organic basis of leukemia. ▶ leukemia

Leukotomy: ▶ lobotomy

Leukotrienes: Leukotrienes are 20 carbon carboxylic acids with one or more conjugated double bonds and some oxygen substitutions. They are formed from arachidonic acid by lipoxygenase. They control inflammatory and allergic reactions such as asthma and, indirectly, obesity. Leukotrienes may activate the transcription factor peroxisome proliferator-activated receptor (PPAR) subunits that are involved in the regulation of enzymes of fatty acid oxidation, control of development, adipocyte differentiation, glucose metabolism, and, indirectly, in inflammatory reactions through macrophages. Leukotriene C4 synthase (LTC4S), a trimer, is encoded in human chromosome 5q35 (Schmidt-Krey I et al 2004 Structure 12:2009). The FLAP protein is required for the biosynthesis of leukotrienes. Its crystal structure shows that inhibitors bind in membrane-embedded pockets of FLAP, which suggests how these inhibitors prevent arachidonic acid from binding to FLAP and subsequently being transferred to 5-lipoxygenase, thereby preventing leukotriene biosynthesis. Leukotrienes play important roles in respiratory and cardiac functions (Ferguson AD et al 2007 Science 317:510). The cysteinyl leukotriene-1 receptor (CysLT₁) is encoded at Xq13-q21; its crystal structure is identified (Ago H et al 2007 Nature [Lond] 448:609) ▶[lipoxygenase](#), ▶[arachidonic acid](#), ▶[fatty acids](#), ▶[peroxisome](#), ▶[integrin](#), ▶[anemia](#), ▶[hemolytic anemia](#), ▶[PPAR](#), ▶[prostaglandins](#), ▶[myocardial infarction](#); Funk CD 2001 Science 294:1871.

Levorotatory: The plane of polarized light is rotated counterclockwise.

Levy-Hollister Syndrome: ▶[LADD syndrome](#)

Lewis Blood Group: The Lewis blood group is characterized by the expression of the *Le* gene coding for α -L-fucosyltransferase. Four different types can be characterized with the frequencies indicated: (1) *Lea*^{+/+}, 0.7 (genotype *Le/le Se/se*); (2) *Lea*^{+b-}, 0.20 (genotype *Le, se*); (3) 0.09 (genotype *le, Se/se*); (4) *Lea*^{b-}, 0.01 (genotype *le, se*). The ABH blood group may cause less severe reaction in incompatible application in blood transfusion than the ABO, yet it may cause serious hemolytic problems. The *Le*^y oligosaccharide non-protein antigen is overexpressed in the majority of human carcinomas. ▶[ABH antigen](#), ▶[ABO blood group](#), ▶[Bombay blood group](#), ▶[secretor](#)

Lewy Body: Lewy bodies are round (or other size and shape) structures in neural cytoplasm composed mainly of α -synuclein (see [Fig. L33](#)). They occur in Parkinson's disease and in other diseases with neuronal degeneration (Alzheimer's disease, Hallervorden-Spatz disease, Pick's disease, Gaucher's disease). Besides mutation in α -synuclein, Lewy bodies may

Figure L33. Lewy body in the brain. (Courtesy of National Institute of Genome Research and Dr. Wong, K. 2004 Armed Forces Institute of Pathology)

also occur by mutation in a leucine-rich repeat kinase 2. LB-like bodies have also been observed if the mitochondria were inhibited (Shults CW 2006 Proc Natl Acad Sci USA 103:1661).

Human α -synuclein transgenic mice vaccinated with α -synuclein antibodies promoted the degradation of the synuclein aggregates and lead to neuronal degeneration. Thus vaccination may be a potential therapeutic tool for Parkinson's disease (Mesliah E et al 2005 Neuron 46:857). ▶[synuclein](#), ▶[Parkinson's disease](#), ▶[ubiquilin](#); Gasser T 2001 Adv Neurol 86:23.

lexA: A gene of *E. coli* (map position 91) that controls resistance/sensitivity to X-rays and UV. It is a repressor of all SOS repair operons. Its protein product is autoregulated. The RecA protein cleaves the LexA repressor protein (22 kDa) and subsequently, the genes that it represses become activated. ▶[DNA repair](#); De Henestrosa F et al 2000 Mol Microbiol 35:1560; Luo Y et al 2001 Cell 106:585.

Lexicon Genetics: A public gene trap for mouse functional genomics (Skarnes WC et al 2004 Nature Genet 36:543).

Lexitropsins: Lexitropsins are organic molecules with the ability to recognize G-C in the minor groove of DNA. There are three major types of lexitropsins: pyrole, imidazole, and hydroxypyrole. They are of potential use for targeting genes and controlling their function. ▶[netropsin](#); Goodsell DS 2001 Curr Med Chem 8:509.

Leydig Cells: ▶[Wolffian ducts](#)

λ FIX: A replacement vector very similar to λ DASH. ▶ [\$\lambda\$ DASH](#)

LFA (lymphocyte-associated proteins): LFA belong to the integrin family present on T lymphocytes. They

promote cell adhesion and stimulate T cell activation in association with ICAM, CD28, and myosin motor proteins. ►CD28, ►ICAM, ►myosin, ►T cell receptor, ►antigen presenting cell, ►JAB

LFT: A low frequency transducing lysate generated when aberrant excision of a phage particle takes place from a single lysogen. ►HFT, ►lysogen

LGT (lateral gene transfer): A lateral gene transfer may occur during evolution. It is postulated on the basis that some genomes contain nucleotide sequences absent from close relatives but present in more distant ones. ►lateral transmission, ►transmission

LH (luteinizing hormone): ►luteinizing hormone, ►animal hormones

LHCP (light-harvesting chlorophyll protein complex): ►chlorophyll-binding protein complex

Lhermitte-Duclos Disease: ►multiple hamartoma syndromes, ►PTEN

LHX: LIM homeobox genes of mammals and similar genes in invertebrates. ►LIM, ►homeobox

Liability: The appearance of many human traits cannot be explained by simple genetic mechanisms because they show up more frequently in certain human families than in others or in the general population and yet the proportions of afflicted individuals vary a great deal. The manifestation of these traits is commonly explained by polygenic systems. Various environmental effects that make predictability of the manifestation quite difficult generally influence polygenic systems. The frequency of diabetes, schizophrenia, hypertension, dental caries, peptic ulcers, various forms of cancers, etc., belongs to these categories. Until a certain threshold is reached the person is considered healthy but beyond that point medical attention is necessary. The passing of the threshold requires special unidentified environmental conditions. Naturally, it is important to have some predictive ability regarding the liability of individuals to succumb to such diseases. A relatively simple statistical procedure exists to assess the heritability of the liability based on the normal distribution of these traits. In order to proceed with the empirical calculation, refer Table L1.

Q = the incidence of the trait, t = Student's t distribution with one-tail of the normal distribution, z = is the truncation point at the t value.

Assume that the incidence of the trait in the general population is $Q_p = 0.001$ and the incidence among the offspring of an afflicted individual is $Q_a = 0.1$. The truncation point in the general population thus is $t_p = 3.090$ (first column) and that in the afflicted family is $t_a = 1.282$ (6th column). The mean liability of the affected parent is $\mu^1 \cong z_a/Q_a = 0.0037/0.001 = 3.7$.

The mean liability of the offspring of the affected parent is $\mu^2 \cong t_p - t_a = 3.090 - 1.282 = 1.808$.

The heritability of the liability of the trait determined by offspring-parent regression is $h^2 = 2b_{OP}$ (where regression is on one parent rather than on the midparent value) and $b_{OP} = \mu^2/\mu^1 = 1.808/3.7 \cong 0.49$; hence heritability is $h^2 = 2 \times 0.49 = 0.98$. This hypothetical value is obviously very high for heritability. It must be kept in mind, however, that the trait has low penetrance for being controlled by a single gene and most likely it is under the control of multiple genes and is not expected to occur frequently because of the threshold event needed for its manifestation. Would have been the incidence of the trait in the general population $Q_p = 0.005$ and that of the afflicted family $Q_a = 0.500$, the heritability would have come out by this calculation as 0.65. The liability increases with consanguinity of the parents. ►normal distribution, ►Student's t distribution, ► z , ►correlation, ►heritability, ►polygenic inheritance, ►GTL, ►consanguinity, ►penetrance, ►recurrence risk, ►risk, ►threshold trait

Libido: Sexual drive. Libido is the motive for sexual contact although it may exist even in the absence of sexual potency such as in sterile mules.

Library, Genetic: A collection of cloned fragments, representing the entire genome (at least once). The construction of the library requires cutting up of the genome by one or more restriction enzymes or mechanical shearing. Subsequently, the DNA fragments are ligated into appropriate cloning vectors and transformation is carried out in a suitable host (most commonly into *E. coli*). The screening of the cloned colonies requires either nucleic acid hybridization, south-western analysis, immunochemical procedures, recombinational assays, or genetic analysis

Table L1. Liability calculation

| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | ← Columns |
|------------|--------|--------|---------|---------|---------|---------|---------|-----------|
| Q → | 0.001 | 0.005 | 0.010 | 0.050 | 0.100 | 0.150 | 0.200 | |
| t → | 3.090 | 2.576 | 2.326 | 1.645 | 1.282 | 1.036 | 0.842 | |
| z → | 0.0037 | 0.1446 | 0.02665 | 0.10314 | 0.17550 | 0.23316 | 0.27996 | |

and identification through one or more of these final steps. ►gene bank, ►vectors, ►transformation, ►restriction endonucleases, ►south-western method

Licensing: The legal authorization for using or, in some cases, even patenting research inventions by another party (industry) for profit. ►patent; Thursby JG, Thursby MC 2003 Science 301:1052.

Licensing Factor (replicational licensing factor): Licensing is a quality control instrument in the immune system for the distinction of self from nonself molecules. Natural killer cells recognize and spare self by the attached self-ligands. ►MCM, ►geminin, ►killer cell; DePamphilis ML et al 2006 Current Opin Cell Biol 18:231.

Lid Domain: An oligopeptide that covers the top layer of the 26S proteasome. It is used for the recognition of ubiquitin, ubiquitin isopeptidase and some proteins with homology to signal transduction complexes. ►proteasome, ►ubiquitin

Liddle Syndrome (pseudoaldosteronism): An autosomal dominant moderate hypertension encoded in human chromosome 16p13-p12. It is involved in the control of a Na⁺ ion channel and renal sodium reabsorption. ►aldosteronism, ►mineral cortical syndrome, ►hypertension, ►degenerin, ►Bartter syndrome, ►Gitelman syndrome

LIF: Laser-induced fluorescence detector.

LIF: ►leukemia inhibitory factor, ►APRF

Life Beginning on Earth: Latest evidence indicates that life began on earth ~3,800 Myr before present. ►Myr

Life Cycle: The successive changes in generations of organisms, including the modes of reproductions. In higher organisms this includes the generation of gametes, fertilization and other modes of propagation and the development of the adult forms. ►gametophyte, ►sporophyte, ►germline, ►alternation of generations, and see also the name of individual organisms.

Life Expectancy: ►longevity

Life-Form Domains: Life-form domains include bacteria, archaea, and eukarya (see Fig. L34). ►archaea, ►prokaryotes, ►eukaryotes; Pace NR 2006 Nature [Lond] 441:289.

Figure L34. Life-form domains

Life Span: ►longevity

Li-Fraumeni Syndrome (LFS): In some families several types of cancers (breast, sarcomas, brain, lung, laryngeal, adrenal cancers, melanomas, prostate cancer, gonadal germ cell tumor, and leukemias) are found with about 50-fold increased incidence as compared to the general population. The assumption is that alleles of the dominant p53 tumor-suppressor gene segregate these families. LFS is encoded in human chromosome 17p13.1. In some LFS cases the p53 gene appears normal but various single nucleotide substitutions occur in the CHK2 gene. Some gain-of-functions mutations of p53 cause new types of symptoms and have increased effect compared to loss of p53 in mouse (Olive KP et al 2004 Cell 119:847; Lang GA et al 2004 Cell 119:861). (The human gene is homologous to the budding yeast G2 checkpoint kinase RAD53 that normally phosphorylates protein CDC25C.) ►tumor suppressor genes, ►P53, ►malignancy, ►cancer, ►Lynch cancer families, ►substitution mutation, ►RAD53, ►checkpoint, ►CDC25, ►small cell lung carcinoma

Lifting: ►phasmid

Ligand: A molecule that can bind (by noncovalent bonds) to a receptor by virtue of special affinity. Ligands include transcription factors, growth factors, activators, DNA-binding proteins, hormones, neurotransmitters, antigens, morphogens, and membrane receptors. Target-guided combinatorial assembly can screen ligands. In the first step, a set of potential binding elements, including common chemical linkage groups, are prepared. Then, their interaction with the selected target (enzymes, receptors, etc.) is determined. In a third step the combinatorial library of linked binding elements are connected by flexible linkers and in the fourth step this library is tested and classified for tightness of binding to the biological target. Understanding ligands that can selectively enhance or inhibit macromolecular function is important for drug development. Ligand-target relations can be studied by functional effects and nuclear magnetic resonance spectroscopy. ►NMR; Maly DJ 2000 Proc Natl Acad Sci USA 97:2419; Looger LL et al 2003 Nature [Lond] 423:185; Carlomagno T 2005 Annu Rev Biophys Biomol Struct 34:245; <http://www.genome.ad.jp/dbget/ligand.html>; <http://www.modelling.leeds.ac.uk/sb/>; protein ligand affinities: <http://www.agklebe.de/affinity>; ligand and protein structure: <http://www.idrtech.com/PDB-Ligand/>; functional residue templates and ligands: <http://firedb.bioinfo.cnio.es/Php/FireStar.php>.

Ligand Dependence Receptor: A ligand dependence receptor, when it is unoccupied by the proper ligand,

may be exposed to degrading enzymes (e.g., caspase) and initiate apoptosis.

Ligand-Activated Site-Specific Recombination: The Cre recombinase is fused to a ligand-binding domain of the estrogen receptor (ER) and thus the recombinase may be activated by tamoxifen (but not by estradiol). A DNA sequence flanked by loxP sites can then be excised. ▶[Cre/loxP](#), ▶[site-specific recombination](#), ▶[tamoxifen](#), ▶[estrogen](#), ▶[estradiol](#); Feil R et al 1996 Proc Natl Acad Sci USA 93:10887.

Ligase Chain Reaction: In a ligase chain reaction two pairs of complementary oligonucleotides are added at immediate vicinity of each other to both strands of denatured DNA and amplified. The ligation products are useful only for the signal amplification but not for amplifying other DNA copies. The method has wide applicability for diagnostics. (See Rodriguez H et al 2000 Methods 22:148).

Ligase, DNA: DNA ligase are enzymes that tie together the ends of single polynucleotide chains. The *E. coli* enzyme requires 5' phosphate and 3' OH termini and NAD, and the T4 enzymes require ATP for the reaction. The T4 enzyme can ligate both cohesive and blunt ends although the latter reaction is much slower; monovalent cations (NaCl) and polyethylene glycol (PEG) can increase its efficiency though. Human cells contain at least four ligase isozymes and all are ATP-dependent. The efficiency of these ligases depends on the total concentration of the substrates and also on the closeness of the ends to be ligated. Mammals have three known DNA ligases and they have an essentially natural role in replication and recombination. Ligase I joins Okazaki fragments and seals excision repair nicks. Ligase IV (3q22-q34) deficiency is lethal in mice and V(D)J joining is absent. Ligase IV is required for the repair of double-strand breaks and nonhomologous end joining. In the laboratory, DNA ligases are used for the sealing of DNA in vectors or for joining any DNA molecules. The proliferating cell nuclear antigen (PCNA), after being loaded onto the DNA by replication factor C, enhances ligase I activity up to five-fold. ▶[replication](#), ▶[recombination](#), ▶[vectors](#), ▶[V\(D\)J](#), ▶[Ku](#), ▶[DNA-PK](#), ▶[NHEJ](#), ▶[RF-C](#); Tom S et al 2001 J Biol Chem 276:24817.

Ligase, RNA: RNA ligase mediate the joining of RNA 5' and 3' ends in the presence of ATP; they have an important role in the final processing of RNA transcripts. There are a very large number of RNA ligase ribozymes that structurally belong to three classes and within those classes to several families. ▶[ligase DNA](#), ▶[ribozyme](#); Stage-Zimmermann TK, Ehlenbeck OC 2001 Nature Struct Biol 8:863.

Ligation: The covalent joining of nucleotide ends by DNA or RNA ligase, respectively.

Ligation of Embryos: Process of imposing a constriction on an embryo, e.g., *Drosophila* embryo. The development of the thoracic (central) structures requires the cooperation of both poles. Ligation at the blastoderm stage interferes with the development of only one segment. Ligation has various medical applications. ▶[morphogenesis](#), ▶[morphogenesis in Drosophila](#)

Light: ▶[electromagnetic radiations](#), ▶[HVEM](#)

Light Chain: ▶[DNA heavy chain](#), ▶[antibody](#)

Light Controlled Reactions in Plants: See Simoni RD, Grossman AR 2001 J Biol Chem 276:11447; Jiao Y et al 2007 Nature Rev Genet 8:217.

Light Directed Parallel Synthesis: Light directs simultaneous synthesis on solid support. The pattern of masking light activates different regions of the solid-state support and facilitates the chemical coupling reactions. The activation is the result of the removal of different photolabile protecting groups. After deprotection of the first set of building blocks (amino acids or nucleotides bearing the photolabile compound) the entire surface is exposed to light and the reaction takes place only in the areas which were exposed to light in the preceding step. Subsequently, the substrate is illuminated by using another mask and then a second block is activated. The masking and illumination pattern determines the location and the ultimate product. This way, complex molecules can be fabricated in a combinatorial manner and the product may be useful for industrial and molecular biology studies. ▶[array hybridization](#), ▶[microarray hybridization](#), ▶[DNA chips](#); Lipshutz RJ et al 1999 Nature Genet 21(Suppl 1):20; Barone AD et al 2001 Nucleosides, Nucleotides Nucleic Acids 20 [4-7]:525.

Light Harvesting Chlorophyll Protein Complex: ▶[LHCP](#), ▶[CAB](#)

Light Intensities: The light intensities of various emitters (in Lambert units [1 Lambert = 1 new candela/cm²/π]) are: sunshine at noon, 519,000; sun at the horizon, 1,885; moonlight, 0.8; Tungsten bulb of 750 watt, 7,500; mercury vapor light of 1,000 watt, 94,000. These are approximate average data. ▶[illumination](#), ▶[electromagnetic radiation](#)

Light Microscopy: Light microscopy is used for the study of small biological specimens, biological tissues, cells, and subcellular organs down to a resolution of 0.2 μm. The most essential elements of the light microscope are the objective lenses for viewing details of different sizes. The nosepieces

generally contain objectives with numerical aperture 0.1 (4X), 0.25 (10X), 0.65 (high dry, 40X), and 1.25 (oil-immersion, 100X) lenses. Eyepieces are usually 10X and permit the viewing of objects at about 1,000-fold larger, at maximum. The condensor focuses the light coming from a special low voltage illuminator. The microscope stand includes a stage for the slides on which the specimens are moved. It also has various adjustment knobs for focusing and adjusting light intensities. The light microscopes may be equipped with other devices too, e.g., the camera stand or built-in camera, and filters. The common light microscopes require special handling of the specimens before viewing, e.g., fixation, staining, and sectioning. On the slides, the specimen is generally covered by a very thin (about 0.13–0.25 mm) cover glass (slips). For viewing natural specimens in three dimensions, stereomicroscopes are used that may permit magnifications within the range of 2X to 160X, generally with zooming capabilities. ▶[resolution optical](#), ▶[fluorescence microscopy](#), ▶[phase-contrast microscopy](#), ▶[Nomarski](#), ▶[confocal microscopy](#), ▶[electron microscopy](#), ▶[fixatives](#), ▶[stains](#), ▶[sectioning](#)

L

Light Reactions: Light reactions can only be carried out in light. ▶[DNA repair](#)

Light Repair (of DNA): The splitting of pyrimidine (thymine) dimers by visible light-inducible enzymes. ▶[DNA repair](#)

Light Response Elements (LRE): Light response elements are nucleotide sequences binding transcriptional regulators of light receptor protein (e.g., phytochrome) genes. ▶[phytochrome](#), ▶[hormone response elements](#), ▶[photomorphogenesis](#)

Light-Sensitivity Diseases: ▶[albinism](#), ▶[xeroderma pigmentosum](#), ▶[Bloom syndrome](#), ▶[trichothiodystrophy](#), ▶[ataxia telangiectasia](#), ▶[Fanconi anemia](#), ▶[Cockayne syndrome](#), ▶[Hartnup disease](#), ▶[protoporphyrria](#), ▶[Rothmund-Thompson syndrome](#), ▶[RAD](#), ▶[DNA repair](#), ▶[excision repair](#)

Light-Sensitivity in Natural Populations: Light has many different functions in plant physiological processes, such as photosynthesis, photoperiodic response, diurnal rhythm of synthetic and catabolic reactions, etc. Relatively very large variations exist in *Arabidopsis* in light-sensitivity compared to some other plant species (See Maloof JN et al 2001 Nature Genet 29:441).

Lignin: A rigid woody polymer of coniferyl alcohol (derived from phenylalanine and tyrosine) and related compounds, occurring in plants along with cellulose. It is the industrial source of vanillin, dimethyl

sulphoxide. Lignin is used in manufacturing certain plastics, rubber, precipitation of proteins, etc.

Ligule: A “tongue-like,” frequently hairy outgrowth on the upper and inner sides of the leaf blade (at the leaf sheath) of grasses.

Likelihood: A statistical concept dealing with a hypothesis based on experimental data. It can be expressed as $L(H/R)$ where L is the likelihood, H is the hypothesis, and R the results obtained experimentally. In contrast, probability is fixed by the fit of the data to a preconceived null hypothesis (see [Fig. L35](#)). The likelihood ratio $LR = \text{likelihood of data model} / \text{likelihood data of null hypothesis}$ or the log likelihood ratio, i.e., $\log(LR)$. ▶[maximum likelihood](#), ▶[lod](#)

$$\lambda = -2 \ln(L_{H_0}/L_{H_1})$$

likelihood ratio λ , H_0 and H_1 are the 2 hypotheses

Figure L35. Likelihood ratio

Lilac: The plant *Syringa vulgaris* is an ornamental shrub ($2n = 46, 47, 48$); lilac is also a rodent fur color determined by the epistatic action of certain gene combinations.

Liliaceae: A family of monocotyledonous plants, many of which have been exploited for cytological studies because of their large chromosomes: *Lilium* subspecies ($2n = 24, \sim 1.8 \times 10^{11}$ bp), onion (*Allium cepa*, $2n = 16, 32$), hyacinth ($2n = 16$), *Trillium* subspecies, ($2n = 10$), *Bellevallia* $2n = 8, 16$). In 1928, John Belling counted 2,193 chromomeres in the pachytene chromosomes of *Lilium pardalinum*. He believed this number represented the number of genes in the species. In *Fritillaria davisii* ($2n = 24$), the DNA content in the somatic nuclei was estimated to be 295 pg (approximately 50 times the amount in human somatic cells or $\sim 1,000$ times that of *Arabidopsis* or *Drosophila*). ▶[DNA](#), ▶[genome](#), ▶[chromomeres](#), ▶[dalton](#), ▶[measurement units](#)

LIM Domain: A cysteine-rich zinc-binding unit facilitating protein-protein interactions in signaling molecules, transcription factors, cytoskeletal proteins, motor neuron pathways, axon guidance, etc. LIM has the properties of an organizer. The LIM proteins do not have functional relationships beyond the common feature of protein-protein binding and may convey both inhibitory and activation functions. The RLIM corepressor inhibits the LIM homeodomain transcription factors by recruitment of the histone deacetylase complex. ▶[adaptor proteins](#), ▶[Aurora](#), ▶[LHX](#), ▶[LMO](#), ▶[CRIP](#), ▶[CRP](#), ▶[PINCH](#), ▶[NLI](#),

LIM Kinase: ►Williams syndrome

Lima: Lima are long interspersed nuclear genomic elements (LINEs) common across mammals.

Limb Bud: An embryonic cell group initiating limb development. The NF- κ B transcription factors and the regulatory REL proteins are required. NF- κ B seems to transmit fibroblast growth factor (FGF) signals between the ectoderm and the underlying mesenchyme cells during limb differentiation. ►AER, ►ZPA, ►NF- κ B, ►FGF, ►organizer; Capdevila J et al 2001 Annu Rev Cell Dev Biol 17:87.

Limb Defects in Humans: In humans, limb defects can be isolated but are most commonly associated with particular syndromes. In some cases entire limb(s) are absent (amelia) or there is a partial reduction (meromelia), i.e., frequently missing some parts between the extremities (hand or foot) and the trunk (phocomelia). Not uncommonly, extra fingers or toes are involved, or fusion or deformation(s) observed. The defects may be caused by teratogenic factors, chromosomal defects or mutations and may be accompanied by a variety of other symptoms of complex syndromes. ►adactyly, ►polydactyly, ►syndactyly, ►Holt-Oran syndrome, ►Moebius syndrome, ►Roberts syndrome, ►De Lange syndrome, ►Poland syndrome, ►ADAM complex, ►Chotzen syndrome, ►Pfeiffer syndrome, ►Greig's polysyndactyly, ►thrombocytopenia, ►orofacial-digital syndromes, ►Majewski syndrome, ►Patau's syndrome, ►exostosis, ►arthrogryposis, ►clubfoot, ►EEC, ►renal dysplasia and ►limb defects

Limb Girdle Muscular Dystrophy: ►muscular dystrophy

***Limnaea peregra*:** A freshwater snail displaying delayed inheritance of its shell shape (see Fig. L36). Left-right handed shell shape variations are common in various snail species (Ueshima R, Asami T 2003 Nature [Lond] 425:679). ►delayed inheritance, ►maternal effect genes

Figure L36. *Limnaea*

Limpet: ►keyhole limpet hemocyanin

LIMS (Laboratory Information Management System): LIMS is a guide to storage and to easy access of

experimental data. It has particularly great use in drug development laboratories or any type of large-scale genome and proteome research. (See Prilusky J et al 2005 Acta Crystallogr D Biol Crystallogr 61:671).

Lincoln, Abraham (1809–1865): President Abraham Lincoln is suspected to have had the relatively mild form of spinocerebellar ataxia although earlier it was also suggested that he might have had the Marfan or the Marfanoid syndrome. ►ataxia, ►Marfan syndrome, ►ataxia; Ranum LP et al 1994 Nature Genet 8:280.

Lincomycin: A 6-[1-methyl-4-propyl-2-pyrrolidinecarboxamidol]-1-thio-o-erythro-D-galacto-octopyramide antibiotic of Gram-positive bacteria and chloroplasts. It inhibits protein synthesis in the 23S and 16S 70S ribosomal RNA genes. (See Cséplő A et al 1993 Mol Gen Genet 236:163).

Line: A genetic stock with defined characteristics.

LINE (L1): L1 are long (≈ 5 –7 kbp) interspersed repetitive DNA sequences, including retroposons, genated by reverse transcription (see Fig. L37). They may occur in 10^4 to 10^5 copies in the eukaryotic genome. Sequencing of the human genome revealed 535 Ta and 415 pre-TA L1 elements. The LINE elements do not have long terminal repeats like the retrotransposons and yet they retain reverse transcriptase sequences which are frequently (>95%) non-functional. These are remnants of ancient retroviral insertions, but once they were inserted—because of the loss of the LTR [transposase] function—they generally remained at the position of insertion and can be used to trace phylogenetic descent of various species and wider taxonomic groups (Nishihara H et al 2006 Proc Natl Acad Sci USA 103:9929). The elements have internal promoters for RNA polymerase. The cDNA copies can then be inserted at new locations. The LINE endonuclease is a target-primed reverse transcription protein. DNA site recognition probably proceeds by accommodation of an extrahelical nucleotide within an enzyme pocket (Weichenrieder O et al 2004 Structure 12:975). At the mammalian telomeres endonuclease-independent LINE-1 transposition can take place (Morrish TA et al 2007 Nature [Lond] 446:208). The L1 elements are regulated by SOX type of proteins. In humans, L1s (mainly mariner type) are the most common retrotransposons. They, directly or indirectly, represent about 17% of the genome. The majority of these elements are truncated

Figure L37. LINE element

and only 3,000 are of full length; ~40–100 are active retrotransposons. The retrotransposition-competent elements are about 6-kb long and contain 5'-UTR (untranslated sequences), two open-reading frames (ORF) and 3'-UTR in a poly-A tail. ORF1 encodes a DNA-binding protein and ORF2 encodes an endonuclease and reverse transcriptase (Badge RM et al 2003 Am J Hum Genet 72:823). The transposition of human L1 is subject to RNAi control (Soifer HS et al 2005 Nucleic Acids Res 33:846).

Several human pathological conditions involve LINE insertions. Blood coagulation protein VIII gene insertions were found to cause hemophilia. L1 endonuclease has limited specificity and thus the element can be inserted at many sites, including genes. L1 elements were indentified in Duchenne muscular dystrophy (DMD), adenomatous polyposis cancer (APC), and the β -globin genes. In mice, about 10% of the spontaneous mutations seem to be due to transposition. In humans, 1/600 to 1/1200 mutations may be due to retrotransposition and 1/8 to 1/50–100 individuals may carry an endogenous insertion. About 0.1% of the human mutation causing diseases are due to L1 movements.

The activity of the different L1 elements depends on their base sequences (Lutz SM et al 2003 Am J Hum Genet 73:1431). Regular L1 elements may be quite inefficient in movement but a synthetic one with 24% of the nucleotides altered, without changing the amino acids, displayed a 200-fold increase in transposition (Han JS & Boeke JD 2004 Nature [Lond] 429:314). The synthetic L1 element, *ORFeus*, containing two synonymously recoded open reading frames (ORFs) relative to mouse L1 was significantly more active for retrotransposition in cell culture than all native L1 elements tested. In a transgenic mouse model, in which a constitutive heterologous promoter controlled *ORFeus* expression, *ORFeus* retrotransposition activity was 20-fold higher, in both germ line and somatic tissues. Somatic transposition events occurred in 100% of the *ORFeus* donor-containing animals, and an average of 17 different insertions were easily recovered from each animal. The number of somatic insertions per animal exceeded this number by perhaps several orders of magnitude. Nearly 200 insertions were precisely mapped (An W et al 2006 Proc. Natl Acad Sci USA 103:18662). The human LINE retrotransposons can also mobilize the transcripts of other genes and thus create processed pseudogenes. Insertion of the L1 element into the Factor VIII gene can cause hemophilia A. Insertion into the Factor IX may be responsible for hemophilia B. Movement into the dystrophin gene can result in Duchene muscular dystrophy. Insertions may be responsible for X-linked dilated cardiomyopathy, β -thalassemia, chronic granulomatous disease, and retinitis pigmentosa. Somatic chromosome insertions

of L1 can account for colon cancer. L1 elements appear to regulate the inactivation of the mammalian X chromosome (Bailey JA et al 2000 Proc Natl Acad Sci USA 97:6634) as postulated by the Lyon hypothesis. Han JS et al (2004 Nature [Lond] 429:168) regard the L1 elements as general “rheostats” (fine-tuning regulators) of transcription. LINE 1 elements appear subject to RNAi degradation (Soifer HS et al 2005 Nucleic Acids Res 33:846). L1 can deliver siRNA and cause silencing (Yang N et al 2005 Nucleic Acids Res 33(6):e57). Variations in L1 contribute to genetic diversity in human populations (del Carmen M et al 2006 Proc Natl Acad Sci USA 103:6611). L1 transposition can also take place in nondividing human somatic cells (Kubo S et al 2006 Proc Natl Acad Sci USA 103:8036). All hA3 proteins of the APOBEC3 family are able to differentially suppress uncontrolled transposition of L1 retroelements (Kinomoto M et al 2007 Nucleic Acids Res 35:2975).

R2 is a non-LTR retrotransposable (LINE-like) element with rigid sequence specificity for a target site in the 28S rRNA genes of arthropods, platyhelminthes, tunicates, and vertebrates. As Christensen notes, R2 protein subunits bind both upstream and downstream of the 28S gene insertion site. The protein subunit bound upstream of the integration site cleaves the bottom DNA strand and uses the newly generated 3' end to prime reverse transcription of the R2 RNA starting at the 3' end of the R2 RNA transcript bound to this subunit. The protein subunit bound downstream of the integration site cleaves the top DNA strand. The strand cleavage sites are 2 bp apart. The N-terminal DNA domain has been shown to bind the downstream DNA sequences by means of highly conserved zinc-finger and myb motifs. The C-terminal domain encodes an endonuclease and apparently binds the upstream DNA sequences. The central domain of the ORF encodes the reverse transcriptase (Christensen SM et al 2006 Proc Natl Acad Sci USA 103:17602).

►SINE, ►Ta, ►T α , ►retroposon, ►retrotransposon, ►reverse transcriptase, ►mariner, ►HERV, ►alu, ►antihemophilic factors, ►muscular dystrophy, ►globins, ►p40, ►cis preference, ►SOX, ►processed pseudogene, ►APOBEC, ►lyon hypothesis, ►RNAi; Sheen F-M et al 2000 Genome Res 10:1496; Ostertag EM, Kazazian HH Jr 2001 Annu Rev Genet 35:501; Ostertag EM et al 2002 Nature Genet 32:655; Brouha B et al 2003 Proc Natl Acad Sci USA 100:5280; human, mouse, rat: <http://l1base.molgen.mpg.de>.

LINE1 (L1): The major mouse LINE that can be used for DNA fingerprinting of YAC sequences from the mouse genome. ►DNA fingerprinting, ►YAC

Lineage: The line of descent from an ancestral cell or ancestral individual(s). ► [cell lineage](#)

Lineage Addition: A feature of cancer cells whereby they maintain some of the properties of the original cell type from which they arose. On this basis antagonist therapies can be developed. ► [drug development](#)

Lineage Priming: A low level of transcription of genes involved in differentiation before actual differentiation is turned on at full extent.

Linear Energy Transfer: ► [LET](#)

Linear Function: A set of data (variables, parameters) without powers or multiplication of quantities, e.g., $3x_1 \pm 2x_2 \pm x_3$.

Linear Ion Trap Analyzer (L1): A linear ion trap analyzer is similar to quadrupole technology. LIT, optionally, can perform slow scanning and increased resolution. It has been effectively applied for the detection of post-translational phosphorylation of proteins (Olsen JV, Mann M 2004 Proc Natl Acad Sci USA 10:13417). ► [proteomics](#), ► [mass spectrum](#), ► [ion trap mass analyzer](#), ► [quadrupole](#)

Linear Programming: The analysis or solution of problems when linear functions are maximized or minimized.

Linear Quartet: Four megaspores in the embryo sac of plants; in the asci of some fungi, the four spores are arranged in the order they were formed during meiosis (See [Fig. L38](#)). ► [megaspore](#), ► [embryosac](#)

Figure L38. Spore quartet

Linear Regression: ► [correlation](#)

Linearization: The conversion of a covalently closed circular nucleic acid to an open linear form.

Lineweaver-Burk Equation: The Lineweaver-Burk equation is reciprocal of the Michaelis-Menten equation:

$$\frac{1}{v} = \frac{K_m + (S)}{V(S)} = \frac{K_m}{V} \left(\frac{1}{S} \right) + \frac{1}{V}.$$

Where v = velocity constant of the reaction,

$$K_m = \left(\frac{(E) - (ES)(S)}{(ES)} \right),$$

(S) = substrate concentration, V = maximal velocity of reaction.

The formula provides a simpler solution for representing enzyme kinetics; $1/v$ is plotted against $1/(S)$ or $(S)/V$ against (S) . ► [Michaelis-Menten equation](#) and the ► [Eadie-Hofstee](#)

Linkage: Linkage is the association of genes within the same chromosome but which can be separated by recombination. In a test cross, four phenotypic classes are expected in equal numbers if the segregation is independent (absence of linkage). These four classes can be designated AB (a), Ab (b), aB (c) and ab (d) for the n individuals. For the verification of linkage chi square tests (χ^2) can be used. First the segregation for A can be examined,

$$\chi^2_1 = \frac{[a + b - c - d]^2}{n}$$

Then, in a second step, the χ^2_2 (for B) = $\frac{[a - b + c - d]^2}{n}$ is determined. The linkage χ^2_L = $\frac{[a - b - c + d]^2}{n}$. Example: AB : 191, Ab : 37, aB : 36, ab : 203, and the Total is 467. Without linkage in each class 116.7 is expected in a test cross (see [Table L2](#)).

The segregation of each marker is very normal but the linkage chi square is extremely high indicating that the segregation is not independent. Another simpler formula that does not take into account the transmission of the markers (p = parental, r = recombinant) is shown below:

$$\chi^2 = \frac{(\text{observed}_p - \text{expected}_r)^2}{(\text{observed}_p - \text{expected}_r)}$$

Similarly, for F_2 , the chi squares for the A and the B locus and for linkage can be determined for the

Table L2. Linkage chi square determination in a hypothetical example

| | χ^2 | Degree of Freedom | Probability of Greater χ^2 |
|-----------------------|----------|-------------------|---------------------------------|
| Segregation for A — a | 0.259 | 1 | >0.5 |
| Segregation for B — b | 0.362 | 1 | >0.5 |
| Linkage | 220.645 | 1 | <10 ⁻¹⁰ |
| Total | 221.266 | 3 | |

$AB (\frac{9}{16}n)$, $Ab (\frac{3}{16}n)$, $aB (\frac{3}{16}n)$, $ab (\frac{1}{16}n)$ classes designated as a, b, c and d, respectively:

$$\chi^2_A = \frac{[a + b - 3c - 3d]^2}{3n},$$

$$\chi^2_B = \frac{[a - 3b + c - 3d]^2}{3n}$$

and

$$\chi^2_L = \frac{[a - 3b - 3c + 9d]^2}{9n}$$

Mather suggested the following χ^2 formula for the detection of linkage in F_2 in case the segregation is not normal:

$$\chi^2 = \frac{(a_1a_4 - a_2a_3)^2n}{(a_1 + a_2)(a_3 + a_4)(a_2 + a_4)(a_1 + a_3)}$$

Fisher proposed to detect linkage by using repulsion and coupling information combined in case of abnormal transmission as shown in Table L3.

Table L3. Abnormal transmission and linkage

| | ab | Ab | aB | AB | Sum |
|-----------|-----|-----|----|-----|-----|
| Repulsion | 30 | 70 | 2 | 24 | 126 |
| Coupling | 519 | 119 | 12 | 349 | 999 |

Then add separately for the repulsion and coupling data the $ab + AB$ and designate as α_1 and the $Ab + aB$ as α_2 . So, α_1 represents the recombinants in repulsion but the parentals in coupling and α_2 represent the parentals in repulsion and the recombinant in coupling (see Table L4). In the absence of linkage α_1 and α_2 are expected to be near equal. A 2×2 contingency chi square (►association test) can then be set up and the χ^2 is computed with the null hypothesis that there is no linkage:

$$\chi^2 = \frac{(868 \times 72 - 1341 \times 54)^2 1125}{126 \times 199 \times 203 \times 922} > 146$$

and for 1 degree of freedom it absolutely rules out independent segregation.

When we want to estimate the probability of finding a linkage all over the genome, the chance of

Table L4. Hypothetical alpha values for repulsion and coupling

| | α_1 | α_2 | Σ |
|-----------|------------|------------|----------|
| Repulsion | 72 | 54 → | 126 |
| Coupling | 131 | 868 → | 999 |
| Σ | 203 | 922 | 1125 |

finding one is relatively very small. The P value obtained by the χ^2 procedure can be converted to an actual estimate of linkage based on a Bayesian estimate: Probability of linkage = $1 - \left(\frac{P}{P + f_{\text{swept}}} \right)$ where P is the value obtained by χ^2 and f_{swept} is the fraction of the genome that appears to be linked around the marker within the so-called swept radius. The swept radius is the maximal distance on both sides of the marker between two loci with a certain probability. Usually a probability limit of 0.95 is chosen to be significant. Thus, the swept radius is (shown in parenthesis) for 10 cM (21%), 20 cM (35%) and 30 cM (44%), respectively, for this critical probability.

Estimating linkage in human populations is difficult because of small family sizes. Also, there are frequently other complications, such as paternity, penetrance, expressivity, etc. Classical human genetics devised a different formula (u statistics) for double backcrosses ($AaBb \times aabb$) as $u_{11} = (a-b-c+d)^2 - (a+b+c+d)$. For single back crosses: ($AaBb \times Aabb$): $u_{31} = (a-3b-c+3d)^2 - (a+9b+c+9d)$. For the progenies resembling: F_2 : $u_{33} = (a-3b-3c+9d)^2 - (a+9b+9c+81d)$; (a, b, c and d indicate the four genotypes as indicated above.) More recently, the lod scores are used for family data. In the case of no difference between female and male recombination the Z score = $\log \frac{P(F|\theta)}{P(F|0.5)}$ and where there is a sex difference the formula $\log \frac{P(F|\theta', \theta'')}{P(F/(0.5)(0.5))}$ is applicable. θ is the recombination fraction (θ' for males and θ'' for females). Linkage in humans is generally studied now by somatic cell hybridization, radiation hybrids, or by molecular techniques. For multipoint linkage analysis, the following computer programs are generally used: Vitesse (O'Connel R, Weeks DE 1995 Nature Genet 11:402) or MAPMAKER (Lander ES et al 1987 Genomics 1:174) or MENDEL (Lange KD et al 1988 Genet Epidemiol 5:471), or JOINMAP (Stam P 1993 Plant J 3:739) or several others listed by Terwilliger JD et al 1994 Handbook of Human Genetic Linkage, Johns Hopkins University Press, Baltimore, Maryland. This book includes sources of availability.

Microarray hybridization data indicate that, in yeast, 37% of the expression traits show two simultaneous linkages and 14% of the traits display epistatic interactions. Each gene expression level can be considered as a quantitative trait and computational methods have been developed for the simultaneous mapping of these loci (Storey JD et al 2005 PLoS Biol 3(8):e267). ►recombination frequency, ► F_2 linkage estimation, ►tetrad analysis, ►recombination mechanisms, ►mapping genetic, ►mapping function, ►interference, ►coincidence, ►linkage group, ►chi square, ►sex linkage, ►sex-linked lethal mutation, ►lod score, ►affected-sib-pair method,

Linkage, Complete: Linkage is practically complete in the heterogametic sex in insects, e.g., in the majority of the species of *Drosophila*, male (XY), and in the silkworm, female (WZ). Recombination in male flies has been observed, however, in the presence of transposable elements causing hybrid dysgenesis. Linkage is practically complete within inversions because the recombinant gametes or zygotes are lethal (balanced lethals). In cases of multiple translocations involving all or most of the chromosomes, even the genes situated in different chromosomes do not segregate independently and this is a characteristic of complex heterozygotes. ►inversions, ►translocations, ►hybrid dysgenesis, ►complex heterozygote; Morgan TH 1912 Science 36:719.

Linkage Detection, Non-Parametric: ►affected-sib-pair method; Abreu PC et al 1999 Am J Hum Genet 65:847.

Linkage Detection, Tetrads: The linear spore tetrads can be arranged as PD, TT, and NPD. At linkage the frequency of the double recombinant class (NPD) must be smaller than the single recombinant (TT) class. If the deviation between TT and NPD is very small a chi square test may be necessary by using the formula: $\chi^2 = \frac{(PD - NPD)^2}{PD + NPD}$. ►tetrad analysis, ►chi square, ►linkage

Linkage Disequilibrium (LD): Certain groups of genes are syntenic in higher frequency than expected on the basis of unhindered genetic recombination. In random mating populations linkage disequilibrium should disappear with time. In self-fertilizing plants—because of homozygosity—linkage disequilibrium is generally low but exceptions (*Hordeum*) of modest LD have been found (Morell PL et al 2005 Proc Natl Acad Sci USA 102:2442). The tighter the linkage between genes, the less the chance to reach linkage equilibrium. If two loci are independent, the frequency of their joint occurrence is the product of the two independent frequencies. A cause of persistent association may be based on their selective advantage as a group or recent introgression. With these possibilities in mind the linkage disequilibrium determined for several loci may provide information on the chromosomal location of a gene. Disequilibrium is expected to be the greatest for a group of markers that are closest to the gene which needs to be

assigned to a position. The quantitative measure of linkage disequilibrium is:

$$\delta = (p_D - p_N)/(1 - p_N)$$

where p_D and p_N represent the two different linkage phase chromosomes. The decline (Δ_n) of the linkage disequilibrium depends on the recombination frequency (unless a particular gene block has high selective advantage and linkage drag exists): $\Delta_n = \Delta_0(1-r)^n$ where r = recombination frequency, n = number of generations, and Δ_0 is the beginning of disequilibrium. Linkage disequilibrium may shed light on the origin or changes within and among populations. Hitchhiking may affect the linkage disequilibrium. In human populations, the extent of linkage disequilibrium varies in different chromosomes and chromosomal regions, depending also on the closeness of the physical location of the alleles studied. Recently, single nucleotide polymorphisms (SNP) have been successfully used to map genes on the basis of linkage disequilibrium. Gene flow between distinct populations generates admixture linkage disequilibrium. Errors in genotyping may seriously affect the outcome of the estimate. Studied at the molecular level, the exchange hot spots are not distributed at random and the intensity of exchange may vary considerably. In the human genome the variation may be two orders of magnitude (Clark AG et al 2003 Am J Hum Genet 73:285). In human chromosome 12q, a 987-kb block (including the gene ataxin 2 [ATXN2/SCA2]) is preserved in Americans of European descent (Scherer SE et al 2006 Nature [Lond] 440:346). These facts may affect the outcome of the calculations of linkage disequilibrium. Linkage disequilibrium may persist for a very large number of generations and different human populations can be characterized on the basis of linkage disequilibrium units (LDU) (Tapper W et al 2005 Proc Natl Acad Sci USA 102: 11835). ►Hardy-Weinberg equilibrium, ►genetic equilibrium, ►Haplotype blocks, ►Hap-Map, ►Recombination, ►genetic, ►coupling, ►repulsion, ►syntenic, ►mutation dating, ►transmission disequilibrium test, ►association mapping, ►sib TDT, ►SWT, ►hitchhiking, ►mitochondrial genetics, ►introgression, ►SNP, ►MALD, ►family-based association test; Huang J, Jiang Y 1999 Am J Hum Genet 65:1741; Reich DE et al 2001 Nature [Lond] 411:199; Jorde LB 2000 Genome Res 10:1435; Pritchard JK, Przeworski M 2001 Amer J Hum Genet 69:1; Rannala B, Reeve JP 2001 Am J Hum Genet 69:159; Jeffreys AJ et al 2001 Nature Genet 29:217; Morris AP et al 2002 Am J Hum Genet 70:686; linkage disequilibrium map: Dawson E et al 2002 Nature [Lond] 418:544; Wall JD, Pritchard JK 2003 Nature Rev Genet 4:587; <http://www.sph.umich.edu/csg/abecasis/GOLD/>.

Linkage Drag: Undesirable genes are preserved in a population on the basis of hitchhiking if no recombination occurs between the selected desirable genes and the undesirable genes. ▶hitchhiking, ▶Hill-Robertson effect, ▶genetic load; Hospital F 2001 Genetics 158:1363.

Linkage Equilibrium: ▶genetic equilibrium

Linkage Genome Screening: Linkage genome screening is used to approximately locate genes with low penetrance and/or expressivity to chromosomes on the basis of the λ_s value and maximum likelihood. ▶ λ_s , ▶maximum likelihood

Linkage Group: Syntenic genes (situated in one chromosome) belong to a linkage group. Therefore, the number of linkage groups equals the number of chromosomes in the basic set. When the linkage information about a chromosome is incomplete, it is possible to see two or more linkage groups for a particular chromosome because gene clusters may recombine freely when the distance between them is 50 map units or more. Linkage groups are generally designated by Roman numerals and chromosomes are identified by Arabic numerals. If trisomic analysis is used, all syntenic genes must appear as a linkage group, irrespective of their dispersal along the chromosome. In multiple translocations (complex heterozygotes) several interchanged chromosomes are transmitted together and form “super linkage groups” such as in the *Oenotheras* plants. Similar translocation complexes may also exist in animals. In the termite *Kaloterms approximatus*, meiotic chains of 11 to 19 chromosomes have been observed, forming a single male-determining linkage group.

▶mapping, ▶synteny, ▶trisomic analysis, ▶complex heterozygote

Linkage in Autotetraploids: ▶recombination in autotetraploids

Linkage in Breeding: In applied genetics, linkage may be very useful if advantageous traits are controlled by closely linked genes. The opposite is true if disadvantageous characters are syntenic. The breeder may benefit by knowing about linkages with neutral, visible, or easily detectable chromosome markers that permits the monitoring of the inheritance of sometimes hard-to-recognize quantitative traits. The male silkworm produces 25–30% more silk than the female. By having a dominant color (dark) gene in the Y chromosome, the less productive female-producing eggs (XY) can be separated by an electronic sorter before hatching, and eliminated. In baby chickens it is difficult to identify the males by genitalia, but the presence of the *B* (*Barring*) X-chromosome-linked gene reduces the color of head spots more effectively in two (XX) males than in single dose (XY) females. Thus, by autosexing, the males can be assigned to meat early on, and the females to egg production regimes.

The use of RFLP techniques facilitates the recognition of the linkage of quantitative trait loci with DNA markers. The knowledge of recombination frequency may facilitate the planning of the size of the populations for selecting a combination of desirable genes. The yellow seed coat color gene in flax is very tightly linked to the high quantity and high quality of oil. Unfortunately, low yields and susceptibility to disease are also linked in coupling. Therefore, it is practically difficult to produce a

Table L5. Expected recombination of desired genes depends on linkage intensities

| Recombination frequency | Genetic construction of the F ₁ | | |
|-------------------------|--|---------------|---------------|
| | (+++/- - -) | (+ + -/- - +) | (+ - +/- - -) |
| | (- - -/+++) | (- - +/+++) | (- + -/+ - +) |
| 0.000 | 62,500 | 0.000 | 0.000000 |
| 0.075 | 33,498 | 1.448 | 0.000063 |

| 0.500 | 244 | 244.141 | 244.140625 |

The frequency of 6-fold double homozygous dominants for desirable genes located in two chromosomes. The numbers in the body of the table indicate the number of individuals carrying 12 advantageous alleles (+) in an F₂ population of 10⁶ size. (After Power, L. 1952. In *Heterosis*, Gowen, J. W., ed. Iowa State College Press, Ames, p. 315.)

commercially acceptable flax variety with yellow seed coat. The availability of appropriate linkage information may also facilitate the positional cloning of agronomically desirable genes. If the frequency of recombination is known the expected frequency of double homozygous dominant offspring can be predicted by the following formulas: for coupling, $0.25(1-p)^2$ and for repulsion, $0.25(p)^2$ where p = recombination frequency. Genetic transformation by cloned genes has an enormous advantage over classical breeding methods because it does not have to go through the tedious and long-lasting period of selection after crossing if the linkage is tight. ▶QTL, ▶autosexing, ▶gain, ▶chromosome substitution, ▶positional cloning, ▶transformation

Linkage Map: ▶genetic map, ▶mapping, ▶genetic, ▶physical map

Linked Genes: Linked genes are in the same chromosome and their frequency of recombination is less than 0.5. ▶linkage, ▶recombination

Linker: Very short DNA sequences (commercially available) that can be added by blunt-end ligation to DNA termini to generate particular cohesive ends for insertion of passenger DNA fragments in molecular cloning or transformation. ▶blunt-end ligation

Linker (in nucleosomes): The 40–60 nucleotides (generally associated with H1, and, sometimes, with H5 histone) that connect the cores of nucleosomes. ▶nucleosome, ▶histones

Linker Insertion: The insertion of a DNA sequence in place of deleted sequences to test for specific functional units in the region deleted. ▶linker scanning

Linker Scanning: A molecular method for the identification of upstream regulatory elements (see Fig. L39). The procedure is as follows: in defined lengths of upstream DNA fragments deletions are induced at different positions. The gaps are filled in such a way that the total original length of all fragments is neither reduced nor extended even by a single base pair. If the linker falls into the gaps that were normally the site of a regulatory element in front of the gene, expression is reduced or abolished, serving as evidence that the site of the deletion (now the linker) involved an essential upstream element. ▶linker, ▶promoter; Laumonnier Y et al 2000 J Biol Chem 275:40732.

Linking Library: The 5'-end of many genes is rich in NotI restriction enzyme recognition sites (GC↓GGCCGC). A NotI linking-clone containing, e.g., the transferrin receptor gene can be used as a point of jumping over NotI sequences and thus mapping genes. ▶jumping library, ▶Slalom library; Koshuba VI et al 1997 FEBS Lett 419:181.

Linking Number: A linking number indicates the number of times one strand of DNA double helix crosses over the other strand in space. The linking number may reflect the degree of supercoiling in a closed DNA molecule. The linking number has two components: the writhing number (W) and the twisting number (T); a change in linking number $\Delta L = \Delta W + \Delta T$. A change in the linking number requires the breakage of at least one strand. Molecules that are the same as their linking numbers are called topological isomers. After a break, one strand can be rotated about the other and such a reaction may change one isomer into the other by the action of

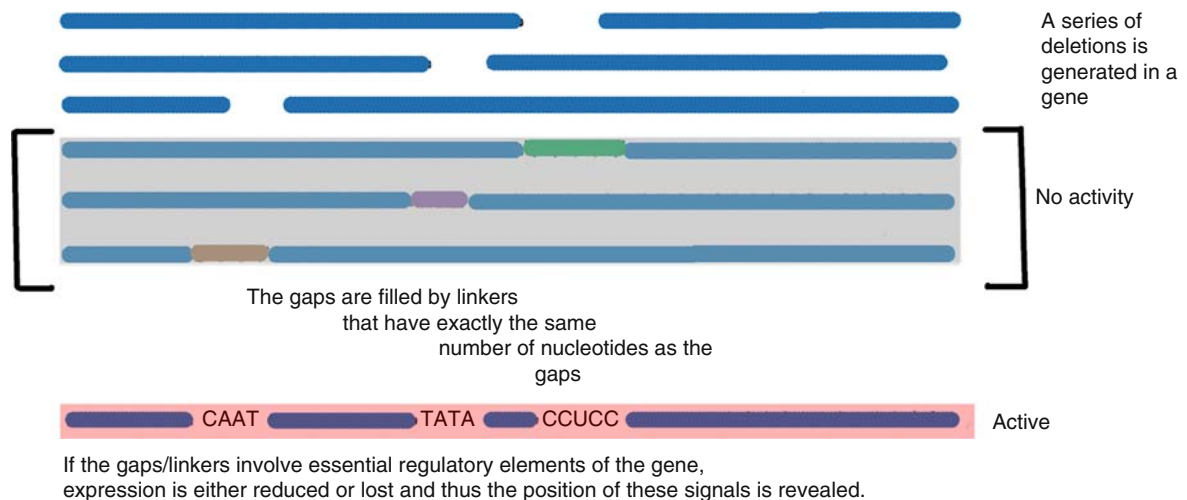

Figure L39. Linker scanning for the identification of the position of essential regulatory elements

DNA topoisomerases. These topological processes are the requisites for several functional activities of DNA such as replication, recombination, transcription and others. ▶ [Writhing number](#), ▶ [isomer](#), ▶ [topoisomerase](#), ▶ [supercoiled DNA](#); Quian H, White JH 1998 J Biomol Struct Dyn 16:663.

Linking Number Paradox: In a nucleosome the DNA is coiled by about 1 and 3/4 turns over the histone octamer and forms close to -2 superhelical turns. Yet, when the histones are removed from the DNA-histone fiber, only -1 negative supercoiled turn is found. The explanation of this paradox may be that the DNA released from the histones becomes more tightly coiled than in the nucleosome-restricted form, i.e., the bound DNA has different structural periodicity than the free form. ▶ [nucleosome](#), ▶ [supercoiled DNA](#), ▶ [histones](#); Prunell A 1998 Biophys J 74:2531.

linotte: A P element homing sequence gene where insertion may occur up to 20% frequency. ▶ [P element](#), ▶ [homing](#); Tailleburg E, Dura J-M 1999 Proc Natl Acad Sci USA 96:6856.

Linseed: ▶ [flax](#)

Linux: A free operating system similar to that of the UNIX. ▶ [UNIX](#)

Lion (*Panthera leo*): 2n = 38; lion x panther [leopard] (*Panthera pardus*) hybrids are sterile.

Lipase: Lipase are enzymes that digest triacylglycerols into fatty acids and mediate energy supply in the cell. ▶ [triacylglycerol](#), ▶ [lipids](#), ▶ [fatty acids](#)

Lipase Deficiency: Hepatic lipase (HL) dominant 15q21, the liposome lipase (8p22), results in triglyceride-rich high- and low-density lipoproteins. It also occurs in a recessive form at the same locus and its deficiency is then called chylomicronemia or hyperlipoproteinemia, respectively. There also is an autosomal dominant hormone-sensitive lipase (HSL). The pancreatic lipase deficiency and the lysosomal acid lipase are autosomal recessive. The lipoprotein lipase gene (LPL, 10 exons) was mapped to human chromosome 8p22. Endothelial lipase normally reduces the level of HDL in the liver, lungs, kidneys, and placenta but not in the skeletal muscles. Lysosomal acid lipase (LAL, 10q24-q25) is Wolman's disease. Lipase deficiency loci are also found at 15q21-q23 (hepatic triglyceride lipase, LIPC), at 9q34.3 (carboxylester bile-salt-dependent lipase, CEL) and at 10q26.1 (pancreatic lipase, PNLIP). ▶ [lipids](#), ▶ [HDL](#), ▶ [Wolman's disease](#); Henderson HE et al 1996 Biochem Biophys Res Commun 227:189; Du H et al 2001 Hum Mol Genet 10:1639.

Lipid Antigen: Lipid antigens are recognized by CD1a proteins, which present foreign antigens to the T cells.

The alkyl chains of amphipathic lipids are fitted into a deep hydrophobic groove of the CD1 heavy chain. This places carbohydrates or other hydrophilic elements of the antigen on the outer surface of CD1 and can directly contact T cell receptors. This way they play an antibacterial effect. ▶ [antigen](#), ▶ [T cell](#), ▶ [CD1](#); Moody DB et al 2004 Science 303:527.

Lipid Bilayer: The main structural element of membranes with two layers of hydrophobic lipid tails facing each other and the hydrophilic heads exposed at the outer parts (see [Fig. L40](#)). Proteins occur within the lipids and some transmembrane proteins pass through the lipid bilayer. ▶ [cell membrane](#), ▶ [seven-membrane proteins](#)

Figure L40. Lipid bilayer

Lipid, Neutral: A neutral lipid is soluble only in very low polarity solvents. ▶ [lipids](#), ▶ [lipids cationic](#)

Lipid Peroxidation: Lipid peroxidation may be a substantial source of mutagenic/carcinogenic alterations in DNA. ▶ [malondialdehyde](#)

Lipid Storage Disease: ▶ [lysosomal storage disease](#)

Lipidogenesis: The biosynthesis of lipids proceeds through fatty acids and it is essential for the formation of many cellular functions of membranes, steroids, hormones, cholesterol, isoprenoids, etc.

Lipidome: All the lipids of an organism.

Lipidoses: ▶ [lysosomal storage diseases](#), ▶ [sphingolipidoses](#), ▶ [lipid storage disease](#)

Lipids: Lipids are usually large molecules polymerized from fatty acids and associated frequently with sugar, protein, and inorganic components. Lipids are the principal material of membranes; they are insoluble in water but readily soluble in nonpolar organic solvents and detergents. The genetic analysis of lipids in higher organisms is quite difficult because of their indispensable function in maintaining cell viability. In *E. coli*, several mutations have been identified in the phospholipid biosynthetic pathways. Lipids I and II are involved in the synthesis of bacterial cell wall peptidoglycans (Mahapatra S et al 2005 J Bacteriol 187:2747). Antibiotic peptides (polycyclic peptides or unusual amino acids) can remove lipid II from the bacterial cell division site (septum) and thereby block

cell wall synthesis. They thus represent a novel type of antibiotic action (Hasper HE et al 2006 Science 313:1636). ►fatty acids, ►sphingolipids, ►sphingosine, ►steroids, ►cell membranes, ►low-density lipoproteins, ►high-density lipoproteins, ►liposome, ►phosphoinositides; Dowhan W 1997 Annu Rev Biochem 66:199; Kersten S 2001 EMBO Reports 2:282; <http://www.lipidat.chemistry.ohio-state.edu>; pathways: <http://www.lipidmaps.org/>; <http://www.lipidmaps.org/data/structure/>; <http://www.lipidmaps.org/tools/>.

Lipids, Cationic: Cationic lipids are synthetic molecules which form a bilayer. They are suitable for the construction of nucleic acid delivery vehicles and enhance the internalization of nucleic acid fragments 5–20-fold and that of antisense oligonucleotides up to 3 orders of magnitude. The cargo may pass through the nuclear pores into the nucleus but its degradation is more likely than in liposomes. They are made of 12–18 carbon atom chains and single or multiple cations of amines. The vehicles frequently use DOTMA (*N*-[2,3-dioleoyl-oxy]propyl]-*N,N,N*-trimethyl ammonium chloride), DOGS and DOPE (dioleoyl phosphatidylethanolamine). Cationic lipids are not allergenic and are nontoxic and can be administered through the vascular system. In case the vector is equipped with cell or tissue-specific promoters, its expression may be successfully targeted. Monoclonal antibodies or other ligands to (tumor) cell surface antigens may facilitate targeting. In addition, the cationic lipids may be immunostimulatory, a feature meaningful for cancer gene therapy. In some instances DOPE and other lipids have reduced the expression of the gene that they carried. Various versions of liposome-mediated gene transfer are under clinical trials (<http://clinicaltrials.gov/ct/gui/c/r>). ►liposomes, ►DOGS, ►cancer gene therapy, ►gene therapy, Audouy S, Hoekstra D 2001 Mol Membr Biol 18(2):129.

Lipinski's Rule: The criteria to be met for orally administered drugs. 1). Molecular mass <500 daltons; 2). hydrogen bond donor <5; 3). hydrogen bond donors <10; 4). coefficient of passing biological membranes <5 (Lipinski CA et al 1997 Drug Delivery Rev 23:3). ►drug development

Lipoate: A carrier of H atoms and acyl groups in α -keto acids.

Lipocalin: A family of secreted proteins that recognizes and transports small molecules, retinol, and pheromones and has diverse functions (Akerstrom B et al 2000 Biochim Biophys Acta 1482:1).

Lipo-Chitooligosaccharide: ►nodule

Lipodystrophy, Familial: A complex of autosomal dominant, recessive and X-linked anomalies of partial or predominant loss of lipid tissues especially in some areas of a body and an increase at others. Familial lipodystrophy may be associated with cystic angiomatosis (neoplasia of the blood vessels or lymphatic ducts), microphthalmia or anophthalmia (reduced eyes), mental retardation, and insulin resistant diabetes. It is surprising that both obesity and lipodystrophy can cause diabetic symptoms. The Seip-Berardinelli congenital lipodystrophy is at 9q34.1. Another locus at 11q13 is also responsible for the recessive Berardinelli-Seip syndrome involving much-reduced adipose tissue and severe insulin resistance at birth. In addition, acanthosis nigricans, hyperandrogenism, hepatomegaly, and hypertriglyceridemia are typical. The Kobblerling-Dunnigan syndrome, a partial lipodystrophy (human chromosome 1q21-q22), involves defects in lamins and is encoded at the same location as the LMNA gene. ►lamin, ►angioma, ►eye diseases, ►obesity, ►diabetes mellitus, ►SREBP, ►acanthosis nigricans, ►hepatomegaly, ►triacylglycerols, ►androgen, ►Dunnigan syndrome, ►Berardinelli-Seip congenital lipodystrophy; Magré J et al 2001 Nature Genet 28:365; Phan J, Reue K 2005 Cell Metabolism 1:73; Agarwal AK, Garg A 2006 Annu Rev Genomics Hum Genet 7:175.

Lipofection: Lipofection is genetic transformation by liposome-mediated transfer. ►liposomes, ►lipids cationic

Lipofuscin: A yellow/brown pigment product (aging pigment) of blood cell breakdown. It accumulates in aging heart muscles, macula, liver, and in earwax. ►lipofuscinosis, ►Macular degeneration, ►Stargardt disease

Lipofuscinosis: ►ceroid lipofuscinosis

Lipoic Acids: ►lipoate

Lipomatosis: Lipomatosis is the development of usually benign tumors in fat tissues. They may be under autosomal dominant control and are frequently associated with breakpoints in human chromosome 12q13-q14. An autosomal recessive lipomatosis of the pancreas (Schwachman-Bodian syndrome) involves frequent chromosomal breakage. ►cancer, ►high-mobility group proteins

Lipophilic: A lipophilic is soluble in nonpolar solvents such as fat, chloroform, benzene, etc., and poorly soluble in a polar solvent like water.

Lipopolysaccharide: ►LPS

Lipoprotein: A lipid-protein (apolipoprotein) complex that transports hydrophobic lipids. ►LDL, ►HDL, ►cholesterol, ►coronary heart disease

Lipoprotein Lipase Deficiency: ►hyperlipoproteinemia

Liposarcoma, Mixoid: A mixoid liposarcoma usually involves balanced translocations (t(12;16)(q13;p11), but additional chromosomal aberrations also occur. The C/EBP transcription factor (also called CHOP, 12q13.1-q13.2) forms a fusion protein with the product of chromosome 16.

Liposomes: Liposomes are delivery vehicles from macromolecules to cells. Within a protective coat of unilamellar vesicles consisting of phosphatidyl serine and cholesterol (1:1), they can carry DNA first to the cell membrane, and then, after fusion, to the nuclear membrane, and eventually into the nucleus. The loading of the liposomes requires DNA in a buffer and thoroughly mixed with the ether-lipid mixture. The ether is then removed. The delivery may be facilitated by polyethylene glycol, polyethyleneimine, and dimethyl sulfoxide. With appropriate coating (e.g., monoclonal antibody, DNA, viral vectors, drugs, etc.), they can be targeted to specific sites within the cell. Guanidinium-cholesterol cationic lipids (BGSC, BGTC) can be used for construction of eukaryotic vectors. Good results are obtained by the use of the cationic lipid DOTAP (dioleoyl trimethylammonium propane) and the so-called neutral helper lipid DOPE (dioleoyl phosphatidyl ethanolamine) mixtures and also with the mix of DOPC (dioleoyl phosphatidylcholine) and DOTAP. DMR1E (1,2-dimyristoyloxypropyl-3-dimethylhydroxyethyl ammonium bromide) promotes the transfer of reporter and therapeutic genes. The delivery of the DNA is quite efficient when the linear cationic lipid monolayer is transformed into hexagonal lattices. Apparently, endocytosis mediates the uptake of liposomes. The entry of the liposomal content into the nucleus is not efficient but it can be increased by four orders of magnitude if human papilloma-virus enhancer elements are incorporated into the upstream regulatory region in the plasmid replicon. Liposome vehicles can deliver very large amounts of DNA (1 Mbp) and, in contrast to viral vectors, they do not evoke an immune response. Liposomes are also used for the delivery of vaccines and drugs. ►lipids, ►lipids cationic, ►DOGS, ►fusogenic liposome, ►cytofectin, ►lipofection, ►raft, ►vaccines, ►deoxyribonucleotide-gated channels, ►immunoliposome, ►vectors, ►polyplex; Chesnoy S, Huang L 2000 Annu Rev Biophys Biomol Struct 29:27; Torchilin VP et al 2003 Proc Natl Acad Sci USA 100:1972.

Lipotropin: Adenocortical peptides controlling lipolysis. ►opiocortin

Lipoxygenase (LOX): Oxygenates arachidonic acid into leukotrienes. 15-lipoxygenase integrates into membranes of cellular organelles and mediates the access of proteases to the integral and luminal membrane proteins. As a consequence, in some special cells (e.g., erythrocytes, eye lens) mitochondria are degraded. 12-lipoxygenase controls the angiotensin pathway and 5-lipoxygenase mediates leukotriene metabolism. Lipoxygenase-3 and lipoxygenase-12 mutations may be involved in non-bullous congenital ichthyosiform erythroderma (17p13.1). The lipoxygenase activating protein (ALOX5AP, 13q12-13) almost doubles the risk of myocardial infarction and stroke by an increase in leukotriene and inflammation of the arterial wall (Helgadottir A et al 2004 Nature Genet 36:233). 5-Lipoxygenase is part of a complex trait and has pleiotropic effects on body fat, lipid levels, and bone density (Mehrabian M et al 2005 Nature Genet 37:1224). ►leukotriene, ►arachidonic acid, ►angiotensin, ►cyclooxygenase, ►integrin, ►erythroderma, ►myocardial infarction, ►stroke; van Leyen K et al 1998 Nature [Lond] 395:392; Feussner I, Wasternack C 2002 Annu Rev Plant Biol 53:275.

Lip-Print: The pattern on the human lip is rather characteristic for each individual and it had been considered as a substitute for the dermal ridges of the fingers and palms (see Fig. L41). ►fingerprints, ►forensic genetics

Figure L41. Lips

Liprin: ►synaps

Liquid Crystal: ►mesogen

Liquid-Holding Recovery: A type of genetic repair, which takes place in irradiated cells if kept in liquid medium (and allowed to utilize energy) for two days before plating.

Liquid Scintillating Counter: ►scintillation counters

LIR (long inverted repeat): A DNA sequence of about 100 or more base pairs that is either palindromic, or may have an insertion between the inverted repeats.

Such motifs are conducive to recombination or to deletion. ►repeat inverted, ►palindrome

LIR: ►ILT

LISA (localized in situ amplification): ►PRINS, ►amplification, ►PCR

Lisch Nodule: Lisch nodules are bloody spots (hamartomas) on the iris, a characteristic sign of neurofibromatosis. ►neurofibromatosis, ►hamartoma

Lissencephaly, Norman-Roberts Type (Xq22.3-q23): The Norman-Roberts type of lissencephaly involves “smooth” brain, cerebellar hypoplasia, abnormal migration of cortical neurons, and abnormal connectivity of axons. The incidence of the dominant disease is about $2-3 \times 10^{-5}$ or less. The “double cortex” anomaly is at the same location. The 388-kDa RELN (reelin) protein is encoded at the same chromosomal site at 7q22. There are other diseases with lissencephaly. ►PAF-AH, ►Miller-Dieker syndrome, ►tubulins

Listeria monocytogenes: A 2.95-Mb bacterium, which causes abortion, heart/lung infections, diarrhea, and inflammation of the brain. It also causes similar ailments in sheep and cattle. Its surface protein internalin binds to the intestinal transmembrane protein E-cadherin for infection. The bacteria move along the cytoskeleton within the cells by taking advantage of the ezrin protein, which links the plasma membrane and the cytoskeleton. They move from cell to cell in a protected state with the aid of cell protrusion (Pust S et al 2005 EMBO J 24:1287). The host specificity of the different virulent forms depends on the amino acid sequence of the cadherin molecule. Mouse chromosomes 5 and 13 modify susceptibility to this bacterium. ►cadherins, ►ezrin, ►inflammasome, ►vaccines, ►herpes, ►Lactobacillus salivarius, ►host-resistance genes; Boyartchuk VL et al 2001 Nature Genet 27:259; database: <http://leger2.gbf.de/cgi-bin/expLeger.pl>.

Literature Mining: Literature mining involves information retrieval (IR) including entity recognition (ER), e.g., of a certain gene. In case specific facts and functions are also retrieved during the search it is called information extraction (IE). ►text mining; Jensen LJ et al 2006 Nature Rev Genet 7:119.

Literature Search Assistance: ►MeSH, ►databases, ►literature mining

Lithium: A drug used for the treatment of manic depression. It causes various developmental anomalies in diverse organisms. It appears that lithium antagonizes the enzyme glycogen synthase kinase-3 β , which affects bipolar human disorders as well as

the circadian clock (Yin L et al 2006 Science 311:1002). ►manic depression, ►circadian rhythm

Lithography, Photo: ►DNA chips

Litter: A litter refers to youngsters given birth to at the same time by a multiparous animal.

Liver: ►hepatocyte

Liver Cancer (liver cell carcinoma, LCC): Liver cancer is generally initiated upon the integration of the hepatitis B virus in one or more chromosomal location. Antitrypsin deficiency, hemochromatosis, and tyrosinemia may also constitute conditioning factors. When the viral infection takes place in an individual genetically susceptible to the liver carcinoma he/she may have an eventual incidence of 0.84 (males) and 0.46 (females) of the cancer. Without the viral integration the chances for the cancer are 0.09 and 0.01, respectively, even when the genetic constitution is permissible for its development. One of the viral integration sites (17p12-p11.2) is near the p53 tumor suppressor gene. The flanking sequences are homologous to the autonomously replicating sequence (ARS1) required for the replication of the *Saccharomyces cerevisiae* integrative plasmids. Other integration sites identified are 11p13 and 18q11.1-q11.2. ►cancer, ►antitrypsin, ►hemochromatosis, ►tyrosinemia, ►ARS, ►yeast vectors, ►hepatitis B virus, ►tumor suppressor gene, ►chi elements

Liverwort: ►bryophytes

L19 IVS (intervening sequence lacking 19 nucleotides): The 395-nucleotide linear RNA left after 19 nucleotides were consumed by the *Tetrahymena* ribozyme intron which was originally 414 nucleotides long. This RNA molecule is capable of nucleotidyl transferase activity and can elongate various nucleotide sequences in a protein enzyme type manner. Preferred substrates are the nucleotide sequences that can pair with guanylate rich sequences in L19IVS, i.e., have C residues. ►ribozyme, ►intron, ►Tetrahymena

LKB: ►polyposis hamartomatous; Alessi DR et al 2006 Annu Rev Biochem 75:137.

LMO: A class of proteins with only LIM domain. ►LIM, ►CRIP, ►CRP, ►PINCH

LMO (living modified organism): LMO is the same as GMO. ►GMO

LMP-2, LMP-7: Proteasomal subunits. ►proteasome

LM-PCR (ligation-mediated PCR): Ligation-mediated PCR is used for the study of DNA double-strand breaks. ►PCR

LMYC: ►MYC

LNA: ►locked nucleic acids

LNFR: A low molecular weight nerve growth factor receptor. ►HNGFR, ►nerve growth factor [NGF]

Load: ►genetic load

Loading Test: Heterozygotes for many metabolic defects appear usually very close to the normal because the normal allele is dominant under ordinary conditions. In case large amounts of the metabolite are given to them, which the homozygotes would be unable to process, the heterozygotes are also slower than the normals to clear them from the system. For example, normal persons and phenylketonuria heterozygotes, at fasting, displayed the following concentrations of phenylalanine ($\mu\text{moles/mL}$) in the plasma: 0.067 ± 0.032 and 0.103 ± 0.029 (1.54), respectively. An hour after an oral dose of 0.1g phenylalanine/kg body weight, the observations were 0.55 ± 0.186 and 1.14 ± 0.18 (2.07), respectively. Histidine loading in case of heterozygosity for B₁₂ or folate deficiency increases excessively the amounts of formiminoglutamic acid in the urine. ►heterozygote proportions, ►phenylketonuria, ►vitamin B₁₂ defects, ►His operon, ►folic acid

Lobotomy: Surgery of the skull for (nowadays questionable) psychotherapeutic ends during the first half of the twentieth century before psychotherapeutic drugs were discovered.

Localized Determinants: In some species, different parts of the egg determine the formation of different

blastomeres depending on what cellular portions they received during cleavage. ►blastomere, ►cleavage

Localized Mutagenesis: Localized mutagenesis involves in vitro and in vivo manipulations. An amber mutation in a phage can be corrected by synthesizing a short DNA sequence complementary to a section of ΦX174 DNA single strand having a single mismatch at one base (A) corresponding to the amber codon (see Fig. L42).

The synthetic sequence will have, correctly, C (cytosine) there. The short synthetic DNA is then extended to a double-stranded form. After a cycle of replication the corrected strand makes a correct complementary copy of itself, and its progeny is thus permanently corrected by localized mutagenesis (see Fig. L43). The other old single strand of the DNA will produce another amber mutant phage.

Similar methods can be applied to any DNA that can be transferred to cells by transformation. Site-directed transposon mutagenesis is feasible by identifying genes, which contain a P element within or near a particular gene. P elements are preferentially inserted at the 5'-ends of genes and thus gene-specific promoters can be placed there. ►insertional mutagenesis, ►site-specific mutagenesis, ►hybrid dysgenesis, ►gene replacement, ►PCR-based mutagenesis, ►TAB mutagenesis, ►Kunkel mutagenesis, ►cysteine-scanning mutagenesis, ►homologue-scanning mutagenesis, ►targeting genes

Location Score: The natural logarithm of the likelihood of the odds ratio for linkage. It is determined by multiplying the lod score by 4.6. ►lod score

Figure L42. An amber mutation is corrected by a short DNA sequence containing a cytosine rather than an adenine in the codon. Adding the appropriate nucleotides and through the use of a DNA polymerase the synthetic nucleotide strand is completed and the strands are tied together by DNA ligase. The new single-stranded DNA has a single mismatch. After transfection of the phage to *E. coli* bacteria, each strand replicates and both amber and wild type Φx174 genomes are made. By selective screening the wild-type phages can be isolated as the result of this directed, local mutation. (Modified after Itakura K, Riggs AD. 1980 Science 209:1401)

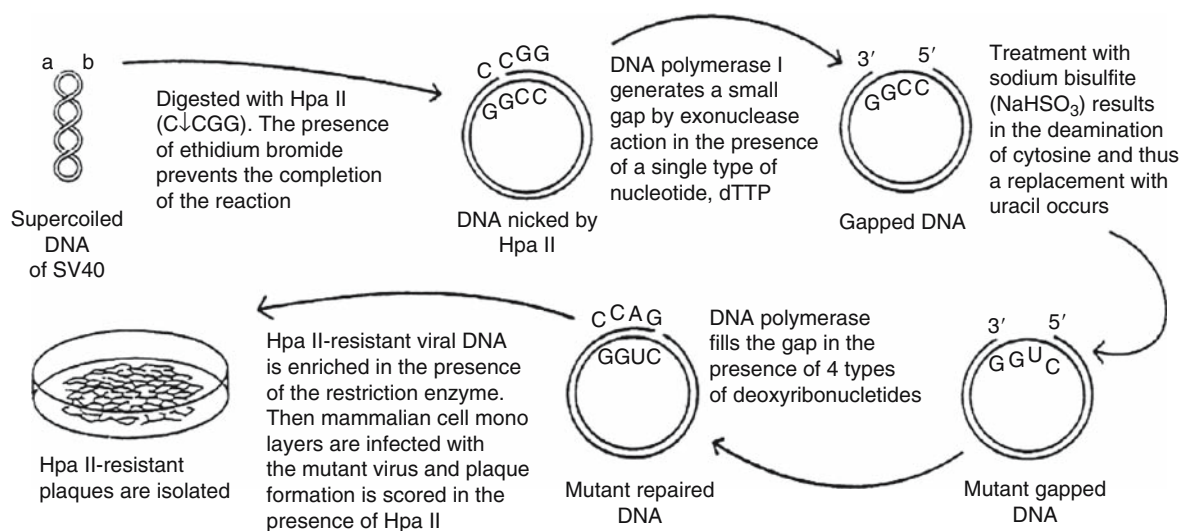

Figure L43. Local mutagenesis using restriction endonuclease gapping and in vivo mutagenesis followed by DNA polymerase correction of the gap. (After Shortle D and Nathans D 1978 Proc. Natl. Acad. Sci. USA 75:2170)

Locational Candidate Region: ►genomic screening

Locked Nucleic Acids (LNA): 2'-O,4'-C methylene-bridged (MOE) nucleic acids display enhanced binding to double-stranded DNA (see Fig. L44). Double-stranded DNA has very high hybridization to nucleic acids and is extremely resistant to nucleases. It is potentially applicable to gene therapy by stabilizing siRNA (Elmén J et al 2005 Nucleic Acids Res 33:439). In animal experiments hepatotoxicity was observed as early as four days after a single administration of LNA. In contrast, the corresponding MOE showed no evidence of toxicity while maintaining the ability to reduce target mRNA (Swayze EE et al 2007 Nucleic Acids Res). ►triple-helix-forming oligonucleotide, ►antisense technologies, ►RNAi, ENA; Uneda OS 2001 Bioorg Med Chem 9:1001; Di Giusto DA, King GC 2004 Nucleic Acids Res 32(3):e32.

Figure L44. LNA

Locule: A fruiting body of fungi; the cavity of the ovary of plants occupied by the ovule; or the place of the uterus of some mammals where the embryo is attached (see Fig. L45).

Figure L45. Locule

Locus: The site of a gene in the DNA (or RNA) or the site of a gene in the chromosome.

Locus Content Map: A locus content map displays the observations on the presence or absence of genes in chromosome fragments produced by ionizing radiation. This information may not be suitable for genetic mapping if contrasting alleles are not available. The data obtained can be confirmed by physical mapping. ►radiation hybrids; Teague JW et al 1996 Proc Natl Acad Sci USA 93:11814.

Locus Control Region: ►LCR

Locus Exclusion: Locus exclusion occurs when both alleles at a locus are prevented from expression in deference to allele(s) at another locus. ►allelic exclusion, ►idiotype exclusion

Locus Heterogeneity: When the same phenotype is produced by more than one combination of the genetic constitution it is termed locus heterogeneity.

LocusLink: Provides information about genes as a central hub. On 1 March 2005 it was replaced by ENTREZ GENE (<http://www.ncbi.nlm.nih.gov/entrez/>)

query.fcgi?db=gene). ►RefSeq, ►gene prediction, ►entrez gene

Locus Specific Database (LSDB): A human mutation database: <http://www.hgvs.org/entry.html>.

Locust: *Locusta migratoria*, 2n = 23; B chromosomes occur (see Fig. L46).

Figure L46. Locust (*Paratettix texanus*)

Lod Score: A lod score expresses the relative probability of linkage compared to the odds against linkage (log odds) because the score is obtained by dividing the sum of logarithms indicating linkage by the sum of logarithms suggesting independent segregation. The principle briefly is:

Probability of linkage (P) = $\frac{\text{Recombination Frequency } \theta}{\text{Recombination Frequency } 1/2}$

Here θ stands for any value of recombination, and 1/2 recombination indicates independent segregation. In case several linkage probabilities exist, the formula above can be rewritten as (see Table L6):

Relative linkage (P) = $\frac{p_1(\theta_1)p_2(\theta_2) \dots p_n(\theta_n)}{p_1(1/2)p_2(1/2) \dots p_n(1/2)}$

hence the relative odds of linkage is expressed as:

$$\begin{aligned} &\text{Log}_{10}(\text{odds of linkage}) \\ &= \frac{\log p_1(\theta_1) + \log p_2(\theta_2) + \log p_n(\theta_n)}{\log p_1(1/2) + \log p_2(1/2) + \log p_n(1/2)} \\ &= \text{lod score} \end{aligned}$$

Table L6. Z(θ) values of lod scores

| θ | θ^2 | $(1 - \theta)^2$ | $2[\theta^2 + (1 - \theta)^2]$ | Z(θ) |
|----------|------------|------------------|--------------------------------|---------------|
| 0 | 0 | 1 | 2.00 | 0.30303 |
| 0.05 | 0.0025 | 0.9025 | 1.81 | 0.25768 |
| 0.10 | 0.0100 | 0.8100 | 1.64 | 0.21484 |
| ↓ | ↓ | ↓ | ↓ | ↓ |
| 0.50 | 0.2500 | 0.2500 | 1.00 | 0 |

The lod scores for all θ (recombination frequency) values summed up is expressed as Z(θ) (see Table L6). This value may be empirically defined at various values of θ : Thus a lod score, if $\theta = 1/2$, is 0 because $\log 1 = 0$. A lod score >3 indicates approximately 95% probability of linkage but a lod score of >4 gives a probability of about 99.5%. A lod score of -2 indicates independent segregation. Lod scores between -2 to 3 are considered inconclusive. It is most useful for sequential data as available from (human) pedigrees. It is widely used also for mapping restriction fragments (RFLP). The homogeneity of the lod scores among different families can be tested by chi square analysis. The probability of two genes being independent may also be obtained by the formula based on Bayes' Theorem, e.g., for the 22 human autosomes:

$$P(\theta) = 1/2 = \frac{21}{\lambda + 21}$$

where λ is the average value of $\lambda(\theta)$ and it is equal to antilog Z(θ).

The chance that any particular unknown gene would be in a human autosome is 21/22 and the chance for another gene being in the same chromosome is 1/22. The computation, based on maximum likelihood, is somewhat complicated when multi-point crosses are evaluated but computer programs (e.g., Mapmaker, Joinmap, LINKAGE, MENDEL, VITESSE, FAST-LINK, LODLINK) are available for linkage estimation. The lod score can be used for other biological comparisons too, e.g., evolutionary relationships of nucleotide or protein sequences. ►mapping genetic, ►linkage, ►antilog, ►genomic screening, ►word score, ►Mod score; O'Connel JR, Weeks DE 1995 Nature Genet 11:402; Lander E, Kruglyak L 1995 Nature Genet 11:241; Nyholt DR 2000 Am J Hum Genet 67:282; Ott J 2001 Advances Genet 42:125.

Lodicule: The scale-like structures at the base of the ovary of grasses; they mediate the opening of the flower when the pollen is shed in allogamous species (see Fig. L47).

Figure L47. Lodicule

Loeys-Dietz Syndrome (LDS, aortic aneurism, 9q33-q34, 3p22): The Loeys-Dietz syndrome is caused by dominant mutations in the transforming growth factor receptor (TGFBR) with variable expression. Its symptoms include hypertelorism, cleft palate, arterial twisting (tortuosity), aneurysm heart disease, and mental retardation. Patients suffering these diseases may also benefit by the use of artan, an antagonist of angiotensinogen II receptor and TGF- β . ▶[TGF](#), ▶[hypertelorism](#), ▶[cleft palate](#), ▶[aneurysm](#), ▶[glucose transporters](#), ▶[Marfan syndrome](#)

Löfgren (Loefgren) Syndrome: ▶[sarcoidosis](#)

Lognormal Distribution: Logarithms of the data may approximate the normal distribution. Mutation rates may show this type of distribution and the variance $(\sigma^2) \sim \mu$ (mean).

Log Phase: ▶[exponential growth](#)

Loganberry (*Rubus loganobaccus*): A fruit shrub, $2n = 42$.

Logarithm: A logarithm can be defined as $x = b^y$ and from this $y = \log_b x$ or, in words, y is the logarithm of x to the b base. The common (Briggs) logarithm uses base 10, the base of the natural logarithm is called e and it is 2.71828 (to five digits). Logarithms can be determined to any base and can be converted to each other, e.g., the natural logarithm, \log_e (commonly designated also as \ln), can be converted to common logarithms as $\log_{10} x = \log_e x (1/\log_e 10)$. ▶[antilogarithm](#)

Logarithmic Growth: ▶[exponential growth](#)

Logarithmic Stability Factor: The logarithmic stability factor (LSF) measures the developmental homeostatic values of individuals of certain genotypes under

different environmental conditions. LSF is calculated as the absolute difference between two logarithmic means. If $LSF = 0$ the developmental homeostasis is maximal. ▶[homeostasis](#); Li SL, Rédei GP 1969 Theor Appl Genet 39:68.

Logic: The study of the methods of reasoning; it deals with propositions, their implications, possible contradictions, conversions, etc. Symbolic logic employs mathematical symbols for the propositions, quantifiers, mutual relations among propositions, etc. Logic is one of the most important tools of science for interpreting the experimental data. ▶[syllogisms](#)

Logic Gate: A concept of Boolean algebra where complex statements are connected by “and”, “not”, and “or” relations. Such a system may be used in synthetic biology for the generation of novel interacting networks. ▶[Boolean algebra](#), ▶[synthetic biology](#)

Logistic Regression: Regression analysis for binary variables using logit transformation such as $\text{logit}(p) = \ln \frac{p}{1-p}$ where p tends to be 0 and $\text{logit}(p)$ tends to be $-\infty$, and as p tends to be 1, $\text{logit}(p)$ tends to become $+\infty$. ▶[binary variables](#), ▶[Logit](#); Agresti A 1990 Categorical Data Analysis. Wiley, New York.

Logit: Logit is very similar to the cumulative normal distribution. The transformation is: $l = \log (P/1-P)$. ▶[probit](#)

Logo: ▶[sequence logo](#)

LOH: Loss of heterozygosity or LOH is mediated by mutation (deletion) or somatic recombination or gene conversion. It is a common cause of cancer when a cancer suppressor gene is lost. Nontoxic levels of several mutagenic agents increased LOH by an order or two orders of magnitude in mouse stem cells (Donahue SL et al 2006 Proc Natl Acad Sci USA 103:11642). ▶[pseudodominance](#), ▶[tumor suppressor gene](#), ▶[LOS](#), ▶[mitotic recombination](#), ▶[gene conversion](#)

Lollipop Structure: When single strands of DNA carrying palindromic terminal repeats are allowed to fold back, the complementary ends pair while the noncomplementary sequences in-between remain single-stranded and thus form a stem and loop configuration as shown in [Figure L48](#). Denatured insertion elements may also display lollipop structures if the complementary sequences are allowed to pair within the single strand. ▶[palindrome](#), ▶[insertion element](#)

Figure L48. Lollipop structure of nucleic acids

Lon: A monomeric eukaryotic polypeptide with one of the domains associated with ATPase and functions as a chaperone; the other domain functions as a protease.

►C/p

Long Branch Attraction: The placement, in evolutionary trees, of sequences that are not truly relevant to their phylogenetic relationship. ►evolutionary tree; Qiu YL et al 2001 Mol Biol Evol 18:1745.

Long-Day Plants: These plants usually require more than 12 hr daily illumination to be able to develop flower primordia. ►photoperiodism, ►short-day plants, ►primordium

Long Interspersed Nucleotide Element: ►LINE

Long-Patch Repair: The repair of longer mismatches. In humans, DNA polymerase β may have the major role although pol δ and pol ϵ are also repair polymerases. Base excision and nucleotide excision repairs are short-patch repairs. ►DNA repair, ►excision repair, ►mismatch repair, ►DNA polymerases, ►PARP; Podlasky AJ et al 2001 EMBO J 20:1477.

Long-Term Selection: ►artificial selection

Long Terminal Repeat (LTR): Retroviruses at the two flanks may have 2–8 kb repeated nucleotide sequences; similarly a few hundred repeats are found at the ends of retrotransposons. ►retroviruses, ►transposable elements, ►retrotransposons, ►solitary LTR

Longevity: Longevity represents the length of life. It can be measured as replicative aging or as chronological aging. Life span is the biologically determined potential of an organism to live. Life expectancy is the actual, expected duration of life under certain conditions. The average human life expectancy in years in the USA in 1850 was 38.3 for males and 40.5 for females; by 1950 it became 66.5 and 73.0, respectively. It has increased since by approximately 7–8 years. In 2003, the life expectancy in the USA for white males was 75.4 years, for black males 69.2, for white females 80.5, and for black females 76.1. It is quite likely that the current trend of widespread obesity will reduce life expectancy in the twenty-first century. Raymond Pearl, an American pioneer of

human population genetics, found (during the early years of the twentieth century) that the life expectancy at birth of sons of fathers who died before ages 50, 50–79 and over 80 to be 47, 50.5 and 57.2 years, respectively. Despite regression, approximately similar life expectancy differences continued after the age of 40. Currently, the average life expectancy is in the mid-70s in the USA and if the present trends continue it may increase by about 10 years in about 50 years. Presently, the estimated maximal human life span is about 120 years. Compared to the US 1900 cohort, male siblings of centenarians were about 17 times as likely to attain age 100 themselves, while female siblings were at least eight times as likely (Perls TT et al 2002 Proc Natl Acad Sci USA 99:8442). Some theories predict that aging does not affect the evolution of longevity because at older ages the reproductive rate diminishes. On the other hand, longevity has selective fitness value for descendants because the support provided for the offspring assures greater survival of the youngsters. Thus, parental or grandparental care is of selective value for longevity (Lee RD 2003 Proc Natl Acad Sci USA 100:9637). A Danish study found 0.26 heritability of longevity for males and 0.23 for females (Herskind AM et al 1996 Hum Genet 97:319). In humans, few genes are known that affect longevity although apolipoproteins seem to have an effect (Corder EH et al 1996 Arch Neurol 53:418; Atzmon G et al 2006 PLoS Biol 4(4):e113). Lower levels of apolipoprotein APOC3 involved lower hypertension, less cardiac disease and diabetes. Christensen K et al (2006 Nature Rev Genet 7:436) tabulated the candidate genes affecting human life span. Many genes with small individual effects and environmental factors—diseases in particular—determine longevity.

In *Drosophila*, increased egg-production, receipt of male accessory fluid and courtship shorten the life span. Mating and courtship also shorten the life span of flies. Caloric restriction in the diet or mutation in a sodium dicarboxylate co-transporter or overexpression of a protein repair methyltransferase extends the life span of flies. The gene *Indy* (for I am not dead yet) encodes a membrane protein that transports Krebs cycle intermediates. The hermaphrodite *Caenorhabditis* has a shorter life if mated, but this is independent from egg production or receipt of sperm. The males of this species are not affected by mating. Some single genes of *Caenorhabditis* (*daf*, *age-1*) may extend the life span two to three times. Two 14-3-3 proteins interact with Sir2 and Sir1 proteins in *Caenorhabditis* and activate the DAF-16 transcription factor and extend the life span (Berdichevsky A et al 2006 Cell 125:1165). In this nematode the life span is also regulated by sensory perception and defects in the sensory neurons. Some suggestions were made

regarding correlation between longevity and MHC alleles, apolipoproteins E and B, angiotensin-converting enzyme, upregulation of superoxide dismutase activity, etc. When the insulin-like growth factor (IGF-1) receptor DAF-2 reduces the level of the DAF-16 (a forkhead/winged helix type transcriptional regulator [FKH]) protein the worm's life span is doubled. Besides DAF-16, DAF-12 (a nuclear hormone) plays a beneficial role. This pathway (DAF-2) is under germline-controlled negative regulation. The somatic gonad also affects aging. In *Caenorhabditis*, about 50 genes have major effect on longevity. Reduction of the activity of microRNA *lin-4* reduces the life span of nematodes and accelerates aging. Overexpression of *lin-4* reduces the expression of microRNA *lin-14* and prolongs the life span. The *lin-4*-*lin-14* pair affects longevity through the insulin/insulin-like growth factor 1 pathway (Boehm M, Slack F 2005 Science 310:1954). In *Drosophila*, the loss of an insulin-receptor substrate protein significantly extends the life span. *Drosophila* longevity is increased by 4-phenylbutyrate without apparent side effects (Kang H-L et al 2002 Proc Natl Acad Sci USA 99:838). Abolishing the expression of the Rpd3 histone deacetylase extends the longevity of *Drosophila*. The p66^{Shc} protein (encoded by SHC gene) protects mammalian cells from oxidative stress (ROS) and may increase the life span of mice by 30% and homozygosity for the Prop^{df} and Pit1^{dw} mutation (affecting growth factor production) may expand the life span by 50 to 40%. Mutation in lipid metabolism in the mitochondria extends the life span in *Drosophila* (Mourikis P et al 2006 Proc Natl Acad Sci USA 103:1307). In the fungus *Podospora anserina*, the inactivation of subunit V of the mitochondrial COX5 gene channels respiration to an alternative pathway decreases the production of reactive oxygen species and strikingly increases longevity. In *Saccharomyces*, the activation of the gene silencing protein Sir2 by NAD contributes to longevity (Anderson RM et al 2003 Nature [Lond] 423:181). Longevity among taxonomic groups may be positively correlated with the size of the genome. ▶mortality, ▶aging, ▶replicative aging, ▶chronological aging, ▶age and mutation, ▶age-specific birth and death rates, ▶copulation, ▶apolipoproteins, ▶MHC, ▶angiotensin, ▶menopause, ▶superoxide dismutase, ▶Dauer larva, ▶eIF-4E, ▶FKH, ▶SHC, ▶ROS, ▶COX, ▶silencer, ▶NAD, ▶insulin, ▶sirtuin, ▶ecdysone, ▶microrna, ▶protein 14-3-3 Tuljapourkar S et al 2000 Nature [Lond] 405:789; Clancy DJ et al 2001 Science 292:104; Chavous DA et al 2001 Proc Natl Acad Sci USA 98:14814; Larsen PL, Clarke CF 2002 Science 295:120; Perls T et al 2002 Current Op Genet Dev 12:362; Muñoz MJ, Riddle DL 2003 Genetics 163:171; <http://www.mortality.org/>.

Longhorn Cattle: A primitive form, used extensively as draft farm animal before the era of mechanization. Longhorn cattle resemble the cattle depicted (15,000 years ago) by neolithic humans in European caves. ▶Lascaux cave

Long-Period Interspersion: Long sequences of repetitive DNA alternating with long unique sequences.

Long QT Syndrome (KCNQ1/LQT1, 11p15.5; LQT2, 7q35-q36): The long QT syndrome involves voltage-gated potassium channel defects. Congenital long QT syndrome involves ventricular heart arrhythmias and sudden death. Among the 1,534 descendants, the proportion of genetically affected offspring was significantly greater than that expected: 870 were carriers of a mutation (57%) and 664 were noncarriers (43%, $P < 0.001$). Among the carriers, the allele for the long QT syndrome was transmitted significantly more often to female (55%) offspring than to male (45%) offspring (Imboden M et al 2006 New England J Med 355:2744). ▶ankyrin, ▶LQT, ▶Ward-Romano syndrome, ▶ion channels, ▶arrhythmogenic right ventricular cardiomyopathy; Marx SO et al 2002 Science 295:496; zebrafish model: Arnaout R et al 2007 Proc Natl Acad Sci USA 104:11316.

Longitudinal Study: A longitudinal study is carried out for a longer time through age and developmental stages. ▶cross-sectional study

Long-Term Depression: ▶memory

Long-Term Potentiation (LTP): The activation of synaptic junctions in the brain relating to memory. The non-associative LTP is induced by high-frequency stimulation of the presynaptic termini. The associative type LTP increases the probability that neighboring synapses on the same neuron will be strengthened if activated within milliseconds. This provides an opportunity to encode associations between different events if they occur concurrently. Ca²⁺/calmodulin-dependent protein kinase (CaMKII) and cAMP both regulate LTP. A single phosphorylation site on eIF2 α is a key regulator of LTP and long-term memory in mice (Costa-Mattioli M et al 2007 Cell 129:195). Inhibition of protein phosphatase-1 (PP1) can substitute for the cAMP function, which uses PP1 to gate CaMKII signaling. ▶memory, ▶Hebbian mechanism, ▶cAMP, ▶calmodulin, ▶eIF2, ▶ATF; Malenka RC, Nicoll RA 1999 Science 285:1870; Matynia A et al 2002 Annu Rev Genet 36:687; review: Malenka RC, Bear MF 2004 Neuron 44:5.

Look-Through Mutagenesis: A method to generate mutation in the complementarity-determining regions (CDR) of the variable heavy and variable light

domains of antibodies by synthetic procedures. Nine amino acids, representative of chemical functionalities (small, nucleophilic, hydrophobic, aromatic, acidic, amide, basic), were used in a combinatorial fashion. The best replacement combinations improved affinities by 500–870-fold and neutralized TNF- α by 15–30-fold. Such non-stochastic mutagenesis greatly and systematically increases antibody effectiveness and appears superior to other procedures of site-specific mutagenesis. It can find therapeutic application in a variety of conditions, from organ rejection and cancer to autoimmune diseases. ▶CDR, ▶site-specific mutation, ▶TNF; Rajpal A et al 2005 Proc Natl Acad Sci USA 102:8466.

Loop: Single-stranded (unpaired) nucleic acids sequences (loops) alternating with double-stranded, paired regions in isolated molecules (see Fig. L49). Paired regions of the meiotic chromosomes of inversion heterozygotes, unpaired regions of normal chromosomes “paired” with deletions. The nondeleted strand pops out opposite the deletion. ▶lollipop, ▶inversion, ▶tRNA, ▶deletion, ▶looping of DNA, ▶lampbrush chromosome

Figure L49. Loop

Loop Domains Model: The DNA fibers form 5- to 100-kb loops that are attached to the nuclear matrix (protein) at the matrix attachment region (MAR). These domains of the chromatin are supposed to be transcriptional and replicational units. The matrix is also called nuclear scaffold. The MAR regions are expected to regulate the expression/silencing of genes ▶chromatin, ▶A box, ▶T box

Looping of DNA: DNA looping is brought about by protein binding to DNA at two different positions ranging from ten to thousands of nucleotides apart (see Fig. L50). The association of proteins with specific DNA sequences permits the DNA to fold back from a longer distance to the location of the promoter of the gene and thus regulate the expression, recombination and replication of the genetic material. Looping may involve short (~100 bp) sequences that show the twistability and flexibility of the DNA. One of the several proteins that mediate the changes in the structure of DNA in the bacterial nucleoid is the heat unstable nucleoid protein, which, in association with the galactose repressor, regulates the expression of

the gene by looping the DNA and controlling both promoters of the gene (Lia G et al 2003 Proc Natl Acad Sci USA 100:11373). (See Fig. L50 modified after Lia, G. et al., ▶hormone response elements, ▶transcription factors inducible, ▶regulation of gene activity, ▶LCR, ▶RNA TRAP; Irani MH et al 1983 Cell 32:783; Schleif R 1992 Annu Rev Biochem 61:199; Geanocopoulos M et al 2001 Nature Struct Biol 8(5):432; Cloutier TE, Widom J. 2005 Proc Natl Acad Sci USA 102:3645.

Figure L50. Looping of DNA

Loop-out–Loop-in Mutagenesis: Generation of deletions and the replacing of deleted segments with other sequences.

LOR: Human low-copy repetitive sequences in about five copies per genome. ▶redundancy

Lordosis (curvature of the spine): The term is generally applied to the condition where the curvature is expressed above the normal level such as, e.g., in some types of muscular dystrophy. Rodent females receptive to mating display an arched back and raised tail and hind body parts. ▶muscular dystrophy, ▶scoliosis, ▶kyphosis

Lorisidae: A family of prosimii. *Arctocebus calabrensis* 2n = 52; *Galago crassicaudatus* 2n = 62; *Galago demidovii* 2n = 58; *Galago senegaliensis braccatus* 2n = 36, 37, 38; *Perodicticus potto* 2n = 62. ▶prosimii

LOS: The loss of heterozygosity mutation. In a heterozygote, one of the alleles (infrequently both) is lost. If the remaining allele is nonfunctional or suffers a secondary (somatic) mutation, the normal function of the gene is discontinued. ▶LOH

Loss-of-Function Mutation: Generally results in a recessive phenotype but only 1/3 or 1/4 of the *Drosophila* genes can be classified by phenotype as loss-of-function mutation because of redundancy. ▶gain-of-function mutation, ▶LOH

Lotka-Volterra Formula: Lotka-Volterra formula quantifies the competitive interactions between populations:

$$\frac{dN_1}{dt} = r_1 N_1 \left(1 - \frac{(N_1 + \alpha_{12} N_2)}{K_1} \right) \text{ and } \frac{dN_2}{dt} = r_2 N_2 \left(1 - \frac{(N_2 + \alpha_{21} N_1)}{K_2} \right)$$

Subscripts 1 and 2 stand for the two populations (N); dN_1/dt and dN_2/dt are the calculus symbols for the rate of change; $1/K$ is the effect of an individual of species 1 on the growth of species 1; and, α_{21}/K_1 is the effect of an individual of species 2 on species 1. Similarly, $1/K_2$ and α_{12}/K_2 stand for the influence of one individual of species 1 on species 2, and r is the constant of intrinsic rate of growth. (See Drossel B, Mckane A 2000 J Theor Biol 204(3):467).

Lotoaustralin: A glucoside linked with cyanide and making some white clover varieties toxic or lethal (if 1 to 2 kg is consumed) to animals (50 kg). This toxic effect has been circumvented by breeding white clovers deficient in the synthesis of the glucoside and in linamarase. Several other plant species (Sudan grass, flax, some beans, almond, apricot) produce potentially toxic cyanides. ▶cyanogenic glucosides

Lou Gehrig's Disease: ▶amyotrophic lateral sclerosis

Louis-Bar Syndrome: Ataxia telangiectasia. ▶ataxia

Lovastatin (mevinolin/monacolin K): An inhibitor of the (3S)-hydroxy-methylglutaryl-coenzyme (see Fig. L51). A reductase, which normally reduces its substrate (HMG-CoA) to mevalonate, a precursor of cholesterol. It is a natural product of the fungus *Aspergillus terreus*. ▶cholesterol

Figure L51. Lovastatin (acid)

Low Frequency Transducing Lysate: ▶LFT

Low-Complexity Sequences: Low-complexity sequences contain repetitions of the building blocks or tracts of repetitions.

Low-Copy Repeats: Low-copy repeats may constitute 5% of the genome of 10 to 40 kb size and ~95–97% similarity. These repeats may be responsible for

genomic instabilities and disease because of recombination among these similar sequences (Stankiewicz P, Lukski JR 2002 Current Op Genet Dev 12:312).

Low-Density Lipoproteins (LDL): Low-density lipoproteins form 22-nm diameter particles containing bilayered vesicles of about 1,500 cholesterol molecules, esterified to long-chain fatty acids and form a vehicle of delivery of lysosomes from where the cholesterol is made available for membrane synthesis. If there is a defect in the synthesis of the receptor proteins (19p13.2, 12q13.1-q13.3, 1p34, 2q24-q31, 4p16.3, 11p12-p11.2) the cell may not draw cholesterol from the blood resulting in atherosclerosis and eventually artery disease. LDL receptors are involved in high affinity and broad specificity endocytosis such as the macrophage scavenger receptors that are supposed to mediate cell adhesion, host defense, and atherosclerosis. Mutations in the PCSK9 692-amino acid glycoprotein also cause hypercholesterolemia. In a sample analyzed, African-Americans have much higher frequency (2%) of nonsense mutations in the PCSK9 gene than Whites or Hispanics, <0.1% (Cohen J et al 2005 Nature Genet 37:161). ▶atherosclerosis, ▶cholesterol, ▶lysosome, ▶hypertension, ▶HDL, ▶Alzheimer disease, ▶VLDL, ▶hypercholesterolemia, ▶apolipoproteins, ▶ethnicity

Low-Energy Phosphate: A compound that can release relatively low energy upon hydrolysis, e.g., glucose-6-phosphate.

Lowe's Oculocerebrorenal Syndrome (OCRL): An X-chromosome-linked (Xq26.1) eye defect, mental retardation, aminoaciduria, kidney anomaly, rickets, etc. The defect is in an inositol-5-phosphatase, synaptojanin. ▶mental retardation, ▶synaptojanin

Lowry Test: The test (J. Biol. Chem.193:265 [1951]) quantitatively estimates total protein in tissue extracts using 1% CuSO₄ (0.5 mL), 2.7% Na-K-tartrate (0.5 mL), 2% Na₂CO₃ in 0.1 M NaOH (50 mL). Add 5 mL to 1 mL sample protein (25–500 µmL), mix and allow to stand for 10 min. Then add 0.5 mL Folin & Ciocalteu reagent and mix; after 30 min determine O.D. at 750 nm and compare to bovine serum albumin standard solution series (detergents interfere with the test). ▶Bradford method, ▶Kjeldhal method

Lox (*loxP*): ▶Cre/Lox

L-Phase: Due to various shocks (temperature, osmotic, antibiotics, etc.) the bacteria may lose their walls in a possibly reversible manner and yet they can multiply.

LPS (endotoxin): Lipopolysaccharide, lipid-carbohydrate complexes existing on the walls of some bacteria. The infection of mammalian cells by Gram-negative bacteria leads to the release of

toxic LPS, which in turn activates TNF and other toxic cytokines. ▶TNF, ▶cytokines, ▶endotoxins, ▶capsule

LQT: A cardiac (heart) disease involving left ventricular arrhythmia. Several genetic defects result in the same symptoms (SCN5A, LQT3 [chromosome 3p21], HERG [LQT2, chromosome 7], KVLQT1/KCNQ1 [LQT1, chr. 11p15.5], and another in chr. 4). All of these loci are involved in the control or regulation of muscle cell K^+ or Na^+ ion channels. ▶cardiovascular diseases, ▶ankyrin, ▶ion channels, ▶Jervell and Lange-Nielson syndrome, ▶Ward-Romano syndrome, ▶electrocardiogram for LQT, ▶KCNA, ▶Beckwith-Wiedemann syndrome, ▶Timothy syndrome; Bennett PB et al 1995 Nature [Lond] 376:640; Schwartz PJ et al 2001 Circulation 103:89; Keating MT, Sanguinetti MC 2001 Cell 104:569.

LRE: ▶light response elements

LRF (luteinizing hormone releasing factor): ▶luteinization, ▶corticotropin

LRR (leucine-rich repeats): ▶host-pathogen relations

λ_S : Risk of relatives/population risk may be used to determine the genetic part of a disease. A recessive disease is expected among the relatives of a proband at a frequency of 0.25. If the prevalence of this disease in the general population is say 0.0005, then $\lambda_S = 0.25/0.0005 = 500$. In case a dominant gene controls the disease then λ_S will be larger. The higher is λ_S the greater the risk of recurrence. λ_S larger than 2 indicates a significant genetic component in the disease. In case the disease is under the control of multiple loci, the risk may diminish in successive generations. ▶sibling, ▶risk, ▶prevalence

LSD1 (histone lysine demethylase): LSD1 is involved in epigenetic modifications.

LSDB: See Locus specific database <http://www.hgvs.org/entry.html>.

LSIRF (IRF4): A transcription factor, specific for mature B and T cells.

LT, LTβ: Both are proteins of the TNF/NGF family encoded at the HLA gene cluster. ▶TNF, ▶NGF, ▶HLA

LTD: ▶memory

LTR: Also known as long terminal repeats in movable genetic elements and oncogenic viruses. ▶retroviruses, ▶transposable elements

LUC: The firefly luciferase gene. ▶luciferase

Luciferase: Luciferase can be effectively used as a tissue- or developmental stage-specific reporter of gene expression (see Fig. L52).

Figure L52. *Arabidopsis* plant transgenic for the bacterial luciferase *Luxaβ* genes. The most intense expression is indicated by red color. (From Rédei GP, Koncz C, Langridge, WHR, unpublished)

The luciferase of the firefly (*Photinus pyralis*) is a single polypeptide of 550 amino acids. In the presence of oxygen (O_2), and Mg-ATP (or coenzyme A) it oxidizes luciferin to oxyluciferin, resulting in the visible emission of yellow-green light flashes, which can be monitored also by luminometers, scintillation counters or by extended exposure to highly sensitive photographic film. Other insects also produce luciferases, which produce somewhat different light emission. The light emission spectrum depends on the conformation/amino acid composition of the luciferase enzyme (Nakatsu T et al 2006 Nature 440:372). The generation of the light flashes is part of the courtship process and reproduction in insects. The bacterial luciferases such as the one produced by *Vibrio harveyi* or other similar strains consist of two subunits A and B. The substrate of the bacterial luciferase enzymes is n-decyl aldehyde (decanal) and for the emission of light reduced flavin mononucleotide (FMNH₂) is required. While the aldehyde (RCHO) is converted to acid (RCOOH) in the presence of oxygen (O_2), water (H_2O), FMN and light is generated. The luminescent bacterium *V. fischeri* uses a quorum-sensing signal, which, combined with the enzyme LuxI, activates LuxR, and which in turn binds to specific activating domains in the bacterial DNAs to turn on the genes required for light emission. About 20 additional genes cooperate with, and modulate, the expression of the bacterial luciferase. The light can be monitored in the tissues without destruction by the use of a microchannel plate enhanced photon counting image analyzer that uses a video camera, an image processor, a TV processor, and computerized controls. Such equipments may detect even a single photon. A much less expensive luminometer can also be used with ground tissues. ▶image analyzer, ▶GUS, ▶Quorum-sensing;

Baldwin TO et al 1995 Curr Opin Struct Biol 5:798; Pazzagli M et al 1992 Anal Biochem 204:315; Olsson O et al 1988 Mol Gen Genet 215:1.

Luciferin: Upon activation, cleaves a pyrophosphate off ATP to form luciferyl adenylate. Upon the action of firefly luciferase—in the presence of O_2 —light is emitted. Oxyluciferin is then generated in the presence of CO_2 and AMP. Subsequently, through some steps, luciferin is reformed. These reactions are suitable for monitoring gene expression and for the quantitation of ATP. ▶[luciferase](#), ▶[ATP](#); Wilson T, Hastings JW 1998 Annu Rev Cell Dev Biol 14:197.

Lucy: 3-million-year old *Australopithecus afarensis* skeleton of about 1 m height (discovered in 1974 in Ethiopia), believed to be a representative of the origin of the human family tree. Although—as the name implies—the skeleton was assumed to be that of a female (because of the small size), some paleoanthropologists argue that she was rather a male because the pelvis would not have been sufficient for child bearing. ▶[hominids](#)

Ludwig Effect: Biological habitats are generally divided into numerous microniches and the species respond to these by selection.

Luft Disease: A rare human hypermetabolism due to a defect in the coupling of oxidative and phosphorylation processes in the mitochondria. The genetic determination is not entirely clear; autosomal recessivity is suspected. ▶[mitochondrial disease in humans](#)

Lujan Syndrome: An X-linked mental retardation with marfanoid features. ▶[mental retardation](#), ▶[Marfanoid syndromes](#)

Lumen: The interior compartment of a membrane-enveloped structure in the cell; also a unit of luminous intensity. ▶[lambert](#)

Luminescence: Light emission from cool sources such as excited gases (neon light), fluorescent tubes, television and computer screens, and bioluminescence of fireflies, glowworms and certain fishes and bacterial luciferase. ▶[luciferase](#)

Lung Cancer: ▶[small cell lung carcinoma](#), ▶[non-small-cell lung carcinoma](#), ▶[pulmonary adenoma](#)

Lupines (leguminous plants): Yellow lupine (*Lupinus luteus*, $2n = 46, 48, 52$); blue lupine (*L. angustifolius*, $2n = 40$); and white lupine (*L. albus*, $2n = 30, 40, 50$) are crop plants used for “green manure” or in alkaloid-free forms as forage crops in acid soils. The perennial lupine (*L. polyphyllus* ($2n = 48$)) is an attractive ornamental plant. The alkaloid-free lupines are one of the best examples of scientific plant breeding. ▶[alkaloids](#)

Lupus Erythematosus: A variety of skin and subcutaneous inflammations, each with a specific medical name (see [Fig. L53](#)). The genetic basis is not clear as certain

Figure L53. Lupus erythematosus

drugs (e.g., procaine anesthetics) apparently cause some of the common symptoms. In other cases, viral infection has been suspected because of similar symptoms observed in family dogs. Some indications point to the involvement of steroid hormone problems because of its incidence with the Klinefelter syndrome. In some cases, along with the normal DNA, a low molecular weight DNA was associated with the disease. In other individuals, anti-RNA or antinuclear antibodies were identified. The Ro autoantigen (60 kDa) is a major target in the disease. Ro binds misfolded small RNAs and seems to play a role in RNA quality control. Ro contains a von Willebrand factor A domain and a doughnut-shape domain of HEAT repeats. In this complex the small, so-called Y RNAs bind to the outer surface of the HEAT ring and the single-stranded RNA binds to the toroid hole (Stein AJ et al 2005 Cell 121:529). Lymphocyte defects were also shown in some afflicted individuals. The serum complement deficiencies involve major risk of onset. C1q deficient individuals carry a risk of ~90%. C1q is assembled from 18 polypeptide chains including the C1r and C1s serine protease homodimers. After C1q binds to the antibody the proteases are activated and the C3 convertase is formed from the C2 and C4 complement parts. Females are about eight-fold more likely to be afflicted by it than males in the age group 15–50, but later or earlier the relative risks differences are much less. Protein p21 appears to be responsible for preventing lupus-like diseases in females. The lifetime risk for a US Caucasian female is about 0.15% and much less for Blacks or Hispanics. A mouse model indicates that the secretion of the BAFF protein by T cells or dendritic cells initiates the abnormal stimulation of B-cell proliferation. Furin protease cleaves off BAFF from the surface of the cells that secreted it. When BAFF goes into the blood

stream it recognizes the B cell receptors BCMA and TACI and in cooperation with CD40 activates the B cells. Decoy receptors for BAFF may alleviate the inflammation. Antinuclear antibodies, presumably due to deficiency of DNase1, which normally removes them, characterize the systemic lupus erythematosus (SLE, 4p16-p15.2). As a consequence, immune reactions afflict blood vessel walls, and joints and arthritis symptoms develop as well as cognitive impairment when NMDA reaches BBB, the blood-brain barrier (Kowal C et al 2004 Immunity 21:179). In lupus erythematosus, a molecular mimic of Asp/Glu-Trp-Asp/Glu-Tryr-Ser/Gly pentapeptide is antigenic to double-stranded DNA and it is also present in murine and human NMDA receptor NR2 subunits. As a result, neurons are subject to apoptosis and to this autoimmune disease. B cells may acquire autoreactivity during normal development by a process of somatic hypermutation and the mutation may entail selection of high affinity anti-DNA B cells (Wellmann U et al 2005 Proc Natl Acad Sci USA 102:9258).

A lupus-like disease in mouse develops as a consequence of increase in IL18, which in turn activates INF- γ . Interference with this path (vaccination) may have therapeutic value in humans (Bossù P et al 2003 Proc Natl Acad Sci USA 100:14181).

A major susceptibility gene was localized to 1q31. Earlier, a number of chromosome-1 sites were assumed to be involved but these, as well as the role of CD45, could not be rigorously confirmed (Johannesson B et al 2002 Am J Hum Genet 71:1060). In the human locus 1q41-q42 susceptibility alleles reside in various ethnic groups. An association between the Toll-like receptor regulating inflammatory responses and lupus appears well founded and nonsense mutation at TLR^{392STOP} protects against autoimmunity (Hawn TR et al 2005 Proc Natl Acad Sci USA 1032:10593). Another susceptibility locus was assigned to 12q24 (Nath SK et al 2004 Am J Hum Genet 74:73). The Fc γ RIIB antibody receptor may restore tolerance to lupus in susceptible animals (McGaha TL et al 2005 Science 307:590). Mutations in the interferon pathway (INF5) can increase the risk of lupus erythematosus (Graham RR et al 2006 Nature Genet 38:550). ▶autoimmune disease, ▶gene copy number, ▶von Willebrand disease, ▶toroid, ▶complement, ▶convertase, ▶HLA, ▶procaine anesthetics, ▶RoRNP, ▶p21, ▶B cell, ▶T cell, ▶dendritic cell, ▶TACI, ▶CD40, ▶CD45, ▶NMDA, ▶BBB, ▶decoy receptors, ▶antibody; Gray-McGuire C et al 2000 Am J Hum Genet 67:1460; Yasutomo K et al 2001 Nature Genet 28:313; DeGiorgio LA et al 2001 Nature Med 7:1189.

Luria-Bertani Medium: ▶LB

Luteinization: After ovulation the ovarian follicle is converted into a corpus luteum (yellow body). ▶corpus luteum, ▶Graafian follicle, ▶luteinizing hormone-releasing factor, ▶ovarian cancer

Luteinizing Hormone: pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly:NH₂. ▶animal hormones

Luteinizing Hormone-Releasing Factor (LH-RF or LRF, gonadotropin-releasing factor): A hypothalamic neurohormone stimulating the secretion of pituitary hormones. It is involved in the control of mammalian fertility. When administered to mammals—including humans—it induces ovulation. ▶GnRHA, ▶in vitro fertilization, ▶ART, ▶corticotropin, ▶puberty precocious, ▶uterus; Latronico AC, Segaloff DL 1999 Am J Hum Genet 65:949.

Lutheran Blood Group: This blood group is so named after the first patient identified in 1945. The Lu(a⁻b⁻) phenotype is determined by either dominant or recessive alleles of the gene in human chromosome 19cen-q13, distinguishable by hereditary pattern and by serotype. The frequency of Lu(a) allele is about 0.04 and that of Lu(b) is about 0.96. The Lu phenotype may be caused by dominant inhibitors identified as mice antigens A3D8 and A1G3 under the control of a locus in human chromosome 11p. This 80-kDa antigen apparently has different epitopes on the same protein molecule. The Lu system appears to be identical to the Auberger blood group. ▶blood groups, ▶epitope

Lux: ▶luciferase genes of bacteria, ▶LUC

LUX: A unit of illumination; 1 Lux = one lumen/m². ▶lambert

Luxuriance: The hybrid vigor displayed by the somatic tissues of hybrids between different species or genera that are sterile or have reduced fertility. ▶hybrid vigor

Luxury Genes: These genes are not involved in functions indispensable for the viability of a cell and common basic function, but rather only in differentiated, special cells.

Luzula purpurea (Juncaceae, n = 3): *Luzula purpurea* and other related plant species have holocentric chromosomes and polyploid as well as aneuploid series. ▶holocentric, ▶polyploid, ▶aneuploid

LW Blood Group: Produces the rodent anti-Rhesus antibody. ▶Rh blood group

LXR: A group of liver hormone receptors regulating cholesterol metabolism. ▶cholesterol

Lyase: An enzyme that catalyzes additions or the removal of double bonds.

Lychnis: A dioecious plant species. *Melandrium* and *Silene* are synonyms. Male karyotype is shown in Figure L54 (After Warmke HE 1946 Am J Bot 33:648).

Figure L54. *Lychnis*

Lycopene ($C_{40}H_{56}$): A carotenoid pigment. ▶carotenoids

Lyell Syndrome (toxic epidermal necrolysis, TEN): An adverse reaction to drugs due to lytically active FAS ligand causing apoptosis. ▶FAS

LYL: A lymphoid leukemia oncogene, encoded in human chromosome 19p13.

Lymantria: *Lymantria dispar*, $2n = 62$. It has been used for studies on sex determination. The heterogametic female (see Fig. L55) and the homogametic male (see Fig. L52) have different colors. The intersex forms may resemble more the male than the female and frequently display light-color sectors. Its English name is gypsy moth. *Lymantria* is an obnoxious invader in the US and causes serious damage and extermination of deciduous trees (Johnson DM et al 2006 Nature [Lond] 444:361). ▶intersex

Lyme Disease (borreliosis): ▶*Borrelia*, ▶*Ixodoidea*

Lymph A transparent fluid filtered through the capillary blood vessels from blood.

Lymph Glands: (yellowish or sometimes pinkish): Lymph glands are hematopoietic (blood-forming) organs of insects (*Drosophila*). (See Mandal L et al 2007 Nature [Lond] 446:320; Krzemien J et al 2007 Nature [Lond] 446:325).

Lymph Nodes: Lymph nodes are small (1 to 25 mm) nodules in the body where lymphatic vessels, lymphocytes, and antigen-presenting cells accumulate.

They play defensive roles by removing toxic and infectious agents. ▶lymph, ▶lymphocytes, ▶lymphoma, ▶Hodgkin's disease, ▶thymus, ▶T cell, ▶T cell receptor, ▶antigen-presenting cell

Lymphedema Distichiasis (FOXC2, Meige disease, 16q24.3): The failure of the lymphnodes to drain properly. Symptoms include double eyelashes that turn against the eyeball. Translocations involving site 16q24 also cause the disease. Another lymphedema (Milroy disease) involving the VEGFR-3 gene was mapped to chromosome 5q35.3. Hypotrichosis-lymphedema-telangiectasia is caused by a defect in the SOX18 transcription factor, encoded at 20q13 (Irrthum A et al 2003 Am J Hum Genet 72:1470). ▶eyelashes, ▶long, ▶distichiasis, ▶VEGF, ▶hypotrichosis, ▶telangiectasia, ▶SOX, ▶forkhead; Finegold DN et al 2001 Hum Mol Genet 10:1185.

Lymphedema, Hereditary (Milroy disease, 5q35.3): Hereditary lymphedema is dominant with incomplete penetrance; In general, it displays edema below the waist. The basic defect is in the epidermal growth factor receptor/receptor tyrosine kinase or VEGFR-3. ▶EGFR, ▶receptor tyrosine kinase, ▶VEGF

Lymphoblast: A lymphocyte progenitor, which, after enlargement, divides about four times daily eventually forming a clone of about 1,000 lymphocytes. ▶lymphocytes

Lymphoblastoid Cell: A B cell infected with the Epstein-Barr virus. ▶Epstein-Barr virus

Lymphochips: Microarrays facilitating the recognition of genes that are turned on/off in the process of the development of the immune reaction. ▶microarray hybridization

Lymphocyte Homing: The immune processes are systematically distributed through movement of lymphocytes from their origin (bone marrow for B cells and thymus and bone marrow for T cells) to lymph nodes, glands, tonsils, and spleen. In these organs, microbial antigens are deposited and the naïve B and T cells are exposed to them. That propels their differentiation into memory cells and effector cells, respectively. These differentiated cells then home in on the bone marrow (B cells) or to extralymphoid effector sites (T cells). These are

Figure L55. *Lymantria* larva and imagos; the male is at right

complicated processes and may go through multiple and reversible substeps. The passage from the blood vessel requires an interaction of the lymphocyte receptors with vascular ligands, activation by G-protein-linked receptors and finally passage through the vessel wall (diapedesis). After stepping out and entering special tissues they home in on, e.g., B cell follicles or T zones during memory cell formation in germinal centers. They also seek sites of inflammation. In each of these niches lymphocytes are subject to various regulatory forces by attaching, e.g., to TGF β -regulated integrin that directs them to intraepithelial sites by attachment to cadherin. They exchange signals with antigen presenting cells, surface receptors, chemoattractant receptors, immunoglobulins, antigen receptors, chemokines, etc. Probably the RHO homolog of the RAS oncogene plays a central role in the signaling paths and the antigens also affect trafficking. There is also some sort of competition and orderly assignment of the various lymphocytes to specific sites. ▶memory immunological, ▶germinal center, ▶TGF β , ▶integrin, ▶cadherin, ▶RHO, ▶antigen presenting cell, ▶chemokines, ▶immunoglobulins, ▶antigen, ▶signal transduction, ▶receptors, ▶ligand; Wiedle G et al 2001 Crit Rev Clin Lab Sci 38:1.

Lymphocytes: Lymphocytes are cells produced in fetal hepatocytes and in adults by bone marrow (see Fig. L56). They may differentiate into T lymphocytes

Figure L56. T Lymphocyte

and B lymphocytes. In the thymus, the T cell receptor immunoglobulins undergo rearrangement and the terminal nucleotidyl transferase generates additional diversity. The T lymphocytes are involved in cell-mediated immunity; the B cells are responsible for the humoral antibodies. During the development of B cells the secreted and the membrane-bound immunoglobulin (Ig) undergoes a series of events. The B cell antigen receptor (BCR) is formed by complexing a membrane Ig with the heterodimer of Ig- α and Ig- β (pro-B stage). The complex now contains an extracellular Ig-like domain, a transmembrane

domain and a short cytoplasmic domain. The signal transducing part of the receptor contains a two-tyrosine motif in the α and β cytoplasmic domains. When the hematopoietic stem cell of the bone marrow becomes committed to B cell development the Ig gene undergoes a series of rearrangements. In the first step a D_H (diversity heavy chain; ▶immunoglobulins) joins a J_H (junction heavy chain) gene. The one of the V_H (variable heavy) is attached to the D_H J_H segment in order to form a functional heavy chain. Under normal conditions a functional μ heavy chain is expressed (pre-BI stage). This transition from pro-B to pre-BI constitutes an important checkpoint, contingent of the formation of Ig- β . The next step (pre-BII) is reached when a temporary light chain immunoglobulin attaches to the VpreBI globulin. After this, the Ig- κ chain undergoes a rearrangement and it joins a V-J _{κ} (variable kappa light chain gene) and the development thus arrives to the Immature B Stage. The λ 5-VpreB chain is replaced by a κ - μ -BCR (B Cell Receptor) complex and the so formed Mature B Cell emerges from the bone marrow in the presence of a functional Ig- α cytoplasmic domain. This B cell is then activated when it comes into contact with an antigen and secretes Ig. This requires the Ig- α cytoplasmic domain and the expression of a cytoplasmic (Btk) tyrosine kinase. For T cell-dependent antigen response Ig- α and Btk are not needed. The tumor infiltrating lymphocytes have potential use in cancer therapy. The differentiation and maintenance of the lymphocytes requires interleukine-7 (IL-7) and its receptor (IL-7R). The transcription factor Ikaros (a Zn-finger protein) is specific for lymphoid cell differentiation. This protein has binding sites in several other genes involved in lymphocyte development such as CD3-T cell receptor, CD4, CD2, terminal nucleotidyl transferase, interleukine-2R α , and NF- κ B. In young adult mice, $2-4 \times 10^7$ new T cells are produced daily by 100 to 200 million thymocytes but only a couple percent enter the T cell pool. The rest are disposed of by apoptosis. The survivors differentiate into CD4⁺CD8⁺ T cells and subsequently to single-positive CD4⁺ MHC Class-II restricted and CD8⁺ MHC Class-I-restricted T cells in the peripheral T cell pool. Selective elimination of the inadequately activated T cell continues. The retained T cells undergo IL-2 stimulated clonal expansion after antigenic challenge. After the challenge some T cells die and others become memory T cells. ▶T cells, ▶T_H, ▶B cell, ▶TCR, ▶ $\alpha\beta$ T cells, ▶immune system, ▶immunoglobulins, ▶antibody, ▶TIL, ▶memory immunological, ▶lymphocyte homing, ▶monocyte, ▶germinal centers, ▶Cd3, ▶CD4, ▶CD8, ▶NF- κ B, ▶dendritic cell, ▶macrophage, ▶monocyte, ▶neutrophil, ▶basophil, ▶eosinophils, ▶immunoglobulins; Israels LG, Israels ED 1999 Stem Cells 17:180.

Lymphoedema: A dominant human chromosome 5q mutation in VEGFR-3 disabling normal lymphatic functions. ►vascular endothelial growth factor

Lymphohistiocytosis, Hemophagocytotic, Familial (HPLH2, 10q22; HPLH1, 9q; HPLH3, 17q25.1; HJCD, 11q25; FHL 6q24): A highly heterogeneous disease involving various anomalies of the immune system. (See zur Stadt U et al 2005 Human Mol Genet 14:827).

Lymphoid Organs: The primary ones are the thymus and bone marrow; the secondary ones are the lymph nodes, spleen, tonsils, mucosal lymphoid tissues, and Peyer's patches. Antigens entering the body are ferried to these secondary lymphoid organs. After prospecting, B and T lymphocytes detect the presence of antigens at these sites wherein antigen-specific B and T cells move in on the cues represented by chemokines. ►chemokines

Lymphoid Protein Tyrosine Phosphatase, Non-Receptor (1p13, 1q32.1): Non-receptor lymphoid protein tyrosine phosphatase is a negative regulator of T lymphocyte activation. Some mutant alleles play roles in autoimmune diseases such as diabetes, Graves disease, and Crohn's disease, and are regarded as general susceptibility factors in autoimmunity. ►autoimmune disease

Lymphoid Protein Tyrosine Phosphatase, Receptor-Type: (CD45, 1q31-q32): The receptor-type lymphoid protein tyrosine phosphatase is essential for the activation of T and B cells. Its deficiency may affect the expression of several diseases involving the immune system. ►CD45

Lymphokines: Proteins secreted by lymphocytes in response to specific antigens. They are involved in multiple ways in serological defense mechanisms of the body and in differentiation. Interferons (IF), interleukins (IL), granulocyte colony stimulating factors (G-CSF), granulocyte-macrophage colony stimulating factors (GM-CSF), macrophage activity factor (MAF or IFN gamma), T cell replicating factor (TRF), migration inhibition factor (MIF), and tumor necrosis factor (TNF) belong to this large group. ►immune system, ►cytokines, ►chemokines, ►interleukins, ►interferons, ►tumor necrosis factor, ►cytotoxic T cells, ►rel; Webb DR et al 1988 Molecular Basis of Lymphokine Action, Humana, Totowa, New Jersey.

Lymphoma: Cancer of the lymphocytes (leukemia); a neoplasia of lymphoid tissues. In follicular B-cell lymphoma, because of a chromosome 18 translocation, the BCL-2 gene expression is aberrant and as a consequence apoptosis is reduced. DNA ligase deficiency may cause it. ►Chédiak-Higashi

syndrome, ►lymphoblastic lymphoma, ►leukemia, ►anaplastic lymphoma, ►Mantle cell lymphoma, ►non-Hodgkin lymphoma, ►diffuse large B-cell lymphoma, ►MALT, ►translin, ►Burkitt's lymphoma, ►Duncan syndrome, ►Hodgkin's disease; Staudt LM 2002 Annu Rev Med 53:303.

Lymphopenia: A recessive deficiency of lymphocytes (cytokines); an autoimmune anemia. ►lymphocyte, ►autoimmune disease, ►cytokines, ►immunodeficiency, ►sphingosine SIR/SIRT

Lymphopoiesis (development of lymphocytes): A continuous process beginning at hematopoietic stem cells. (See Gounari F et al 2002 Nature Immunol 3:489).

Lymphoproliferative Diseases, X-linked (immunoproliferative disease, Xp25, XLP): A protein domain SH2D1A defect may be involved in X-linked lymphoproliferative diseases. This protein was also called SAP (for association with SLAM [signaling lymphocyte activation molecule, 1q23]) and inhibits SLAM signaling. Deficiency of X-linked inhibitor of apoptosis (XIAP, Xq25) is a major cause of the disease (Rigaud S et al 2006 Nature [Lond] 444:110). ►Epstein-Barr virus, ►FAS, ►SH2, ►SAP, ►SLAM, ►Canale-Smith syndrome, ►Duncan syndrome; Morra M et al 2001 Annu Rev Immunol 19:657; CzarMJ et al 2001 Proc Natl Acad Sci USA 98:7449.

Lymphotactin: C type cytokine, i.e., lacking two of the four cystin residues characteristic of chemokines. Lymphotactin is expressed in CD4⁺ T cells and CD4⁺ and CD8⁺ T cell receptor $\alpha\beta^+$ thymocytes. It has no chemotactic activity for monocytes and neutrophils. ►blood, ►lymphocytes, ►monocytes, ►cytokines, ►chemokines, ►T cells; Ju DW et al 2000 Gene Ther 7(4):329; Cerdan C et al 2001 Blood 97:2205.

Lymphotoxins: Lymphotoxins are forms of lymphokines of the tumor necrosis factor family that cause the lysis of some cells, e.g., cultured fibroblasts. They are required for growth, differentiation, and regulation of the immune system. They are encoded within the human HLA gene cluster. Lymphotoxin- α secretion, regulated by galectin-2 (galactose-binding lectin), and may affect myocardial infarction. ►lymphokines, ►HLA, ►TNF, ►immune system, ►ectodermal dysplasia; Yin L et al 2001 Science 291:2162

LYN: Tyrosine protein kinase of the SRC family involved in the differentiation of B lymphocytes. In the nervous system, LYN is associated with the AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionate) receptor. AMPA is a ligand-gated cation channel, which mediates the fast component of the

excitatory post-synaptic currents. It is also a cell-surface signal transducer. LYN is activated by Ca^{2+} and Na^{+} influx and it activates the MAPK signal pathway. ▶SRC, ▶Csk, ▶B lymphocyte receptor, ▶signal transduction, ▶ion channels, ▶BTK; Luciano F et al 2001 *Oncogene* 20:4935.

Lynch Cancer Families: Groups of dominant genes responsible for the development of certain cancer syndromes such as endometrial cancer, adenocarcinoma of the colon and others. The instability may be caused by defects of the genetic repair system. ▶colorectal cancer, ▶Li-Fraumeni syndrome

Lyon Hypothesis: Postulates that in mammalian cells with more than one X chromosome, usually all but one are heteropycnotic (highly condensed and thus dark-stained at all stages) and form $n-1$ Barr bodies. The heteropycnosis may not affect the entire length of the chromosome equally. Mary Lyon, a British geneticist, suggested that the frequently observed mosaicism in these animals is the phenotypic consequence of chromosomal behavior. The heteropycnotic chromosomes carry their genes in an inactivated state (possibly key nucleotides are methylated) and depending on which allele of a heterozygote is expressed, sectorial mosaicism is displayed. In order to carry out the inactivating switch the X chromosome must have an intact inactivation center. During development the X chromosomes may switch between their inactive-active states. These decisions are not made entirely by the X chromosome (s) because in human triploids with XXY constitution both X chromosomes remain active. A typical example is the tortoiseshell cat color that is observed almost exclusively in females heterozygous of yellow-black fur color. The exceptional (less than 1/500) tortoiseshell male cats are of XXY constitution (Klinefelter syndrome). A similar genetic heterogeneity has also been observed in humans when in heterozygous females two classes of lymphocytes were observed, one with normal and the other without testosterone binding capacity. The LINE (L1) elements appear to regulate the inactivation of the mammalian X chromosome (Bailey JA et al 2000 *Proc Natl Acad Sci USA* 97:6634) and may spread the lyonization along the X chromosome or even to translocated autosomal segments fused to the X chromosome. ▶Barr body, ▶heteropycnosis, ▶methylation of DNA, ▶regulation of gene activity, ▶lyonization, ▶dosage effect, ▶LINE; McBurney MW 1988 *Bioassays* 9:85.

Lyonization: Variegation in mammalian females as predicted by the Lyon hypothesis. In an XX mammalian female one of the X chromosomes remains in a condensed state (see Fig. L57). It

Figure L57. Lyonization in rodent

replicates its DNA asynchronously and its genes are not transcribed after the blastocyst stage, 3.5–4.5 dpc in the trophectoderm and 5.5–6.5 dpc in the embryo cell initials of the female mouse. In the germline, the inactive X is reactivated at the time of beginning of meiosis (12.5–13.5 dpc; the average time of gestation in the mouse is 19 days). In the male, X-chromosomal inactivation is limited to the duration of meiosis, presumably to restrict deleterious recombination with the Y chromosome. After fertilization, and before implantation, inactivation recurs in the female. The inactive X chromosome moves to the perinuclear position during S phase where it is silenced (Zhang L-F et al 2007 *Cell* 129:693). The other X chromosome displays a more open structure and its gene content is expressed. The majority of the genes in the inactive X replicate late but those which escape inactivation (>20) replicate synchronously with the active X chromosome. One of the X chromosomes is selected for inactivation by a chromosomal locus, Xic (X-chromosome inactivating center, Xq13). This Xic locus (450 kb) is responsible for counting (encoded within the 6th exon) the number of X chromosomes to be inactivated. In case of more than 2 X chromosomes only one remains active normally. In addition, the Xic must be in cis position to the genes to come under its influence (spreading effect). Thus Xic also selects the chromosome to be inactivated (choice function). If the XIC locus is lost after inactivation has been initiated, the inactive state is maintained. There is another functional site within the XIC locus, Xce (X control element). Xce/Xce homozygotes undergo normal, random inactivation. In Xce heterozygotes there is a higher chance that the chromosome remains active if it carries a strong Xce allele. The Xce locus seems to control non-random (skewed) inactivation. In monozygotic human twins skewed distribution (non-concordance) of inactivation was observed. Skewing may also be due by selection against mutant alleles or chromosomal abnormalities. The product of XIC is XIST (X inactive specific transcript) that is transcribed from the 15-kb site within XIC in only the inactive X chromosome after inactivation has taken

place. In XIST/Xist heterozygotes there is a large RNA transcript (ca. 15 kb) in the nucleus, apparently associated with the inactive X, and it cannot be translated. Thus, it appears that RNA mediates the regulation. During early embryogenesis Xist expression precedes the inactivation of the X chromosome and in XY males it is expressed in the male germ tissues alone and only before meiosis. A protein (not translated from the XIST transcript) is preferentially associated with the inactive X chromosome. This protein called mH2A (macroH2A) bears resemblance in its N-terminal third to H2A histone but the rest of the molecule is different from any of the histones.

The mH2A protein in females accumulates in dense macrochromatin bodies in proportion to the number of inactive X chromosomes. In marsupials, the inactive X chromosome is the paternally transmitted one. Similar observations were also made in the extraembryonic endoderm cells of some rodents and to some extent in humans. About 20 human X-chromosomal short arm genes (especially in the vicinity of the pseudoautosomal region) escape inactivation in a discontinuous manner, e.g., Xg blood group, the closely linked steroid sulfatase locus (ichthyosis) and the tissue inhibitor of metalloproteinases (TIMP1). This region of the human X chromosome appears to be a more recent evolutionary addition (XAR) to the ancestral X conserved region (XCR) and the coordination between the two has not been completed yet. (The marsupials do not have the XAR.) At the tip of the long arm of the human X there is a very short pseudoautosomal stretch that carries one escapee and one inactivated gene. In the inactivation, differential methylation between the active X and the inactive X chromosome is implicated although overall methylation appears to be the same. In the inactive X chromosome, CpG islands in 5' region are mostly methylated whereas in the active ones they are not. The inactive X-chromosomal regions are hypoacetylated at lysine residues of the core histones whereas genes escaping inactivation are hyperacetylated. Aging may reactivate some genes. Microarray hybridization applied to cloned X-chromosomal fragments representing 1,317 genes indicated that rather than silenced, 53 genes displayed elevated activity in the presence of multiple X chromosomes and many just escaped inactivation (Sudbrak R et al 2001 Hum Mol Genet 10:77). The expression is variable for about 10% of genes and 15% escape inactivation (Carrel L, Willard HF 2005 Nature [Lond] 434:400). Although differential inactivation is a common property of X-chromosomal genes, asynchronous replication has been observed between homologous autosomes too, in mice (Singh N et al 2003 Nature Genet 33:339). X chromosomal inactivation is somehow related to imprinting. A

deleted Xist allele in the maternal X chromosome does not affect the viability even of the adults but the Xist allele deleted from the paternal X chromosome prevents survival of the embryo after implantation.

In mouse the presence of two maternal X chromosomes (maternal disomy) is very detrimental to the development of the embryo. In contrast, in humans, maternal X disomy is not detrimental or even trisomy (XXX) or the Klinefelter syndrome (XXY), irrespective of the origin of the Xs, are of the same viability. Although X-chromosomal inactivation occurs in all mammals, the pattern of inactivation varies. The X chromosome of the mouse is acrocentric and it is not covered with Xist RNA while the human X is submetacentric and has Xist. Nevertheless, the mouse and human genes display great homology. The microarray technologies may provide further insight into the factors subjected or involved in inactivation/reactivation. ▶Lyon hypothesis, ▶dosage effect, ▶dosage compensation, ▶ectodermal dysplasia anhidrotic, ▶Wiskott-Aldrich syndrome, ▶Xg, ▶ichthyosis, ▶pseudoautosomal, ▶Barr body, ▶Xic, ▶Xist, ▶Tsix, ▶dpc, ▶imprinting, ▶methylation of DNA, ▶histones, ▶metalloproteinases, ▶tortoise shell, ▶calico; Heard E et al 1997 Annu Rev Genet 31:571; Avner P, Heard E 2001 Nature Rev Genet 2:59; Maxfield Boumil R, Lee JT 2001 Hum Mol Genet 10:2225; Mak W et al 2004 Science 303:666, illustration by courtesy Lyon MF 1963 Genet Res 4:93.

Lyophilization: ▶freeze drying

Lysate: When a cell is lysed (dissolved) its contents are released; the lysis of bacterial cells may produce bacteriophage particles as lysate. ▶lysogeny

Lysenkoism: T.D. Lysenko (1898–1976) infamously presided over one of the greatest scandals in cultural history. Beginning in the 1930s, and culminating with his almost complete victory in 1948, he destroyed genetics and most of biology in the erstwhile Soviet Union. His group of followers from non-scientific and often dubious backgrounds had an unfortunate influence on biology in the Soviet Union and other countries in her political interest sphere, almost totally destroying scientific study. The Lysenkoists rejected the Mendelian inheritance, cytogenetics, biochemical genetics and statistics as “capitalist fraud”. The movement traced its origin to Mitchurin, an uneducated railwayman, who successfully practiced empirical plant breeding and attempted to interpret his observations without being familiar with scientific principles and facts. The Lysenkoists denied the existence of genes, the role of “hard heredity”; rather, they claimed the inheritance of the phenotype and continuous change of heredity under

the influence of nutrition, temperature, day-length and other environmental conditions. This was a revival of the ancient myths of pangenesis, Lamarckism, inheritance of acquired characters, directed genetic change by agrotechnical methods (fertilizers, irrigation), grafting, vernalization (yarowisation), and blood transfusion. Although by themselves these ideas were appalling, the major problem was that Lysenkoism became a political doctrine of the state, imposed on and substituted for all scientific activities in biology, totally subjugating agriculture and making inroads even into medicine. Marx and Engels were supporters of Lamarckism in the hope that the future of the human race may be improved by these doctrines. The Soviet dictator Stalin embraced Lysenkoist ideas as they promised instant increases in agricultural productivity by the application of vernalization, summer culture of potatoes, species transformation, graft hybridization, supplementary pollination, etc., during a period of famines, caused by the senseless social experimentation of the Soviet bureaucracy. The promised results failed to materialize and agricultural productivity further declined, partly because of the application of Lysenkoism. The Lysenkoists then attributed these failures to sabotage. Therefore, after 1948, Stalin granted virtually unlimited power to Lysenko to purge the universities and research institutes from his and the "people's enemies." Thousands of scientists actually lost their lives either by execution or imprisonment. Genetics had enjoyed reasonably good support before 1948, but thereafter even world-renowned scientists of the Soviet Union were persecuted, forced underground or physically eliminated. Resurrection of genetics in Russia would come only after Stalin's death. ► **Lamarckism**, ► **Soviet genetics**, ► **Acquired characters**, ► **pangenesis**, ► **vernalization**, ► **directed mutation**, ► **hard heredity**; Medvedev ZA 1969 *Rise and Fall of TD Lysenko*, Columbia University Press, New York.

Lysergic Acid: A psychomimetic alkaloid-derivative. ► **ergot**, ► **psychomimetic**

Lysidine: A cytidine with a lysine residue qualifying it for recognition of the AUA codon by the tRNA (Ikeuchi Y et al 2005 *Mol Cell* 19235). ► **tRNA**, ► **aminoacylation**, ► **cytidine**, ► **genetic code**

Lysin: A complement-dependent lytic protein such as hemolysin, bacteriolysin and the sperm lysin, which creates a hole in the egg envelope for penetration. Mutation in lysin may lead to reproductive incompatibility and speciation. ► **complement**, ► **antibody**, ► **speciation**

Lysine Biosynthesis ($\text{NH}_2[\text{CH}_2]_4\text{CH}[\text{NH}_2]\text{COOH}$): Some fungi and algae synthesize the positively charged amino acid, lysine, from α -amino adipic

acid ($\text{HO}_2\text{CCH}[\text{NH}_2]\text{CH}_2\text{CH}_2\text{CH}_2\text{COOH}$). Bacteria, some fungi and higher plants make lysine from ($\text{HOOCCH}(\text{NH}_2)(\text{CH}_2)_3\text{CH}(\text{NH}_2)\text{COOH}$), diamino-pimelic acid. Aspartate semialdehyde is also a precursor of lysine. For mammals it is an essential amino acid and they rely on the diet to meet their needs. Some food or feed may have very low levels of this amino acid to be able to meet the requirements and it results in human malnutrition or low weight. Some mutant plants, e.g., high lysine maize may be used to avoid nutritional problems. The degradation of lysine may take place in a number of different ways. A common intermediate is α -ketoglutarate. Mono-, di-, and trimethylation of histones are important for epigenetic regulation of gene expression and protein function (Simon MD et al 2007 *Cell* 128:1003). ► **high-lysine corn**, ► **Kwashiorkor**, ► **lysine intolerance**, ► **lysine malabsorption**, ► **hyperlysinemia**, ► **histones**; Galili G 2002 *Annu Rev Plant Biol* 53:27.

Lysine Intolerance (lysinuric protein intolerance, LPI): A recessive human disorder (14q11.2) resulting in periodic vomiting, growth retardation, muscle hypotonia, hepatosplenomegaly (liver and spleen enlargement) and possibly coma based on a defect in the membrane transporter (γ^+ LAT-1, also named SLC [solute carrier]) of basic (cationic) amino acids. ► **lysine biosynthesis**, ► **dibasic aminoaciduria**

Lysine Malabsorption: Lysine malabsorption causes excessive amounts of lysine in the urine and low levels in the serum due to a recessive autosomal mutation. ► **lysine biosynthesis**

Lysinuria (lysinuric protein): ► **lysine intolerance**

Lysis: The disruption of the (bacterial) cell (before the release of a virus or plasmid from a cell) by spontaneous or any other means such as exposure to a lysozyme, by boiling or alkaline treatment, or the dissolution of eukaryotic cells or cellular organelles by a lysozyme or detergents (see Fig. L58). ► **lysis inhibition**, ► **rapid lysis**, in the Fig. L58: spread of the folded *E. coli* chromosome by courtesy of Dr. Ruth Kavenoff, Brian C Bowen 1977 *Stadler Symp.* 9:159.

Lysis From Without: When too many phages (>20) attack a single bacterial cell, the bacterium may disintegrate because of the perforations suffered.

Lysis Inhibition (LIN): In case of shortage of bacterial cells (that the phage senses by some means) it postpones lysis for several hours and produces the maximal possible number of virions from that cell (e.g., 400 copies of T4). Lysis is controlled by the *r* genes of the phage. ► **rapid lysis**

Lysogen: A bacterium with phage integrated into its genome. In such a state the replication of the phage DNA is under the control of the host and the phage's own replication system is repressed (stable lysogen).

L

Figure L58. Lysis

Rarely does the suppression of the replication of the phage fail after insertion (abortive lysogeny) and the prophage not replicated and lost by dilution during subsequent divisions of the host. ▶[lambda phage](#); McAdams HH, Shapiro L 1995 Science 269:649; Kihara A et al 2001 J Biol Chem 276:13695.

Lysogenic Bacterium: Lysogenic bacterium can harbor temperate phage in an integrated state in the chromosome; after induction, phage particles can be formed and released. ▶[prophage](#), ▶[lysis](#)

Lysophosphatidic Acid (acyl/oleoyl-sn-glycero-3-phosphate): Derived from L- α -phosphatidic acid dioleoyl by the action of phospholipase A. It stimulates smooth muscle contraction and may affect blood pressure, cell adhesion, mitogenesis, etc. ▶[Pyk-2](#), ▶[endophilin](#); Metastasis, Hla T et al 2001 Science 294:1875.

Lysopin: An octopine type opine. ▶[opines](#)

Lysosomal Storage Diseases: These involve defects in lysosomal hydrolase enzymes (~ 50) and accumulation of the products of these hydrolases which affect, in a variable manner, various organs. The cumulative prevalence may be 5×10^{-4} . Glycosphingolipid storage diseases are the Tay-Sachs disease and Gaucher's disease, and according to a mouse model *N*-butyldeoxynojirimycin may hinder the accumulation of the substrate for β -hexosaminidase A and may alleviate the symptoms of the Tay-Sachs disease. Enzyme replacement or modified autologous bone marrow transplantation have been attempted in some types of these diseases. Gene transfer into hematopoietic cells or into the central nervous system using herpes or adenovirus vectors is also being studied. Some mucopolysaccharidoses may be treated by implantation of neo-organs, tissues of skin fibroblasts, secreting β -glucuronidase or α -L-iduronidase. ▶[mucopolipidoses](#), ▶[mucopolysaccharidoses](#), ▶[lipidoses](#), ▶[neuroaminidase deficiency](#), ▶[glycoprotein storage disease](#), ▶[glutamyl ribose-5-phosphate glycoproteinosis](#), ▶[lipase deficiency](#), ▶[Tay-Sachs disease](#), ▶[Gaucher's disease](#), ▶[Farber's disease](#), ▶[Fabry's disease](#), ▶[Hurler's syndrome](#), ▶[Hunter syndrome](#), ▶[Sanfilippo syndrome](#), ▶[Maroteaux-Lamy syndrome](#), ▶[Hermansky-Pudlak syndrome](#),

Lysosomes: Lysosomes are cytoplasmic organelles (in eukaryotes) containing hydrolytic enzymes. The digestion is either by phagocytosis-type mechanism or by selective ingestion and lysis of molecules. The latter type process requires Mg-ATP or molecular chaperones (heat shock proteins 73 and 70). The receptor for the uptake may be a 96-kDa (Lamp2) lysosomal membrane protein. Clathrin also plays a role in targeting proteins to the lysosomes by its KFERQ amino acid sequence motif. Within the lysosomes, in an acidic environment, inter- and intrachain disulfide bonds of the proteins are destroyed by the enzyme thioredoxin. ►lysosomal storage diseases, ►lysozymes, ►LDL receptor, ►clathrin, ►thioredoxin, ►endocytosis, ►phagocytosis, ►proteasomes, ►Wolman disease, ►Griscelli syndrome, ►Chédiak-Higashi syndrome, ►Hermanski-Pudlak syndrome; de Duve C, Wattiaux R 1996 *Annu Rev Physiol* 28:435; Dell'Angelica EC, Payne GS 2001 *Cell* 106:395.

Lysozymes: Enzymes capable of digesting bacterial cell walls; they have an important role in phage infection and liberation. The protein has served as a model for the study of protein folding, enzyme catalysis and mechanism, x-ray crystallography, enzyme evolution, and protein engineering. Certain

mutations in the enzyme render the protein amyloidogenic. The protein has been synthesized by chemical procedures (Durek T et al 2007 *Proc Natl Acad Sci USA* 104:4846). ►lysosomes

Lyst: ►Chédiak-Higashi syndrome

LYT Oncogene: Associated with lymphoblastic leukemias and non-Hodgkin type lymphomas when the gene (in human chromosome 10q24) is translocated to chromosome 14q11 or 14q32. Genes neighboring the 14q32 area (TNG1, TNG2) activate the T cell leukemia genes TCL1 and TCL2 located at 14q23.1. The normal product of LYT is similar to that of NFκB (NF-κB) products that are transcription factors. ►NFκB, ►REL oncogene, ►Hodgkin's disease, ►leukemias

Lytic: Capable of initiating and performing lysis.

Lytic Cycle: The life cycle of the phage involving infection, growth (one-step-growth) and lysis of the host to liberate the infectious phage particles. ►Lambda phage, ►one-step growth

Lytic Infection: ►lysis of bacteria

λZap: Carries the *lacIq* and tetracycline resistance in an F' plasmid. This vector is very effective for cDNA cloning. Its cloning capacity is about 10 kb at multiple cloning sites. In the presence of helper M13 or f1 helper phages, the cloned DNA is excised and placed into a small plasmid to facilitate the restriction mapping or sequencing of the insert. It is also suitable for making RNA transcripts of either strand using T3 or T7 transcriptases. L►lambda phage, ►F' plasmid, ►filamentous phages, ►cloning site, ►helper phage, ►restriction enzyme, ►sequencing of DNA

Historical vignette

Erwin Chargaff, the discoverer of the Chargaff Rule in 1949, six years before the "breaking of the DNA code" made the following statement (Istituto Lombardo [Rend. Sc.] 89:101, 1955). It must be remembered that his Rule was one of the cornerstones for the construction of the Watson & Crick model of the Double Helix.

"I believe, however, that while the nucleic acids, owing to the enormous number of possible sequential isomers, could contain enough code- scripts to provide a universe with information, attempts to break the communications code of the cell are doomed to failure at the present very incomplete stage of our knowledge. Unless we are able to separate and to discriminate, we may find ourselves in the position of a man who taps all the wires of a telephone system simultaneously. It is moreover, my impression that the present search for templates, in its extreme mechanomorphism, may well look childish in the future and that it may be wrong to consider the mechanisms through which inheritable characteristics are transmitted or those through which the cell repeats itself as proceeding in one direction only."

M

M: Abbreviation for mitosis or in statistics for the mean.

►mitosis, ►mean

M9 Bacterial Minimal Medium: 5 concentrated salt solution g/L H₂O, Na₂HPO₄ 7 H₂O 64, KH₂PO₄ 15, NaCl 2.5, NH₄Cl 5 → 200 µL, 1M MgSO₄ 2 mL, glucose 4 g, fill up to 1 L after any supplement (e.g., amino acids) added.

M Component: Same as paraprotein.

M Cytotype: ►hybrid dysgenesis

M13 Phage: ►bacteriophages, ►DNA sequencing

M Phase: Part of the cell cycle when the structure, movement and separation of chromosomes or chromatids are visible and the nuclear divisions are completed. ►mitosis and ►meiosis

M Phase Histone-1 Kinase: ►growth-associated kinase

M Phase Promoting Factor (MPF): Same as maturation promoting factor.

M RNA: ►Cowpea mosaic virus (CPMV)

M Virus: ►killer strains

Ma (*mille mille annus*): A million years. ►My

MAb: Monoclonal antibody.

Mab: Mouse antibody.

MAC: Mammalian artificial chromosome. ►HAC, ►HAEC, ►YAC, ►BAC, ►PAC, ►SATAC; Grimes B, Cooke H 1998 Hum Mol Genet 7:1635.

MAC-1: The oligonucleotide-binding heparin-like integrin on the surface of neutrophils, macrophages and killer cells (NK). ►integrin, ►heparin, ►killer cell, ►blood

Macaca: Rhesus Old World monkeys. ►cynomolgus, ►Rhesus, ►Cercopithecidae

Macadamia Nut (*Macadamia* spp): A delicious nut, $2n = 2x = 28$.

Macaloid: A clay colloid capable of adsorbing ribonuclease during disruption of cells and can be centrifugally removed from the RNA preparation after extraction by phenol. ►RNA extraction

Macaroni Wheat (hard wheat): *Triticum durum* ($2n = 4x = 28$) varieties containing the AB genome and taxonomically classified as a subgroup of *T. turgidum* (see Fig. M1). The endosperm of the commercially used varieties has more β -carotenes and therefore, the

milled products show yellowish color, desirable for pastas. It is milled to a grainier product (semolina) that favors cooking quality. The durum wheats have higher protein and mineral content than the soft wheats. The turgidum wheats, except the durums, are not used for food. ►Triticum

Figure M1. Macaroni wheat (*Triticum durum*)

Macrozyme: A pectinase enzyme of fungal origin; it is used for the preparation of plant protoplasts in connection with a cellulase. ►cellulase, ►protoplast

MACH (caspase 8): ►caspases

Machado-Joseph Syndrome (Azorean neurologic disease, spinocerebellar ataxia Type 3, MJD): It is a 14q32.1 chromosome dominant defect of the central nervous system involving ataxia, and other anomalies of motor control. In the gene locus, abnormally increased number of CAG repeats (from 13–36 in normal→61–84 in disease) occurs. If the long CAG repeats are translated into polyglutamine, cell death may result. The neurodegeneration may be suppressed by the chaperone HSP70. ►ataxia, ►muscular atrophy, ►fragile sites, ►trinucleotide repeats, ►spinocerebellar ataxia, ►RNAi, ►Josephin domain

Machine, Biological: A set of interacting components performing functional specialized role. ►network

Machine Learning: The study of computer algorithms in the interest of improving the study of scientific data. A machine can learn from experience or extract knowledge from a database. ►support vector machine; Mjolsness E, DeCoste D 2001 Science 293:2051.

Machine Reading: A new form of computer, searching the scientific literature is under development. Its eventual use, if all publishers consent and either the user or the owner(s) of the publications consent it may revolutionize data mining. It may link various concepts across the field of interest, e.g., disease and molecule(s) in an extremely efficient way. See for example: http://arrowsmith.psych.uic.edu/arrowsmith_uiuc/index.html.

Macroarray Analysis: Mutations of unknown function are grown in the presence of compounds that make them sensitive if they are defective, e.g., cell wall-binding calcofluor dyes (fluorescent brightener 28/Tinopal) detects a group of yeast mutations defective in cell wall biogenesis. Mutations in several different gene loci involved in microtubule functions

are sensitive to benomyl/benlate ($C_{14}H_{18}N_4O_3$, a fungicide and ascaricide). Genetic defects in sugar utilization may not grow on the non-fermentable glycerol if the mutation affected a certain domain of the protein product. Thus, this type of analysis can find NORFs involved in certain pathways. ▶genomics, ▶NORF, ▶microarray hybridization, ▶synexpression; <http://strc.herts.ac.uk/bio/BioArray/doc/BioArray.htm>.

Macrocephaly: A common feature of several mental retardations; it is classified as such when the circumference of the head of an individual exceeds by more than 2 standard deviations the mean of the population. ▶microcephaly

Macroconidium: A large multinucleate conidium (see Fig. M2). ▶conidia, ▶microconidia, ▶fungal life cycle

Figure M2. Macroconidium

M

Macrochromatin: ▶lyonization

Macrocycles: These are cyclic macromolecules or a portion of macromolecules or low-molecular weight synthetic compounds. A DNA library can be translated into small macrocycles. These can be targeted to proteins and subjected to selection and used for probing biological functions (Gartner ZJ et al 2004 Science 305:1601).

Macroencapsulation: ▶microencapsulation

Macroevolution: A major genomic alteration, which produced the taxonomic categories above the species level. ▶evolution, ▶microevolution

Macrogametophyte: A megaspore. ▶gametogenesis in plants

Macroglobulinemia (Waldenström syndrome): HLA-linked immunodeficiency resulting in increase in IgM in the blood, thrombosis, skin, nose and gastrointestinal bleeding. ▶immunodeficiency, ▶immunoglobulins, ▶multiple myeloma

Macroglossia: An abnormally large tongue; occurs in Down syndrome, Beckwith-Wiedemann syndrome and other hereditary disorders.

Macrolesion: Visible alterations in the chromosomes in genetic toxicology. ▶Gene-Tox

Macrolide: Type of antibiotic (including more than one keto and hydroxyl groups such as erythromycin, troleandomycin) associated with glycoses. *Streptomyces* bacteria produce these compounds that inhibit the 70S ribosomes by binding to the large (50S) subunit and interfering with peptidyl transferase. ▶antibiotics, ▶maytansinoids, ▶glycoses, ▶*Streptomyces*, ▶protein synthesis, ▶ribosome, ▶hysteresis; Retsema J, Fu W 2001 Int J Antimicrob Agents 18 Suppl 1:3; Berisio R et al 2003 Nature Struct Biol 10:366.

Macromere: A large blastomere. ▶blastomeres

Macromelic Dwarfism (Desbuquois syndrome): A skeletal and digital anomaly.

Macromolecule: Molecules with molecular weight of several thousands to several millions such as DNA, RNA, protein and other polymers; macromolecular structure database: <http://www.ebi.ac.uk/msd>.

Macromutation: A genetic alteration involving large, discrete phenotypic change.

Macronucleus: A larger type of polyploid nucleus in Protozoa. While inheritance is mediated through the small micronucleus, the macronucleus is directing metabolic functions by being transcriptionally active and the latter is responsible for the phenotype of the cells. After the internally eliminated sequences (IES) are removed from the micronuclear DNA, the leftover tracts are joined into macronuclear-destined sequences (MDS) to form the macronucleus. The macronuclear genome is derived at sexual reorganization during conjugation. This involves various chromosomal rearrangements. Also during conjugation, the germline sequences are transcribed to produce double-stranded RNA, which can guide specific DNA deletions in the macronuclei. This mechanism—resembling RNAi—provides a means for elimination of transposons and other invaders (Yao M-C et al 2003 Science 300:1581; Yao M-C, Chao J-L 2005 Annu Rev Genet 39:537). Macronuclear differentiation includes site-specific fragmentation of the micronuclear chromosomes. A 15-bp site that is required for fragmentation marks each fragmentation site. The two ends of the fragments form telomeres and thus become *autonomously replicating pieces* (ARP). Although normally inheritance is mediated by the micronucleus or the mitochondria, in some instance, macronuclear inheritance is detected. In this case, apparently the old macronucleus determines some rearrangements (deletions) in the new macronucleus. The participation of a short scanning RNA (sRNA) has been suggested. The macronucleus contains about 45 copies of the ~300 subchromosomal fragments except the rDNA, which is amplified by ca. 10,000 times. The

macronucleus divides by fission rather than by mitosis yet recombination between and within genes occurs. In the absence of recombination, groups of genes may stay together and this phenomenon is called *coassortment*. The genes of these polyploid macronuclei may sort out to pure form of the initial heterozygous state by a process of *phenotypic assortment*. On the basis of the assortments the genes may be mapped genetically. The macronuclei are formed by the fusion of two diploid micronuclei of the zygotes (see Fig. M3). ▶ *Paramecium*, ▶ *Tetrahymena*, ▶ chromosome diminution, ▶ protozoa, ▶ IES, ▶ RNAi; Katz LA 2001 Int J Syst Evol Microbiol 51(pt4): 1587.

Figure M3. Paramecium

Macronutrient: Required in relatively large quantities by cells.

Macroorchidism: A condition of larger than normal testes. ▶ *fragile X*

Macropexophagy: The reduction of the number of peroxisomes in yeast grown on methanol after exposure to excessive amounts of glucose or ethanol. ▶ *micropexophagy*, ▶ *pexophagy*

Macrophage (Mφ): Phagocytic cell of mammals with accessory role in immunity. Macrophage cells are produced by the bone marrow stem cells as monocytes, which enter the blood stream, and within two days of circulation they enter the various tissues of the body and develop into macrophages. The macrophages may differ in shape but generally, they have single large round or indented nuclei, extended Golgi apparatus, lysosomes and vacuoles for the ample storage of digestive enzymes. The cell membrane is forming microvilli of various sizes, suited for phagocytosis (engulfing particles) and pinocytosis (uptake of fluid droplets) and thus are important as part of the cellular defense mechanism against foreign antigens, including even tumor antigens. The macrophages have a wide array of receptors, including the Fc, complement, carbohydrate, chemotactic peptide and extracellular matrix receptors. Some macrophages phagocytize apoptotic cells (see Fig. M4). Tumor necrosis factor (TNFα) moved from endosomes to the surface of the cells by VAMP facilitates its function in immunity

(Murray RZ et al 2005 Science 310:1492). Macrophages can mediate angiogenesis, cell migration and metastasis of cancer. Because they are genetically quite stable, they may be good targets of therapeutic intervention in some cancers (Condeelis J, Pollards JW 2006 Cell 124:263). ▶ *granulocytes*, ▶ *immune system*, ▶ *antibody*, ▶ *apoptosis*, ▶ *phagocytosis*, ▶ *TNF*, ▶ *VAMP*, ▶ *angiogenesis*, ▶ *metastasis*

Figure M4. Macrophage cell ingesting bacteria.

Macrophage Activity Factor: MAF is a lymphokine, identical to IFN-gamma. ▶ *lymphokine*, ▶ *interferon*

Macrophage Colony Stimulating Factor (M-CSF, 5q33.2-q333): M-CSF's receptor is the KIT oncogene. The receptor MCSFR is a protein tyrosine kinase. It promotes B cell proliferation with the assistance of IL-7. ▶ *FMS*, ▶ *KIT oncogene*, ▶ *colony stimulating factor*, ▶ *RAS*, ▶ *signal transduction*, ▶ *GM-CSF*, ▶ *G-CSF*, ▶ *IL-7*, ▶ *B cell*, ▶ *osteoclast*; ▶ *cherubism*, Csar XF et al 2001 J Biol Chem 276:26211.

Macrophage-Stimulating Protein (MSP): MSP is the 80-kDa serum protein stimulating responsiveness to chemoattractants in mice, that induces ingestion of complement-coated erythrocytes and inhibits nitric oxide synthase in endotoxin- or cytokine-stimulated macrophages. MSP is structurally homologous to hepatocyte growth factor, scatter factor (HGF-SF) but their targets are different. MSP has been located to human chromosome 3p21, a site frequently deleted in lung and renal carcinomas. ▶ *HGF-SF*, ▶ *Met*, ▶ *Ron*, ▶ *macrophage*, ▶ *scatter factor*; Stella MC et al 2001 Mol Biol Cell 12:1341.

Macrothrombocytopathy: ▶ *thrombocytopenia*, ▶ *giant platelet syndrome*

Macrospore: ▶ *megaspore*

Macula: A spot or thicker area, particularly on the retina, often colored. The macula of the eye contains photoreceptor cone cells, critical for color and other aspects of vision. ▶ *retina*, ▶ *choroidoretinal degeneration*, ▶ *macular degeneration*, ▶ *macular dystrophy*, ▶ *foveal dystrophy*

Macular Corneal Dystrophy (MCD, 16q22): MCD involves progressive recessive opacity of the cornea. Two types may be distinguished on the bases of absence (MCDI) and presence (MCDII) of keratan sulphate in the serum. A third type (CHST6) has

a defect involving corneal N-acetylglucosamine-6-sulphotransferase, which has overlapping mutations within the two other types. ► **Stargardt disease**, ► **hypotrichosis**

Macular Degeneration: Dominant-acting 6q25 deletion causing degeneration of the vitelline layer of the eye. The dominant 2p16 located disease Malattia Leventinese and Doyme honeycomb retinal dystrophy are similar, to some extent, to macular degeneration (see Fig. M5) and show drusen (bright speckles on the retina) due to mutation in the epidermal growth factor (EGF)—containing fibrillin-like extracellular matrix protein 1 (EFEMP1).

The Stargardt like STGD3 locus is in human chromosome 6q14. This gene is responsible for ELOVAL4 (elongation of very long chain fatty acid) and autosomal dominant macular dystrophy (see Fig. M6). These diseases manifest with some variations in expression and onset. Age-related macular degeneration (ARMD) causing yellow deposits (drusen) in the outer layer of the retinal epithelium is a very common cause of blindness in the West and it is controlled by several independent as well as by cooperative loci (Majewski J et al 2003 Am J Hum Genet 73:540). One major ARMD locus is at 15q21 (Iyengar SK et al 2004 Am J Hum Genet 74:20). Single amino acid substitution at site 402 (tyrosine→histidine) of the complement H gene accounts for the increased risk factor of ARMD from 4.6 (heterozygotes) to 7.4 (homozygotes) in the families (Klein RJ et al 2005 Science 308:385; Edwards AO et al 2005 Science 308:421). Age-related macular degeneration risk loci were confirmed in complement factor H (*CFH*, 1q32), and functionally related genes in chromosome 10q26.13 (Loc387715) and in genes C2 and BF in chromosome 6q21.3 (Maller J et al 2006 Nature Genet 38:1055; Li M et al Nature Genet 38:1049). Deletion of *CFHR1* and *CFHR3* is associated with lower risk of age-related macular degeneration (Hughes AE et al 2006 Nature Genet 38:1173; see corrigendum in Nature

Genet. 39:567). Polymorphism of the HTRA1 promoter (10q26) greatly increases the risk of developing ARMD (DeWan A et al 2006 Science 314:989).

Nornicotine, a metabolic product of cigarette smoke catalyzes retinal isomerization and is a promoting factor of ARMD (Brognan AP et al 2005 Proc Natl Acad Sci USA 102:10433). Oxidative stress appears to play a role in age-related macular degeneration and *Sod1*^{-/-} mouse appears to be workable model for studies (Imamura Y et al 2006 Proc Natl Acad Sci USA 103:11282). The ApoE E4 (apolipoprotein) allele increases susceptibility to ARMD as well as to Alzheimer disease (Malek G et al 2005 Proc Natl Acad Sci USA 102:11900).

Although several approaches are being suggested to control ARMD, only laser irradiation has limited success to curtail the choroidal neovascularization, the underlying cause of the visual impairment of wet macular degeneration. The newly formed blood vessels leak fluid and blood under the retina, form scar tissues and gradually destroy vision. One potential cure involves injecting antibodies against vascular endothelial growth factor A (VEGF-A) into the eye, a procedure under clinical trial. The ciliary margin of the retina contains active stem cells capable of self-renewal and provides possibilities for the cure of retinal disease (Coles B L K et al 2004 Proc Natl Acad Sci USA 101:15772). Currently RNAi technology is under clinical evaluation. The light-induced blindness, affecting the early microscopists such as August Weismann (1834–1914), has a molecular cause different from macular degeneration, and it is caused by degradation of rhodopsin (Lee S-J, Montell C 2004 Current Biol 14:2076). In June 2006, the US Federal Drug Administration approved the use of two new drugs for treatment. The (48 kDa) is a recombinant humanized monoclonal IgG1 kappa isotype antibody fragment produced in an *E. coli* expression system. It is not glycosylated and is used for intraocular injection. Bevacizumab (149 kDa) is also a recombinant humanized monoclonal IgG1 antibody

Figure M5. Macular degeneration. Left to right: Normal eye, age-related dry macular degeneration, macular degeneration with hemorrhage and fluid leakage. (The photographs are the courtesy of Dr. Timothy Holecamp and Ms. Jackie Bowman)

Figure M6. Peripheral vision in wet macular degeneration

produced in a Chinese-hamster-ovary mammalian-cell expression system, is glycosylated and used for intravenous infusion. Both the antibody fragment and the full-length antibody bind to, and inhibit all the biologically active forms of vascular endothelial growth factor (VEGF) A and are derived from the same mouse monoclonal antibody. Both drugs are promising, require repeated administration and are expensive (Steinbrook R 2006 *New England J Med* 355:1409). ▶*macula*, ▶*eye diseases*, ▶*RNAi*, ▶*stem cells*, ▶*vascular endothelial growth factor*, ▶*angiogenesis*, ▶*Stargardt disease*, ▶*complement*, ▶*monoclonal antibody*, ▶*immunoglobulins*, see Fig. 166; Marx J 2006 *Science* 311:1704; ARMD: de Jong PTVM 2006 *N Engl J Med* 355:1474; review: Rattner A, Nathans J 2006 *Nature Rev Neurosci* 7:860; Stone EM 2007 *Annu Rev Med* 58:477.

Macular Dystrophy: Autosomal recessive (8q24) and X-linked forms with symptoms similar to macular degeneration. The 1.4 Mb vitelline macular dystrophy (VMD2) gene (human chromosome 11q11-q13.1) encodes a 585 amino acid protein (bestrophin), named after the other name of the condition, Best's disease (autosomal dominant at 11q13). Its prevalence in the USA is about 3×10^{-5} . ▶*macula*, ▶*eye diseases*, ▶*Stargardt disease*, ▶*retinal dystrophy*

MAD: Multiwavelength anomalous dispersion analysis is a physical method for the determination of crystal structure of molecules.

Mad (*Mothers against decapentaplegic*): *Drosophila* gene controlling several developmental events in the fly. Its human homolog is called SMAD1 (Sma in *Caenorhabditis*). SMAD is a TGF (transforming growth factor)/BPM (bone-morphogenetic protein) cytokine family-regulated transcription factor involving

serine/threonine kinase receptors. The Mad family of proteins can be found in a wide range of organisms and upon dimerization with MAX they function as transcriptional repressors. The repressor function is correlated with the recruitment of the Sin3 protein binding to the Sin3-Mad interaction domain (Mad-Sid). SMAD is also called hMAD; MADR is its receptor. Mad is a component of the N-CoR/Sin3/RPD complex mediates the repression of certain classes of genes. ▶*tumor growth factor*, ▶*cytokines*, ▶*dpp*, ▶*serine/threonine kinase*, ▶*MYC*, ▶*RPD*, ▶*SMAD*, ▶*Dpp*, ▶*histone deacetylase*, ▶*decapentaplegic*

mad (*many abnormal discs*; 3–78.6): A homozygous disc and cell autonomous lethal, affecting several morphogenetic functions in *Drosophila*.

MAD2, MAD1 (mitotic arrest deficient, MAD2L1, 4q27; MAD2L2, 1p36): These are anaphase-regulating proteins, interacting with estrogen receptor- β . These are essential for normal mitosis checkpoints and their defect may lead to chromosome instability, cancer and embryonic lethality. Mad1 and Mad2 regulate the bipolar orientation of the chromosomes of yeast (Lee MS, Spencer FA 2004 *Proc Natl Acad Sci USA* 101:10655). The kinetochore localization of MADs requires the expression of Hec1/Ndc80p. The human Hec is highly expressed in cancer. Mad2 interacts with the kinetochores (Vink M et al 2006 *Current Biol* 16:755). ▶*anaphase*, ▶*cell cycle*, ▶*spindle*, ▶*BUB*; Skoufias DA et al 2001 *Proc Natl Acad Sci USA* 98:4492; Martin-Lluesma S et al 2002 *Science* 297:2267.

MADM: ▶*Mosaic Analysis with Double Marker*

Mad/Max: Sequence-specific heterodimeric transcriptional repressors.

Mad Cow Disease: ▶*encephalopathy*

MADS Box: A conserved motif of 56 residues in a DNA-binding protein of transcription factors involved in the regulation of *MCM1* (yeast mating type), *AG* (agamous homeotic gene and a root morphogenesis gene of *Arabidopsis*) *ARG80* (arginine regulator in yeast), *DEF A* (deficient-flower) mutation of *Antirrhinum* and SRF (serum response factor in mammals) regulating the expression of the c-fos protooncogene. The MADS box has amino terminal sequence specificity and carboxyl dimerization domains. In addition, the SRF recruits accessory proteins such as ELK1, SAP-1 and MCM1 and relies on MAT α 1 and MAT α 2, STE12 and SFF. MADS box genes control vernalization responses in cereals. (See separate entries, ▶*mating type determination in yeast*, ▶*vernalization*, ▶*MEF*; Jack T 2001 *Plant Mol Biol* 46:515).

Madumnal Allele: Derived from the female. ► [Padumnal allele](#)

MAF (macrophage activity factor): A lymphokine, an oncogene and a regulator of NF-E2 transcription factor. Heterodimers of Maf protooncogene family members promote the association with and the expression of NF-E2, whereas the homodimers are inhibitors of it. ► [macrophage](#), ► [lymphokine](#) 4, ► [oncogenes](#), ► [NF-E2](#), ► [homodimer](#), transcription factors; Swamy N et al 2001 J Cell Biochem 81:535.

MAF: Minor allele frequency.

MAFA (12p12–13): Inhibitory immune receptors on myeloid, mast and natural killer cells.

MAFFT-5: ► [CLUSTAL W](#), ► [interalign](#)

Magainin: ► [antimicrobial peptides](#)

MAGE: The melanoma antigens encoded by several genes and expressed in different tumors. In normal tissue, MAGE is limited to the testes and wound healing. In normal tissues, the MART-1/Melan-A differentiation antigen represents the melanoma lineage. The immunogenic epitopes for MAGE-1 are EADPTGHSY and SAYGEPRKL and for MAGE-3: EVDPIGHLV, FLYGPRALV, MEVDPIGHLV. Each has different HLA specificity. The MART-1 peptide epitopes are: AAGIGILTV, ILTVILGVL, and GIGILTVL. ► [antigen](#), ► [melanoma](#), ► [tumor antigen](#), ► [amino acid symbols in protein sequences](#), ► [Cancer-testis antigen](#); Otte M et al 2001 Cancer Res 61:6682.

MAGE (microarray and gene expression): ► [microarray hybridization](#); <http://www.mged.org/Workgroups/MAGE/mage.html>.

MAGI-2 (membrane-associated guanylate kinase inverted-2): A scaffold protein enhancer of PTEN. ► [PTEN](#); Vazquez F et al 2001 J Biol Chem 276:48627; Wu X et al 2000 Proc Natl Acad Sci USA 97:4233.

Magic Bullet: A specific monoclonal antibody is supposed to recognize only one type of cell surface antigen (e.g., one on a cancer cell) or growth factor receptors or differentiation antigens, and carries either the *Pseudomonas* exotoxin, or the diphtheria toxin, or ricin or maytansinoids (an extract of tropical shrubs or trees) or a radioactive element (such as ^{90}Y) capable of selectively unloading these harmful agents at the target cell and thus killing the cancer cell without much harm to any other cell. One such approach is to develop a special organ-homing peptide motif and combined with pro-apoptotic peptide domain. The homing peptide allows internalization only into the tumor cells where it unloads and disrupts the mitochondrial membranes and causes apoptosis (Ellerby HM et al 1999 Nature

Med 5:1032). Some of these new drugs (Rituximab) carry an anti-CD20 monoclonal antibody and radio-nuclides are effective against B-cell non-Hodgkin lymphoma (Milenic DE et al 2004 Nature Rev Drug Discov 3:488). CD22 and CD33 proteins can be effectively targeted by monoclonal antibodies in lymphomas with the associated CalichDMH (*N*-acetyl- γ -chaliceamicin dimethyl hydrazid), which is a potent DNA-binding antibiotic (DiJoseph JF et al 2004 Blood 103:1807). There may be some problems with monoclonal antibodies because the same tumor tissue may express different antigens (Scanlan MJ et al 2002 Immunol Revs 188:22). ► [ADEPT](#), ► [vascular targeting](#), ► [hybridoma](#), ► [monoclonal antibody](#), ► [receptor](#), ► [antigen](#), ► [diphtheria toxin](#), ► [ricin](#), ► [immunotoxin](#), ► [maytansinoid](#), ► [isotopes](#), ► [CD20](#), ► [CD22](#), ► [CD33](#); Frankel AE et al 2000 Clinical Cancer Rev 6:326.

Magic Number: The 64 triplet (4^3) combinations of the four nucleotides specify the 20 natural amino acids in all organisms. (See Gamov G, Yčas M 1955 Proc Natl Acad Sci USA 41:1011).

Magic Spots: These are pppGpp and ppGpp nucleotides that serve as effectors of the stringent control. RelA has apparently two catalytic sites, one for the synthesis of (p)ppGpp and another for hydrolysis. (p)ppGpp controls the elongation of DNA replication in response to the nutritional status of the cell (Wang JD et al 2007 Cell 128:865). ► [stringent control](#), ► [Rel oncogene](#); Schattenkerk C et al 1985 Nucleic Acids Res 13:3635.

Magnaporthe grisea: Rice blast pathogenic fungus with sequenced genome of 37,878,070 bp and with predicted 8,868 protein coding sequences in 7 chromosomes (See Rice, Dean RA et al 2005 Nature [Lond] 434:980). For efficient initiation of infection of rice, the formation of an appressorium, the conidial cells must die (Veneault-Fourray C et al 2006 Science 312:580). Insertion mutagenesis using *Agrobacterium* vector revealed 202 new pathogenicity loci in the fungus (Jeon J et al 2007 Nature Genet 39:561). ► [rice](#), ► [appressorium](#)

Magnesium Transport: The level of Mg^{2+} is important for many cellular processes such as ATP-dependent reactions and stabilization of membranes and ribosomes. A two-component system acting at the 5'-untranslated sequences regulates magnesium transporter (MgtA) protein synthesis. In *Salmonella* in low- Mg^{2+} environment, the PhoQ senses magnesium and promotes phosphorylation of the DNA-binding PhoP of the two-component regulatory system. Phosphorylated PhoP binds to the single stem-loop structure in the promoter of *MgtA* and

stimulates Mg^{2+} increase into the cytoplasm. When the level of Mg^{2+} reaches a higher level a two-loop structure forms in the 5'UTR and shuts off the transcription of the transporter (Cromie MJ et al 2006 Cell 125:71). ►two-component system

Magnetic Relaxation Switches: The nanometer-size colloidal metal particles may be coupled to affinity ligands and used as chemical sensors. Highly uniform magnetic nanoparticles can be covalently and stoichiometrically attached to oligonucleotides, nucleic acids, peptides, proteins, receptor ligands and antibodies. These nanomagnetic probes can be assembled also into larger units. These superparamagnetic scale particles can efficiently dephase the spins of the surrounding water protons and enhance spin-spin relaxation times. This technology can thus detect at miniaturized scale DNA–DNA, Protein–Protein, Protein–Small Ligand and enzyme reactions. Thus, e.g., non-sense DNA sequences, green fluorescent mRNA can be identified even in cell lysates. (See Perez JM et al 2002 Nature Biotechnol. 20:816).

Magnetic Resonance: ►nuclear magnetic resonance spectroscopy

Magnetic Targeting: Magnetic particles (ferrofluids) bound to mitoxanthrone (a cytostatic anthraquinone derivative) when injected into arteries can be concentrated in an external magnetic field aimed at a tumor (e.g., squamous cell carcinoma) can effectively cause remission without toxicity (Alexious C et al 2000 Cancer Res 60:6641). Similar procedure using superparamagnetic nanoparticles permit the tracking of progenitor cells (Lewin M et al 2000 Nature Biotechnol 18:410) or interaction of biomolecules within cells (Won J et al 2005 Science 309:121). ►magnetic relaxation switches

Magnetoreception: The response of organisms to the magnetic field of the Earth for behavior and orientation.

Magnetosome: Intracellular organelles in microbes that contain mineral crystals within a lipid membrane (see Fig. M7). The aquatic magnetotactic bacteria can follow the magnetic field lines of the earth. The magnetosomes may appear in rows. (See Bazylinski DA, Frankel RB 2004 Nature Rev Microbiol 2:217; Komelli A 2007 Annu Rev Biochem 76:351).

Figure M7. Magnetosome

Magnification: Increase in the units of ribosomal genes, hypothesized to occur by extra rounds of limited replication or unequal sister-chromatid exchange. At the *bobbed* (*bb*, 1–66.0) locus present in both sex-chromosomes of *Drosophila* in about 225 copies organized as large tandem arrays, separated by non-transcribed spacers. The copy numbers of *bb* in wild population Y-chromosomes may vary 6-fold. ►ribosomes, ►microscopy

MAGUKs (membrane-associated guanylate kinases): Mediate nuclear translocation and transcription. Membrane-associated guanylate kinases (PSD post-synaptic density-MAGUKs) mediate synaptic targeting, with remarkable functional redundancy within this protein family. PSD-95 and PSD-93 independently mediate AMPA-Receptor targeting at mature synapses. The loss of either PSD-95 or PSD-93, silences largely nonoverlapping populations of excitatory synapses. In adult PSD-95 and PSD-93 double knockout animals, SAP-102 (synaptic protein) is upregulated and compensates for the loss of synaptic AMPA-Rs (Elias GM et al 2006 Neuron 52:307). ►zona occludens, ►ELL, ►AMPA; McMahon L et al 2001 J Cell Sci 114 (pt 12):2265.

Maintenance Methylase: Keeps up methylation through cell divisions. ►methylation of DNA

Maize (*Zea mays*): It belongs to the family of *Gramineae* (grasses) and the tribe *Maydeae* along with teosinte (*Euchlena mexicana*) and the genus *Tripsacum* (with a large number of species). The male inflorescence of maize is more similar to that of teosinte than the female inflorescence. The ear or maize carries generally 8 to 24 rows of kernels whereas teosinte has only two rows. The teosinte ear is fragile the maize ear is not. The seed as is commonly named is really a karyopse (caryopse), a single-seed fruit (kernel). The basic chromosome number $x = 10$. *Tripsacum* resembles more some members of the *Andropogonaceae* family than to these two closer relatives and its basic chromosome number $x = 18$. Teosinte can be crossed readily with maize and the offspring is fertile whereas *Tripsacum* is more or less strongly isolated sexually and their hybrids are not fully fertile. Teosinte genes display the same chromosomal and gene arrangements as maize in contrast to *Tripsacum* that is more dissimilar. The evolution of modern maize has been traced to teosinte (Jaenicke-Després V et al 2003 Science 302:1206). The seed of teosinte is covered by a tough glume, which does not make it suitable for human consumption. Mutation in a single gene (*teosinte glume architecture*, *tg1*, maize chromosome 4) rendered maize grains naked during evolution and valuable for domestication (Wang H et al 2005 Nature [Lond] 436:714). All three genera have evolved in the

Western Hemisphere. Maize is one of the most thoroughly studied plants in genetics. It is a monoecious species; under natural conditions, it is allogamous. Approximately 500 kernels may be fixed on the cob for easy Mendelian analysis for a good number of endosperm, pericarp and embryo and seedling characters. Mendelian genes have been identified at about 1000 loci and more than 500 have been mapped. RFLP maps are also available. The gene number in maize is estimated to be ~33,000 to 54,000 (Fu Y et al 2005 Proc Natl Acad Sci USA 102:12282). The characteristic pachytene chromosomes facilitate cytogenetic analyses. Several genes controlling meiosis have been identified. Cytogenetic studies with maize contributed significantly to the understanding of chromosomal rearrangements. Transposable genetic elements were first recognized in maize (see Fig. M8).

Figure M8. Segregation in a maize ear

Transformation is possible but requires either electroporation or the biolistic technique. The discovery and the commercial production of hybrid corn (heterosis) made an unprecedented increase in the food and feed supply. ►biological control, ►domestication, ►non-coding DNA, for detailed chromosomal map of 1736 loci see Davis GL et al 1999 Genetics 152: 1137; Doebley J 2001 Genetics 158:487; Liu K et al 2003 Genetics 165:2117; evolution of maize: Doebley J 2004 Annu Rev Genet 38:37; genetics and genomics: <http://www.maizegdb.org>; <http://maize.tigr.org>; molecular and functional diversity: <http://www.panzea.org>; maize database: <http://www.maizegdb.org>.

Majewski Syndrome: The autosomal recessive phenotype has many similarities with oral-facial-digital syndromes, particularly with the Mohr syndrome. It is distinguished from the latter on the basis of laryngeal (throat) anomalies and polysyndactyly of the feet. ►Oro-facial-digital syndromes, ►polydactily

Major Facilitator Superfamily (MFS): These are ubiquitous transporters (more than 1000 members) in all biological groups. They transport ions, sugars, amino acids, peptides, nucleosides, drugs, neurotransmitters, etc. Their mutations may result in various diseases (seizures, diabetes, etc), may be responsible for antibiotic resistance, cancer chemotherapy (controlling drug efflux). ►membrane transport; Huang Y et al 2003 Science 301:616.

Major Gene: Determines clear, qualitative phenotypic trait(s). ►minor gene

Major Groove: The DNA helix as it turns displays two grooves in a 3.46 nm pitch; the wider one (almost 2/3 of the pitch) is the major groove ↗ (see Fig. M9). ►DNA, ►hydrogen pairing, ►Watson and Crick model

Figure M9. Major Groove

Major Histocompatibility Complex (MHC in humans, H-2 in mice): Triggers the defense reactions of the cells against foreign proteins (invaders). Their existence was first recognized by incompatibilities of tissue grafts. The MHC molecules are transmembrane glycoproteins encoded by the HLA complex in humans and by H-2 in mouse. The class I molecules have three extracellular domains at the NH₂ end and the COOH terminus reaches into the cytosol. The extracellular domains are associated with β₂ microglobulin. The class II MHC molecules are formed from α and β chains without the microglobulin. The class I heavy chain and the β₂ microglobulin are translocated to the endoplasmic reticulum before their translation is completed and their assembly takes place there with the assistance of the chaperones, BiP (a heatshock protein) and calnexin (glycoprotein). The MHC I molecules then associate with TAP and is ready for picking up a foreign antigenic peptides. After a peptide is bound, the system is released and after passing through the Golgi where their attached carbohydrates may be modified, exocytosis moves them to the surface of the cell membrane and this provides a chance for the CD8⁺ T cells (CTL) to react to them. At this stage, the cells that recognize self-antigens are eliminated by apoptosis. The MHC molecules resemble immunoglobulins, and the class II molecules, especially the β chains are highly polymorphic (The HLA-DRB 1 locus has more than 100 alleles.). The MHC molecules bind foreign antigens and present them to the lymphocytes. The murine CD1 proteins bear similarities to the MHC molecules but they present to the T cells lipids and glycolipid

antigens. MHC Class I proteins accumulate the cut pieces of peptides from inside the cells whereas Class II MHC proteins are attached to the pieces of antigens from outside the cell. Before a Class II protein is loaded with an invader peptide, it carries a neutral (dummy) peptide called CLIP which is then replaced by foreign pieces regulated by acidic conditions in the presence of DA. The Class I molecules are expressed on practically all cells that T cells recognize. Class II molecules are found on CD4⁺ B cells and other antigen presenting cells. MHC class I peptides (CTL epitopes) stimulate the CD8⁺ cytotoxic T cells and the MHC class II peptides are recognized by the CD4⁺ T cells. The T_H cells destroy any cell that present the antigen with MHC II molecules. The helper T cells do not directly attack the invaders but stimulate the action of macrophages. The MHC genes rely on transactivation by CIITA (non-DNA-binding) and RFX5, NF-X, NF-Y and other DNA-binding transcription factor proteins. There is a great diversity among MHC molecules. Gene conversion may create variations in 10⁻⁴ range in sperms. The histocompatibility system of rabbits is called RLA, in rats RT1, in guinea pigs GPLA. MHC I homologs of herpesviruses may disarm natural killer T cells. ▶HLA, ▶Ii, ▶immune system, ▶blood cells, ▶T cells, ▶αβ T cells, ▶CTL, ▶microglobulin, ▶DA, ▶proteasome, ▶TAP, ▶antigen presenting cell, ▶antigen processing and presentation, ▶Bare lymphocyte syndrome, ▶apoptosis, ▶self-antigen, ▶RFX; Beck S, Trowsdale J 2000 Annu Rev Genomics Hum Genet 1:117; Horton R et al 2004 Nature Rev Genet 5:889; <http://www.meddb.info/index.php.en?cat=6&subcat=104>; DNA and clinical resources: <http://www.ncbi.nlm.nih.gov/mhc/MHC.cgi?cmd=init>.

Majority Class Spores: ▶polarized recombination

Mal de Maleda (MDM, 8q24.3): A rare, recessive keratoderma, redness on the face, brachydactyly and nail abnormalities. The basic defect is in a secreted Ly-6/uPAR domain related protein (defined by disulfide bonding pattern between 8 or 10 cysteine residues). ▶keratoma, ▶brachydactyly; Fischer J et al 2001 Hum Mol Genet 10:875.

Malaria: An infectious disease affecting 300–500 million people annually (Snow RW et al 2005 Nature [Lond] 434:214), and causing 1.5–2.7 million deaths among them. It is caused by one or another species of the *Plasmodium* protozoa (see Fig. M10). Transmission is mediated by *Anopheles* mosquito bites but transplacental infection or transfusion with contaminated blood may transmit it. The infection relies on a Duffy-like cysteine-rich module of the parasites that recognize host cell surface receptors. The crystal structure of this domain has been revealed

Figure M10. *Plasmodium* merozoites

(Kumar Singh S et al 2006 Nature [Lond] 439:741). This disease is prevalent in the subtropical and tropical areas of the world. The symptoms are chills, fever, sweating, anemia, etc. The attacks are recurring according to the major reproductive cycles of the parasite. Heterozygotes of sickle cell anemia are somewhat resistant to the disease and that explains the higher than expected frequency of this otherwise deleterious gene. *Plasmodium* degrades hemoglobin by two plasmalepsin proteases. Hemoglobin C may provide some protection by abnormal display of *P. falciparum* erythrocyte membrane protein 1 (PfEMP1) on the erythrocytes and by reducing their sequestration in the microvasculature (Fairhurst RM et al 2005 Nature [Lond] 435:1117). Two minor and one major quantitative trait loci have been identified in *Anopheles gambiae* that inhibit the development of *Plasmodium cynomolgi* B in the midgut of the mosquito. The human body defends itself by the cytotoxic T cells. The human immune response cannot prevent the infection because the malaria-infected erythrocytes attach and slow down the maturation of the antigen-presenting dendritic cells and thus fail to activate properly the T lymphocytes. In some populations HLA and other ligands may cooperatively down-regulate this immune response. During the development of the parasite, the surface antigens are altered providing immune evasion and chances of reinfection after a period of apparent curing. Some success was obtained by vaccination before the parasite reaches the blood infection stage. Viral vector-delivered multigenic DNA vaccines encoding different epitopes and applied before the parasite would reach the blood stage may overcome the problems caused by the antigenic variations. The PEMP1 protein is responsible for most of the antigenic variation in the parasite. More than 50 var genes encode this multimodular (DBL, CIDR) adhesion protein. Various vaccines are under development either to prevent the multiplication of the parasite (sterilizing immunity) or by anti-disease approach that would prevent the development of malaria-associated pathology of the brain or the placenta in the infected individuals. Antibodies can be generated against many different, known antigens of the parasite but because of mutation in single proteins

may eliminate lasting protection against single antigen. Transcriptome analysis indicates that about 197 proteins can potentially be targeted for vaccine development. The thrombospondin-related adhesive protein (TRAP) and the apical membrane antigen 1 (AMA-1) are expressed in the *Plasmodium falciparum* sporozoite surface microneme vehicles and later proteolytic cleavage generates soluble fragments. These microneme proteins are critical for the invasion of blood and hepatocytes. A subset of serine protease inhibitors can prevent proteolytic cleavage, essential for infection and are good targets for vaccine development (Silvie O et al 2004 J Biol Chem 279:9490; Waters A 2006 Cell 124:689). Application of attenuated sporozoite vaccines have been considered but were plagued by practical, technical difficulties.

One possible means of protection appears to immunize (rodents) by *uis3* deficient sporozoites. The *UIS3* gene (upregulated in infective sporozoites 3) is essential for the early liver-stage development and in its absence, the *Plasmodium berghei* will not establish the blood-stage infection (Mueller A-K et al 2005 Nature [Lond] 433:164). Transgenic mosquitos may fail to transmit the parasites (Ito J et al 2002 Nature [Lond] 417:452). First time gravid humans are more susceptible to malaria because the parasite attaches to the chondroitin sulfate A on the placenta. By subsequent pregnancies a partially protective anti-adhesion response develops. The size of the *Plasmodium falciparum* genome is ~30 Mb (~82% A = T) located in 14 chromosomes. It has two organelle genomes: the mitochondrial is 5.9-kb (tandemly repeated) and ~35-kb in the apicoplast, a plastid-like organelle. The technology of molecular biology greatly facilitates the identification of the biology of the protozoa and the development of more effective control measures. (Le Roch KG et al 2003 Science 301:1503). *P. falciparum*, the most fatal species is rapidly developing resistance to the drug chloroquine and to several newer drugs. More recently high hopes were placed in the protective effect by the old Chinese herbal plant extract artemisinin of *Artemisia* (see Fig. M11). Now even that treatment may result in the development of resistance in *Plasmodium falciparum* (Duffy PE, Sibley CH 2005 Lancet 366:1908). *Plasmodium* has 400 putative genes involved in targeting erythrocytes of which 225 encode virulence proteins and 160 apparently remodel host erythrocytes. Switching to positions conducive to transcription and heterochromatin remodeling regulate virulence genes (*var*), which control antigenic variation (Freitas-Junior LH et al 2005 Cell 121:25). These genes are potential targets of antimalarial drugs (Mart M et al 2004 Science 306:1930). New drugs (fosmidomycin) blocking the non-mevalonate pathway of isoprenoid biosynthesis in the apicoplast

appear promising alternatives. Oil-based suspension sprays containing *Beauveria bassiana* and *Metarhizium anisopliae* directed against both *Plasmodium* and *Anopheles* mosquitos was up to ~90% effective control of malaria transmission (Blanford S et al 2005 Science 308 1638; Sholte E-J et al 2005 Science 308:1641).

Figure M11. *Artemisia*

The cerebral form of malaria attacks the brain and causes mental disorders, hyperthermia and about half of the infections is lethal. Malaria may mitigate Hepatitis B viral infections.

P. falciparum is the major cause of lethal malaria in humans but in chimpanzees, only moderate parasitization and no severe infection occurs. *P. reichenowi* is very similar to *P. falciparum* but affects only chimpanzees and other apes but not humans. This remarkable difference is based on the lack of N-glycolylneuraminic acid on human erythrocytes in contrast to other primates. *P. reichenowi* erythrocyte-binding antigene-175 requires this sialic acid (Martin MJ et al 2005 Proc Natl Acad Sci USA 102:12819; note figures scale bars are correctly 100 μ m). ►hemoglobin, ►thrombospondin, ►microneme, ►sickle cell anemia, ►*Plasmodium*, ►merosome, ►CD36, ►QTL, ►glucose-6-phosphate dehydrogenase, ►cytotoxic T cell, ►HLA, ►immunization genetic, ►apicoplast, ►Oct-1, ►chloroquine, ►refractory genes, ►neuraminic acid, ►serpine, ►Duffy blood group; de Koning-Ward TF et al 2000 Annu Rev Microbiol 54:157; Kappe SHI et al 2001 Proc Natl Acad Sci USA 98:9895; Nature [Lond] 2002 Insight 415: 670–710; *Anopheles* genome: Science 298, 4 Oct. 2002; malaria issue: Nature [Lond] 430:925–944, 2004; <http://www.malaria.org>.

Malate Dehydrogenase: The product of the MDH1 (human chromosome 2p23) is cytosolic whereas the MDH2 enzyme (encoded in 7p13) is located in the mitochondria. ►Krebs-Szentgyörgyi cycle, ►mitochondria

Malattia Leventinese: ►macular degeneration

MALD (mapping by admixture linkage disequilibrium): The mapping on the basis of linkage disequilibrium in a population. Complex diseases, based on more than a single gene are difficult or impossible to map on the basis of conventional linkage. Association mapping is more effective but requires too much genotyping. The efforts can be reduced if neighboring markers of the haplotypes are considered. Unfortunately, even this approach requires 300,000 to 1,000,000 single nucleotide polymorphic markers (SNP) to be successful, and its cost is too high for single disease. When populations are mixed by gene flow (e.g., European, Asian and African ethnic groups), temporarily large haplotypes blocks form linkage disequilibrium. The association of these blocks (disequilibrium) can be statistically analyzed though the centuries and the association of disease with haplotypes markers can be inferred. Such a study requires 200–500 fewer markers than whole genome haplotype mapping. MALD is carried out in five steps. 1. A group of people (cohort) is selected from the admixed population that have high incidence of the disease. 2. Cases and controls are genotyped using markers of high frequency and informative for ancestry. 3. The patchwork of the ancestry is determined for individuals. 4. Chromosomal regions with elevated frequency of the ancestry markers and disease are identified. 5. The candidate genes are located then by the use of SNP-association. This procedure is best suited for diseases, which differ substantially in frequency between the ancestral groups. Environmental differences may confound and frustrate the analysis. It is necessary that the admixture would be higher than 10%. The range of admixture generally varies a great deal geographically. Continued introgression also influences the outcome. The required population size depends on the allele frequencies and extent of the

admixture. Genes displaying similar frequencies in the ancestral populations are not informative. It is also important that the target genes could be safely identified (few false positives). The analysis requires ethical considerations because of racial sensitivities. ▶ [linkage disequilibrium](#); Smith MW, O'Brian SJ 2005 Nature Rev Genet 6:623; Collins-Schramm HE et al 2002 Am J Hum Genet 70:737.

MALDI/TOF/MS: Matrix-assisted laser desorption ionization/time of flight/mass spectrometry can detect minute differences in masses of large DNA molecules ($\sim 2,000$ nucleotide) in \sim femtomole (10^{-15}) size samples. This technology is used for characterization and identification of proteins and protein fragments. It detects post-translational modifications and any alteration in protein mass during development and modulation of function.

For proteomics, generally tryptic peptide mixture is used. Trypsin cuts proteins at arginine and lysine residues and on that basis, unknown proteins may be identified on the basis of matches with known proteins in the databases. For post-translational modification of proteins, the tryptic peptides can be analyzed in two steps. First, the mass spectrum (MS) of the intact peptide fragments can be determined. Second, (MS/MS) peptide ions are fragmented in a gas phase to identify protein sequence and modifications. For these analyses MALDi or electrospray ionization (ESI) are used. By this “bottom-up” approach, the full spectrum of the fragmentation ladder generally cannot be obtained. Alternatively, the “top-down” approach can be used where intact protein ions are introduced into the gas phase of ESI and obtaining molecular mass of the proteins and protein ion fragmentation ladders (see Fig. M12). This latter process permits now fragmentation of

Figure M12. Diagram of the principle of MALDI/TOF/MS at left; MALDI/TOF/MS protein profile (for m/z see Mass Spectrum) Maldi/tof/ms protein profile (for m/z see Mass spectrum)

molecular masses up to 200 kDa (Chait BT 2006 Science 314:65; Han X et al 2006 Science 314:109).

The analytical procedure requires that the target molecules be co-precipitated with an excess matrix consisting of either α -cyano-4-hydroxycinnamic acid or dihydrobenzoic acid (DBH). The material is then dried on a metal surface and irradiated by a flanking nanosecond nitrogen laser at a wavelength of 337 nm to generate ionization. MALDI is used for relatively simple mixtures whereas ESI is integrated with liquids chromatography and is suitable for more complex mixtures. The sample is analyzed by a mass spectrometer (see Fig. M12). Some recent developments make these types of analyses very useful for biomedical applications (proteomics, pathology, tissue imaging, diagnostics, cancer monitoring, metabolomics, identification of biological agents, drug analysis, pharmaceutical process monitoring, in forensics and national security). ►DNA chips, ►proteomics, ►protein chips, ►electrophoresis, ►mass spectrometer, ►mass spectrum, ►fragmentation ladder, ►DESI, ►SIMS genomics, ►CID, ►SNIPS, ►quadrupole, ►electrospray MS, ►ESI, ►mole, ►PMF; Li L et al 2000 Trends Biotechnol 28:151; Mann M et al 2001 Annu Rev Biochem 70:437; Bennett KL et al 2002 J Mass Spectrom 37:179; Cooks RG et al 2006 Science 311:1566, <http://prowl.rockefeller.edu/>, OMSSA.

M

Male Contraceptive: The oldest form is a mechanical barrier to the sperm (condom) to prevent its penetration of the reproductive tract of the female. Primarily females practice physiological fertility control in animals and humans. Adjudin (1-[2,4-dichlorobenzyl]-1H-indazole-3-carbohydrazide) is capable of inducing germ cell loss from the Sertoli cell epithelium. Oral dose of Adjudin (50 mg per kg body weight for 29 d) resulted, however, in liver inflammation and muscle atrophy. If Adjudin is specifically targeted to the testis by conjugating it to a recombinant follicle-stimulating hormone mutant as its vector infertility was induced in adult rats when 0.5 μ g Adjudin per kg body weight was injected intraperitoneally with the same effectiveness as at the high oral dose (Mruk DD et al 2006 Nature Med 12:1323). There may eventually be a chance for human applications. ►contraceptive

Male-Driven Evolution (α): It is indicated by the higher rate of mutation in males than females. The extent of the ratio is not universally agreed upon. (See Makova KD, Li WH 2002 Nature [Lond] 416:624).

Male Gametocide: A chemical that destroys male gametes and thus may facilitate cross-pollination in plants or may serve as a human birth-control agent. ►crossing, ►birth control

Male Gametophyte: ►gametophyte

Male Recombination: It is normally absent in *Drosophila* (except when transposable elements are present; up to 1%) and in the heterogametic sex (females) of the silk worm. In case of the presence of a P element, most of the recombination is site-specific within a 4-kb tract near the element. Recombination then involves either adjacent duplication and deletion of a few to > 100-bp. Genetic markers can be mapped relative to known P element sites. Mitotic recombination may occur, however, even in the absence of the meiotic one. In maize and *Arabidopsis*, certain cases indicate reduced frequency of recombination in the megasporocytes compared to the microsporocytes. In rainbow trout the average female: male recombination ratio is 3.25:1 but shows significant variation according to chromosomal regions and families. Generally, in most species the recombination frequency in the heterogametic sex is slightly lower. ►recombination frequency, ►MR, ►hybrid dysgenesis, ►HEI, ►achiasmate; Meneely PM et al 2002 Genetics 162:1169; Hellig R et al 2003 Nature [Lond] 421:601.

Male-Specific Phage: It infects only those bacterial cells that carry a conjugative plasmid.

Male Sterility: Caused by various chromosomal aberrations, such as inversions, translocations, deficiencies, duplications, aneuploidy, polyploidy, etc., and by cytoplasmic factors. Generally in plants, male sterility is more common than female sterility because the pollen, the male gametophyte, has a more independent life phase than the megaspore and cannot rely well on support by sporophytic tissues. In plants, the male sterility may be caused by a mutation in the male gametophyte or it may be the result of the abnormal development of the anthers or other parts of the flower, e.g., failure to release the normally developed pollen. Common cause of male sterility is an alteration of the mitochondrial DNA, cytoplasmic male sterility (*cms*). Incompatibility between nuclear genes and certain cytoplasm as well as viral infection may also cause male sterility. Certain chemicals (mutagens), chromosome-breaking agents (maleic hydrazide) may have gametocidal effects. Male sterility may result in transgenic plants when a tapetum-specific promoter drives a ribonuclease gene within the anthers and thus destroy the pollen (see Fig. M13). The fertility can be restored if the sterile plants are employed as female in crossing with a male carrying the transgene *barstar* inhibiting the ribonuclease. Other self-destroying–restoring combinations have also been considered. A healthy human male ejaculates 25–40 million sperms each time, and if for any reason this number is reduced to 20,000 or below, male

infertility/sterility may result although only a single sperm functions in fertilization. Polymorphy for hybrid male sterility is a factor in speciation (Reed LK, Markow TA 2004 Proc Natl Acad Sci 101:9009).
 ▶cytoplasmic male sterility, ▶chromosomal defects, ▶gametocides, ▶KIT oncogene, ▶azoospermia, ▶oligospermia, ▶asthenospermia, ▶speciation, ▶hybrid sterility, ▶*msl*; Hackstein JHP et al 2000 Trends Genet 16:565.

Figure M13. The male sterile pollen does not stain and is shrunken

Malécot Equation: Employed for estimation of marker frequency probability in linkage disequilibrium in populations: $(1 - L)Me^{-\epsilon d} + L$, where L is an asymptote of the association for long distance and the intercept M represents association in the population founders, ϵ is a constant. ▶linkage disequilibrium; Lonjou C et al 2003 Proc Natl Acad Sci USA 100:6069.

Male-Stuffing: In some social insects the workers may force (and kill) males into empty cells in order to keep them from using the scarce food and thus making it available to the larvae. The relatedness among workers in single-mated queen colonies is 75% whereas to males it is only 25%. Thus, this behavior is a form of kin selection. ▶kin selection

Malformation: The abnormal formation of body parts.
 ▶dysplasia

Malignant Growth: A defect in the regulation of cell division that may lead to cancer and may cause the spreading of the abnormal cells. ▶metastasis, ▶cancer, ▶oncogenes, ▶cell cycle

Malondialdehyde (MDA): A mutagenic carbonyl compound, generated by lipid peroxidation. ▶adduct, ▶pyrimidopurinone, ▶lipid peroxidation

Malonic Aciduria (16q24): A recessive deficiency in malonyl-CoA decarboxylase and causes abnormally large amounts of malonic acid in the urine. It involves developmental retardation, constipation, abdominal pain and infantile death.

Malpighian Tubules: Excretory channels of arthropods emptying into the hindgut performing kidney-like function.

Malpractice: Improper practice due to negligence or misconduct or inadequate training or lack of adequate experience and causing physical, mental or financial harm in medicine or any other business activity.

Malsegregation: When the two homologous chromosomes are not recovered in 2:2 proportion at the end of meiosis. ▶segregation distorter, ▶meiotic drive, ▶nondisjunction

MALT (mucosa-associated lymphoid tissue lymphoma): It is most common in the gastrointestinal tract and in non-Hodgkin lymphoma. MALT is frequently associated with translocations t(1;14)p22;p32 and to the apoptotic signaling gene BCL10. MALT1 gene is involved in the activation of NF- κ (Talwalkar SS et al 2006 Mod Pathol 19:1402). ▶lymphomas, ▶Hodgkin disease, ▶BCL, ▶apoptosis, ▶fungal diseases

Malt: The specific activator of the bacterial maltose operon. ▶maltose

Malthusian Parameter: It assumes that the age distribution in a population remains constant from one generation to the next. In case the age-specific birth and death rates would continue without any hindrance, the population growth would ultimately reach that level, frequently denoted by r . ▶age-specific birth and death rate, ▶population growth; Fisher RA 1958 The Genetical Theory of Natural Selection. Dover, New York; Demetrius L 1975 Genetics 79:535.

Malthusian Theorem: Postulates that population growth exceeds the rate of food production and thus jeopardizes the survival of humans. This nineteenth century idea was contradicted by the fact that between 1961 and 1983 the available food calories per capita has increased from 2320 to 2660 (over 7% in two decades). Unfortunately, this growth is slowing down again, and from 1984 to 1990, the increase was only about 1%. For about 2,000 years, the global human population grew by an annual rate of about 0.04%. From 1965 to 1970, the rate increased to 2.1% and in 1995 it was about 1.6% per year. ▶human population growth; Black JA 1997 BMJ 315:1686; Lee RD 1987 Demography 24:443.

Maltose (glucopyranosyl glucose): A disaccharide. The Snf1 protein kinase controls the Mig1 transcriptional repressor of *SUC2* (sucrose), *GAL* (galactose) and *MAL* (maltose) genes. Induction of *MAL* requires transcriptional activator. Maltose utilization is controlled by several operons. A common activator of these is a 103-kDa activator MalT. Glucose and the global

repressor *Mlc* repress *MalT*. The maltose transporter system is an integral part of maltose utilization. A maltose transporter is essential for starch degradation and carbohydrate export from the site of photosynthesis (Niittylä T et al 2004 Science 303:87). ► [glucose effect](#), ► [catabolite repression](#), ► [Snf](#); Boos W, Böhm A 2000 Trend Genet 16:404.

Mammaprint: A government approved, high-cost 70-marker microarray test for the prediction of status and prospect of breast cancer at high accuracy (Glas AM et al 2006 BMC Genomics 7:278). (See information for physicians and patients: <http://www.agendia.com/us/>).

Mammary Tumor Virus of the Mouse (MTV): It causes an estrogen-stimulated adeno-carcinoma. The virus is transmitted through the milk. ► [glucocorticoid response element](#); Kang CJ, Peterson DO 2001 Biochem Biophys Res Commun 287:402.

Mammoth (*Mammothus primigenius*): The best known of these now extinct Elephantine species of the Pleistocene era in Siberia. These animals were somewhat comparable to the Asian elephants (*Elephas maximus*) in size but they were well adapted to the harsh climate by having long wool and thick layers of fat under skin all over the body. The nuclear DNA is not well preserved even in the arid caves or permafrost region. The nuclear DNA fragments (average length 84 bp) analyzed matched (to 95% identity) the available sequences of the African elephant (*Loxodonta Africana*) in 30% but only in 0.4% to human DNA. The estimated divergence between the two animals is 5–6 million years. Better specimens of DNA (~89 bp in average length) could be prepared from bone mitochondria and could be

amplified by PCR and the sequences matched in 95.93% to that of the African elephant (Poinar HN et al 2006 Science 311:392). By multiplex amplification, the entire mitochondrial DNA has been reconstructed and mapped (Krause J et al 2006 Nature [Lond] 439:724). The mastodon (*Mammut americanum*) is a North American relative (diverged 24–28 million years ago [mya] from the Elephantine lineage); its mitochondrial DNA has been sequenced from fossil Alaskan tooth. The ancestors of African elephants diverged from the lineage leading to mammoths and Asian elephants approximately 7.6 mya, and mammoths (see Fig. M14) and Asian elephants diverged approximately 6.7 mya. (Rohland N et al 2007 PLoS Biol 5(8):e207). ► [ancient DNA](#), ► [elephants](#), ► [ancient organisms](#); Rogaev EI et al 2006 PLoS Biol 4(3):e73.

MANET: The evolution of protein structure in metabolic networks: Kim HS et al 2006 BMC Bioinformatics 7:351, <http://www.manet.uiuc.edu/>.

Mango (*Mangifera*): A tropical fruit tree, $2n = 2x = 40$.

Mania: A pathological neuronal disorder of mental and/or physical hyperactivity.

Mannans: The yeast cell wall polymers of mannose. ► [mannose](#)

Manic Depression (MAFD1): A psychological condition characterized by recurrent periods of excessive anguish (unipolar) or by manic depression (bipolar). The latter form is accompanied, in addition, by hyperactivity, obsessive preoccupation with certain things or events. Depression and other affective disorders may involve 2 to 6% of the human populations although the incidence of unipolar

depression may be as high 21% among females and 13% among males during the entire lifetime. The concordance among monozygotic twins may be as high as 80% whereas among dizygotic twins, it is about 8%. It appears that the recurrence in the families is higher with the early onset types. Also, the bipolar types appear to have higher hereditary components. The genetic control of depression is unclear, X-linked recessive, autosomal dominant (chromosome 11p) genes have been implicated but the majority of assignments were not well reproducible. These may be major genes but other genes are also involved. Susceptibility loci were assigned to 0 12q23-q24, 18p and 18q, 5q, 8p, 21p22, and others. MFAD2 (major affective disorder 2 or bipolar affective disorder; BPAD) was assigned to Xq28. The physiological bases may also vary from defects in neurotransmitters to electrolyte abnormalities, etc. Commonly recommended therapy involves monoamine oxidase inhibitors, tranquilizers (prozac), lithium, etc. ▶affective, ▶disorders, ▶schizophrenia, ▶bipolar mood disorder, ▶tyrosine hydroxylase, ▶lithium; Molecular genetics of bipolar disorder and depression: Kato T 2007 Psychiatry Clin Neurosci 61:3.

Mannopine: N2-(1'-deoxy-D-mannitol-1'-yl)- L-glutamine. ▶opines, ▶Ti plasmid

Mannose: An aldohexose (see Fig. M15).

Figure M15. D Mannose and L Mannose

Mannosephosphate Isomerase (MPI): A Zn^{2+} monomeric enzyme converts mannose-6-phosphate into fructose-6-phosphate. It is coded in human chromosome 15q22.

Mannose-6-Phosphate Receptor (MPR): Same as insulin-like growth factor; it plays a role in signal transduction, growth and lysosomal targeting. LOH mutation of this receptor (human chromosome 6q26-q27) causes liver carcinoma. MPR is also a death receptor for granzyme B during CTL-induced apoptosis. ▶insulin-like growth factor, ▶LOH, ▶death receptor, ▶granzyme, ▶CTL, ▶apoptosis, ▶RAB, ▶TIP47, ▶GGA

Mannosidosis: The recessive (α -mannosidase B) deficiency has been located to human chromosome

19cen-q12 (MAN2B1) and involves large increase of mannose in the liver causing susceptibility to infection, vomiting, facial malformations, etc. Another mannosidase defect at another autosome (4q22-q25, MANBA) caused excessive mannosyl-1-4-N-acetylglucosamine and heparan in the urine, apparently involving glycoprotein abnormalities and a variety of physical and mental defects.

Mannosyltransferases: Defects in several genes involve mental retardation, psychomotor defects, hypomyelination, coloboma, etc.

Mann-Whitney Test: A powerful non-parametric method for determining the significance of difference between two normal-distributed populations. This method is useful for evaluating scores of samples even if their size is not identical. The procedure is illustrated by small samples, however samples of $n > 20$ are preferred. The scores are ranked (T) in Table M1 (in case of ties the average ranks are assigned to the two):

Table M1. A hypothetical example for the use of the Mann-Whitney test

| | | | | | | | | |
|-------------|---|----|---|---|----|----|-----------------------|---------------------------|
| Populations | I | II | I | I | II | II | Sum of I = $T_I = 10$ | |
| Scores | 1 | 4 | 5 | 7 | 8 | 9 | 10 | Sum of II = $T_{II} = 18$ |
| Rank | 1 | 2 | 3 | 4 | 5 | 6 | 7 | $n_I = 3, n_{II} = 4$ |

The null hypothesis to be tested is that the distribution of the two populations (I and II) is identical. Then the U is determined for sample I: $U_I = n_I n_{II} + \{[n_I(n_I + 1)]/2\} - T_I = 3 \times 4 + (12/2) - 10 = (12 + 6) - 10 = 8$. In case the resulting U value is larger than $(n_I n_{II})/2$ then calculate $U' = n_I n_{II} - U_I$. For large populations, the sampling distribution for U is approximately normal and $E(U) = (n_I n_{II})/2$ and the variance is determined $\sigma^2 = [n_I n_{II} (n_I + n_{II} + 1)]/12$; hence the z value (the standard normal variate) = $[U - E(U)]/\sigma_U$ and the probabilities corresponding to z can be read from statistical tables of the cumulative normal probabilities and a few commonly used corresponding values are as follows for $z = 1.65, 1.96, 2.58$ and 3.29 , the P values are 0.90, 0.95, 0.99 and 0.999, respectively. (See Wilcoxon's signed rank test, Standard deviation, Probability, Null hypothesis).

Mantel Test: Estimates the common odds ratio in two-by-two contingency tables that result from different populations. The formula for the estimation is: $\sum_{i=1}^k a_i d_i / \sum_{i=1}^k c_i b_i$, where k is the number of the two-by-two tables and a_i, b_i, c_i and d_i are the counts in the tables. ▶association test

Mantle Cell Lymphoma (MCL, human translocation [11;14][q13;q32] or mutation at 11q22-q23): A non-Hodgkin type lymphoma. Derived from naïve CD5⁺ B cells of the primary follicles or of the mantle zones of the secondary follicles. The segment deleted from chromosome 11q22-q23 includes the ataxia telangiectasia locus. The translocation juxtaposes cyclin D1 (CCND1) and the transcriptional control element of the immunoglobulin G gene although other factors (c-Myc) are also required for the development of the lymphoma. ▶anaplastic lymphoma, ▶ataxia telangiectasia

Manx Cat: Tailless, because of fusion, asymmetry and reduction in size of one or more caudal vertebrae (see Fig. M16). A dominant gene that is lethal in homozygotes causes this phenotype. The Manx protein is essential also for the development of the notochord of lower animals. ▶brachyury, ▶notochord

Figure M16. Caudal end of Manx cat

MAO (monoamine oxidase): This enzyme is involved in the biosynthetic path of neurotransmitters from amino acids. Mutation in the 8th exon (amino acid position 936) converted the glutamine codon CAG to TAG (chain termination codon) and resulted in mild mental retardation, continued and impulsive aggression, arson, attempted rape, and exhibitionism in human males with this X-chromosomal recessive defect. The block of MAOA resulted in accumulation of normetanephrine (a derivative of the adrenal hormone epinephrine), and tyramine (an adrenergic decarboxylation product of tyrosine) and a decrease in 5-hydroxyindole-3-acetone. The heterozygous women were not affected behaviorally or metabolically; monoamine oxidase B level remained normal. Both enzymes are in human chromosome Xp11.2-p11.4 and the enzymes are located in the mitochondrial membrane. The enzymes may affect various psychiatric disorders such as the Gilles de la Tourette syndrome, panic disorder, alcoholism, etc. ▶mitochondria, ▶Norrie disease, ▶Tourette syndrome

MAP: see Microtubule associated proteins. ▶ASE1, ▶microtubule, ▶centrosome, ▶map genetic

MAP (multi-use affinity probe): A biarsenic tag of amino acids in proteins facilitating easy monitoring

interactions (Cao H et al 2007 J Amer Chem Soc 129: 12123).

MAP-1 (modulator of apoptosis): A mitochondria-associated protein and activates BAX when it is translocated into the mitochondria from the cytosol upon apoptotic signals. RNAi regulates MAP-1. ▶apoptosis, ▶BAX, ▶RNAi; Tan KO et al 2005 Proc Natl Acad Sci USA 102:14623.

MAP-Based Cloning (positional cloning): Isolation of gene(s) on the basis of chromosome walking and propagation usually by YAC and/or cosmid clones. After a genome sequence has been completed, positional cloning will no longer be needed as long as the function of the gene is also known. Positional cloning may be complicated by the fact that some phenotypes are affected by more than a single locus. ▶chromosome walking, ▶chromosome landing, ▶position effect; Lukowitz W et al 2000 Plant Physiol 123:795; Tanksley SD 1995 Trends Genet 11:63.

MAP Distance: Indicates how far syntenic genes are located from each other in the chromosome as estimated by their frequency of recombination; 1 map unit = 1% recombination = 1 centi Morgan. The greater the distance between two genes, the higher is the chance that they are separated by recombination. A single recombination between two genes in a meiocyte produces maximally 50% recombination that is 50 map units. The distance between syntenic genes may exceed 50 map units several times; these longer distances are determined then in a staggered manner, proceeding step-wise from left to right and right to left. In prokaryotes, using conjugational transfer and recombination, map distances are measured in minutes of transfer. ▶conjugational mapping, ▶recombination frequency, ▶radiation hybrids, ▶mapping function

MAP Expansion: The distance between two distant markers exceeds the sum of the distances of markers in between; it is commonly observed in gene conversion. ▶gene conversion; Holliday R 1968 p 157. In: Replication and Recombination of Genetic Material. Peacock WJ, Brock RD (Eds.) Australian Acad Sci, Canberra.

Map, Genetic: The order of genes (markers) in chromosomes determined on the basis of recombination frequencies. ▶mapping, ▶recombination frequencies, ▶physical map, ▶radiation hybrids, ▶RFLP, ▶RAPD, ▶mapping function; Human genes: OMIM; <http://linkage.rockefeller.edu/>; genetic & physical of various organisms: <http://www.ncbi.nlm.nih.gov/Genomes/index.html>.

Map Genetic Versus Physical Map: ►coefficient of crossing-over, ►gene number; Ashburner M et al 1999 Genetics 153:179.

Map Kinase (MPK): A family of serine/threonine protein kinases associated with mitogen activation (growth) and stress responses. Three groups exist: ERK, cJun N-terminal kinase (JNK) and p38. These paths of responses interact at various levels. They have a key role in signal transduction pathways. The p42 and p44 MPKs are also called ERK2 and ERK1, respectively. The MAP kinase family is activated by STE20, RAS, Raf protein serine/threonine kinases. In normal T cells, T cell receptor and CD28 synergistically activate p38. An alternative activation pathway involves Tyr323 by antigen-stimulated T cells but not B cells (Salvador JM et al Nature Immunol 6:390). MAPK81P1 (11p11.2-p12) may be a transactivator of SLC2A2 gene encoding GLUT2 glucose transporter and one of the factors responsible for MODY diabetes. The MAP kinases follow the signaling path: MAPKKK → MAPKK → MAPK. ►cell cycle, ►signal transduction, ►MAPK, ►JNK/SAPK, ►ERK, ►p38, ►STE diabetes, ►MODY, ►GLUT; Cobb MH 1999 Progr Biophys Mol Biol 71:479; English J et al 1999 Exp Cell Res 253:255; Chang L, Karin M 2001 Nature [Lond] 410:37; Dong C et al 2002 Annu Rev Immunol 20:55; Park S-H et al 2003 Science 299:1061; Schwartz MA, Madhani HD 2004 Annu Rev Genet 38:725.

MAP Kinase Kinase (MAPKK): ►Ste 7

MAP Kinase Kinase Kinase (MAPKKK): ►Ste 11

MAP Kinase Kinase Kinase Kinase (MAPKKKK): ►Ste 20

MAP KINASE PHOSPHATASE (MPK): MPK-3 dephosphorylates phosphotyrosine and phosphothreonine and inactivates the MAP kinase family proteins. Binding activates it by its non-catalytic C-end to ERK2 without a need for phosphorylation. The homologous MPK-4 is also activated by ERK2 but also by JNK/SAPK and p38. ►signal transduction and other proteins under separate entries; Zhang T et al 2001 Gene 273:71.

Map Manager v 2.5: The software for storing, organizing genetic recombination data and data base for RI strains of mouse. Information: K.F. Manly, Roswell Park Cancer Institute, Elm & Carlton, Buffalo, NY 14263, USA. Phone: 716-845-3372. Fax: 716-845-8169. kmanly@mcbio.med.buffalo.edu.

Map, Metric: An on-scale ordered FISH map where cosmid clones can orderly be positioned. ►FISH, ►cosmid

Map, Physical: ►physical map

Map, Self-Organizing: Constructed on the basis of mathematical cluster analysis; recognizes and classifies complex multidimensional data such as information of an array of genes involved in differentiation or other complex pathways. ►cluster analysis

Map Unit: 1% recombination = 1 map unit (m.u. or 1 centiMorgan, c.m. or cM). In approximate kilobase pairs equivalent to one centiMorgans in a few species: *Arabidopsis* ≈140; tomato ≈ 510; human ≈ 1,108 (in human chromosome 10 the recombination frequency is 1.32 cM/Mb⁻¹); maize ≈ 2,140. The *Salamanders* have the largest known genetic map 7291 cM. ►recombination frequency

Map Viewer: Provides genomic information by chromosomal location of a variety of eukaryotic organisms from animals to plants, fungi and protozoa. It can be queried by gene name, sequence alignment (BLAST), etc. ►genome, ►BLAST; <http://www.ncbi.nlm.nih.gov/mapview/>.

MAPCS (multipotent adult progenitor cells): These are “universal stem cells” present in small numbers in some adult tissues and have the capacity to produce other types of cells in a manner similar to embryonic stem cells. ►stem cells; Jiang Y et al 2002 Nature [Lond] 418:41; Schwartz RE et al 2002 J Clin Invest 109:1291.

MAPK (mitogen-activated protein kinase): Distinct kinases responding to different environmental cues and sets into motion different development/physiological pathways. The family includes KSS1 (filamentous growth), HOG-1 (hypertonic stress), FUS3 (mating), Mpk1 (cell wall remodeling), SLT-2, sapk-1 (stress activated protein kinase), FRS (FOS regulating kinase), erk-1 (extracellular signal regulated kinase), Smk1 (sporulation), etc. In yeast association with the Ste12 transcriptional activator regulates the specificity. Ste12 in combination with other proteins may bind to the pheromone response element (PRE). Ste12 protein associates with the filamentation and invasion response element (FRES), including A Ste12 protein binding site (TGAAACA) and a neighboring CATTCTY sequences specific for the Tec1 (non-receptor tyrosine kinase) transcription factor. The mating and filamentous growth pathways are initiated in a similar way but for mating the FUS kinase is activated rather than the KSS. In the absence of phosphorylation KSS inhibits the Ste12-Tec1 complex and filamentous growth. The Dig proteins appear to be cofactors of the inhibitory path. In the inhibitory MAPKs (KSS), there is the MKI (MAP kinase insertion) site, which is remodeled upon phosphorylation and thus conversion into an activator. The specificity of the MAPKs is secured also by the complexes of recruited proteins, and each of these

selects the appropriate MAPK. ►signal transduction, ►MAPKK, ►MEK, ►arrestin, ►Ask, ►JNJ FOS, ►Ste, ►anthrax; Ito M et al 1999 Mol Cell Biol 190:7539; Roberts CJ et al 2000 Science 287:873; Pouyssegur J 2000 Science 290:1515; Barsyte-Lovejoy D et al 2002 J Biol Chem 277:9896.

MAPKK (mitogen-activated [MAP] protein kinase kinase): This protein mediates signal transduction pathways by phosphorylating RAS, Src, Raf and MOS oncogenes. When such an active kinase was introduced into mammalian cells, the AP-1 transcription factor was activated and the cells formed cancerous foci and became highly tumorigenic in nude mice, indicating that MAPKK is sufficient for tumorigenesis. ►signal transduction, ►tumor, ►anthrax, ►NPK

MAPKKK: Mitogen activated protein kinase kinase. ►TAK1

Maple (*Acer* spp.): Hardwood trees; sugar maple is used for collecting syrup, $2n = 26$.

Maple Syrup Urine Disease: ►isoleucine-valine biosynthetic pathway

Mapmaker 3.0: A software for constructing linkage maps using multipoint analysis in testcross and F_2 . MAPMAKER/QTL is for quantitative trait loci. Available for Sun (Unix), PC (DOS) and Macintosh. Contact: Eric Lander, Whitehead Institute, 9 Cambridge Center, Cambridge, MA 02142, USA. Fax: 617-258-6505. INTERNET: mapmaker@genome.wi.mit.edu.

Mapping: Establishes the sequential location of genes, restriction fragments or PCR products. Molecular mapping of individual genomic DNA molecules labeled with fluorescent dyes at specific sequence motifs by the action of nicking endonuclease followed by the incorporation of dye terminators with DNA polymerase can be used. The labeled DNA molecules are then stretched into linear form on a modified glass surface and imaged using total internal reflection fluorescence (TIRF) microscopy. By determining the positions of the fluorescent labels with respect to the DNA backbone, the distribution of the sequence motif recognized by the nicking endonuclease can be established with good accuracy in a manner similar to reading a barcode (Xiao M et al 2007 Nucleic Acids Res 35(3):e16). ►genome

projects, ►physical maps, ►recombination, ►restriction endonuclease, ►PCR, ►SNIPs, ►radiation hybrids, ►databases; <http://linkage.rockefeller.edu/>.

Mapping by Admixture Linkage Disequilibrium: ►MALD

Mapping by Dosage Effect: If the activity of enzymes is proportional to their dosage and disomics can be distinguished from critical trisomics, genes (for the enzymes) located in a specific trisome can be identified and assigned to that specific chromosome or in the case of telotrisomic to a particular chromosome arm. Theoretically, the enzyme activity is expected as follows if the locus is situated in the long arm of a particular chromosome (see Fig. M17).

In human trisomy 21 several genes show increased expression ranging from 1.21 to 1.61 relative to the normal disomic condition. Thus, in practice, the dosage effect may not be perfectly additive, yet it may be clear enough for classification. ►trisomics; Carlson PS 1972 Mol Gen Genet 114:273.

Mapping, Genetic: The mapping of chromosomes can be carried out on the basis of recombination frequencies of chromosomal markers, either genes or DNA markers such as RFLPs, RAPDs, etc., or molecular methods used in physical mapping (chromosome walking). As a hypothetical example assuming that genes *a*, *b*, *c*, *d* and *e* are syntenic, the recombination frequencies between them was found to be:

a 0.06 *b* 0.04 *c* 0.06 *d* 0.16 *e* 0.18 *g*

The sum of the recombination frequencies is $0.06 + 0.04 + 0.06 + 0.16 + 0.18 = 0.50$ indicating that the segregation between *a* and *g* is independent. The results shown could be obtained between two genes at a time but such a two-point cross would not have permitted the determination of the order of the genes relative to each other. For the determination of genes at “left” and genes at “right” a three-point cross is required as a minimum, and multipoint crosses are even more helpful ►recombination frequencies. For the results of a hypothetical three-point testcross see Table M2.

According to the data, the number of recombinants in interval I was $10 + 2$ and in interval II $20 + 2$ (the double recombinants had recombination in both interval I and II and their number must be added to the numbers observed). Thus the frequency of

Figure M17. Mapping by dosage effects

Table M2. A hypothetical three-point testcross

| Phenotypic classes → | ABD | abd | Abd | aBD | ABd | abD | AbD | aBd |
|-----------------------|----------|-----|-------------------------|-----|--------------------------|-----|-------------------------------|-----|
| Number of individuals | 34 | 34 | 5 | 5 | 10 | 10 | 1 | 1 |
| | Parental | | Recombinants interval I | | Recombinants interval II | | Recombinants intervals I + II | |
| Total of 100 | 68 | | 10 | | 20 | | 2 | |

recombination between *A* and *B* is $12/100 = 0.12$ and between *B* and *D* $22/100 = 0.22$. The number of recombinations between *A* and *D* is $10 + 20 + 4 = 34$ (the 4 is the double of the number of recombinants in intervals I and II because these represented double recombination events).

Thus the relative map positions are *A* – *B* – *D*. Had it been found that the combined parental numbers were 68 but the recombinants *Abd* plus *aBD* 10 and *ABd* plus *abD* 2, and *AbD* plus *aBd* 20, it had to be concluded that the gene order was *A* – *D* – *B*, because the lowest frequency class ($0.10 \times 0.20 = 0.02$) must have been the double recombinants, and thus the gene order would have been *A* – *D* – *B*. The observed recombination frequencies may have to be corrected by mapping functions because not all double-crossovers might have been detected (see Mapping functions). The recombination frequencies may be biased also by interference when the frequency of double-crossovers are either higher or lower than expected on the basis of the product of the two single-crossovers (see ►Coincidence, Interference). The (corrected) recombination frequencies can be converted to map units by multiplication with 100 and 1 map unit (m.u. or centiMorgan [cM]) is 0.01 frequency of recombination. Recombination frequencies can be estimated also in F_2 by using the product ratio method (see ►Product ratio method). In the latter case recombination frequencies can be calculated only between pairs of loci yet from the data of two pairs involving 3 loci, the gene order can be determined. On the basis of SNIPs human linkage maps of 3.9 cM resolution have been generated (Matisse TC et al 2003 Am J Hum Genet 73:271). Availability of complete nucleotide sequences of the genomes does not obviate the calculations of recombination frequencies because the physical maps and the genetic map lengths are not necessarily identical. ►Recombination frequencies, ►crossing over, ►QTL, ►deletion mapping, ►chromosome walking, ►physical maps, ►mapmaker, ►joinmap, ►maximum likelihood method applied to recombination, ►mapping functions, ►radiation hybrids, ► F_2 linkage estimation, ►genomic screening, ►skeletal map, ►comparative map, ►unified genetic map, ►integrated map, ►consensus, ►SNIPs, ►linkage,

Marfan Syndrome (MFS, FBN1): Common symptoms include tall thin stature, long limbs and fingers, chest deformations. The three most consistent defects are skeletal, heart-vein (cardiovascular) and eye (ectopia lentis) abnormalities. The disease may affect the development of the fetus and may be recognized in early development and the life expectancy in serious cases may not much exceed 30. The cause of death is generally heart failure but the defect may be surgically corrected in some cases. The penetrance appears very good but the expressivity is highly variable. The symptoms frequently overlap with other anomalies, particularly with those of the Ehlers-Dunlop syndrome.

The latter involves a defect in collagen. The primary defect in MFS involves the elastic fiber system glycoprotein, fibrillin. This protein of the connective tissue contains repeats resembling sequences in the epidermal growth factor (EGF) where the lesion observed leads to the identification of the basic molecular cause. Formerly a collagen defect was suspected.

Several investigators confirmed a transversion mutation at codon 293 leading to CGC (Arg) → CCC (Pro) replacement. Similar molecular defects have been identified in *Drosophila*, *Caenorhabditis* and cattle. This dominant gene has been assigned to human chromosome 15q21.1. Interestingly, mosaicism for trisomy 8 causes similar symptoms. The prevalence of MFS/FBN1 is about 1×10^{-4} but this figure may not be entirely reliable because of the wide range of manifestation of the symptoms (see Fig. M19). The recurrence risk is about 50%; 15–30% of the cases may be due to new mutation that is the cause of the most severe cases, whereas the familial incidence generally entails milder symptoms. The estimated mutation rate is $4 - 5 \times 10^{-6}$. FBN1 may be dominant negative. The mutation in fibrillin-1 affects the regulation of transforming growth factor (TGF- β) resulting in apoptosis of the alveolar cells of the lung. Excessive signaling of TGF- β family cytokines can cause aortic aneurysm in mice and can be blocked by angiotensin II type1 receptor blocker drug, Losartan (Habashi JP et al 2006 Science 312:117).

Figure M19. Marfan syndrome. (Courtesy of Dr. D.L. Rimoin, Los Angeles)

A higher probability of ectopia lentis was found for patients with a missense mutation substituting or producing a cysteine, when compared with other

missense mutations. Patients with an FBN1 premature termination codon had a more severe skeletal and skin phenotype than did patients with an inframe mutation. Mutations in exons 24–32 were associated with a more severe and complete phenotype, including younger age at diagnosis of type I fibrillinopathy and higher probability of developing ectopia lentis, ascending aortic dilatation, aortic surgery, mitral valve abnormalities, scoliosis, and shorter survival (Faivre L et al 2007 Am J Hum Genet 81:454).

It has been suggested that President Abraham Lincoln, the famous musician Niccolò Paganini, renowned composer Sergey Rachmaninof and Pharaoh Akhenaten were afflicted with this type of anomaly. ►Marfanoid syndromes, ►coronary heart disease, ►cardiovascular disease, ►connective tissue disorders, ►penetrance, ►expressivity, ►transversion mutation, ►Ehlers-Dunlop syndrome, ►fibrillin, ►angiotensin, ►aneurysm, ►dominant negative, ►TGF, ►apoptosis, ►arachnodactyly, ►inbreeding depression, ►frameshift mutation; Dietz HC, Pyeritz RE 1995 Hum Mol Genet 4:1799; Neptune ER et al 2003 Nature Genet 33:407.

Marfanoid Syndromes: It may resemble the Marfan syndrome but one of the forms has no ectopia lentis (displacement of the crystalline lens of the eye). Another form does not involve cardiovascular defects. The marfanoid-craniosynostosis is called Shprintzen-Goldberg syndrome and the anomaly is caused by mutation in the fibrillin-1 gene. ►Marfan syndrome, ►eye diseases, ►Craniosynostosis syndromes, ►fibrillin, ►Lujan syndrome

Marijuana: ►cannabinoids, ►Cannabis

Mariner: Probably the smallest transposable element in eukaryotes (1,286 bp). It has not been observed in *Drosophila melanogaster* but has been detected in African species of the *D. melanogaster* subgroup, *D. sechellia* (1–2 copies), *D. simulans* (usually 2 copies), *D. yakuba* (about 4 copies), *D. teissieri* (10 copies), and *D. mauritiana* (20 to 30 copies). Mariner-like element has been detected also in soybeans.

Mariner contains 28-bp inverted terminal repeats and a single open reading frame (1,038-bp) beginning with an ATG codon at position 172 and termination

with an ochre (TAA). Overlapping AATAA bases may serve as polyadenylation signal (see Fig. M20).

The target in the untranslated leader of the w^{pch} is 5'-TGGCGTA↓TAAACCG-3'. The arrow marks the insertion and the TATA indicate probably the target site duplication. *Mariner* is different from other transposable elements inasmuch as inducing a high frequency of somatic sectors (4×10^{-3}) at the w^{pch} (white *peach*) locus. Germline mutation is about 2 to 4×10^{-3} , with about twice as high in the males than females (no sex difference in somatic mutation).

Before the transposable element was recognized, the somatic instability was attributed to the factor named *Mos* in chromosome 3. This element also causes dysgenesis but it does not display the reciprocal difference observed in the *P-M* and *I-R* systems, however, *mariner* transmitted through the egg shows higher rates of somatic excisions. *Mariner* homologs occur in other species too, including humans but the (*human*) sequences are pseudogenic although increase unequal crossing over in human chromosome 17p11.2-p12. The mariner type DNA-based transposons are most common in the human genome, representing ~1.6% of it. The *mariner* sequences are also expressed in *Leishmania* and *Caenorhabditis*. ►hybrid dysgenesis, ►transposable elements, ►Charcot-Marie-Tooth syndrome, ►neuropathy, ►HNPP, ►unequal crossover, ►MLE, ►MITE, ►Leishmania, ►sleeping beauty; Hartl DL et al 1997 Annu Rev Genet 31:337; Zhang L et al 2001 Nucleic Acids Res 29:3566; Feschotte C, Wessler SR 2002 Proc Natl Acad Sci USA 99:280.

Marinesco-Sjögren Syndrome (MSS, 5q31): The major symptoms of the recessive hereditary disease are cerebellar ataxia, cataracts, retarded developmental/mental maturation. Hypergonadotropic hypogonadism is also a common feature of the condition. Chylomicron retention deficiency is coded in the same chromosomal region but physiologically not linked to this disease. The SIL1 nucleotide exchange factor for the Hsp70 chaperone BiP mutations are the primary cause of MSS. Affecting the endoplasmic reticulum may explain the multiple consequences of the mutations. ►hypergonadotropic hypogonadism, ►chylomicron, ►nucleotide exchange factor, ►endoplasmic reticulum, ►Hsp70; Senderek J et al 2005 Nature Genet 37:1312.

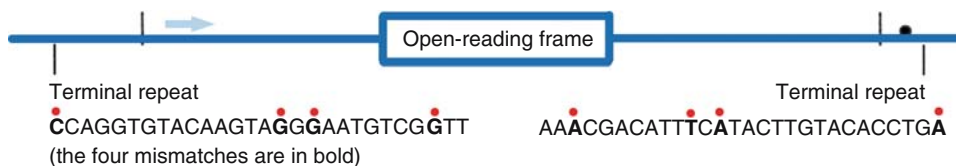

Figure M20. *Mariner* transposable element

Marker: Any gene or detectable physical alteration in a chromosome (e.g., knobs, microsatellites) or cytoplasmic organelle, used as a special label for that chromosome or chromosomal area. Molecular marker is a macromolecule (nucleic acid or protein) of known size and electrophoretic mobility to be used as a reference point in estimating the size of unknown fragments and molecules. In genomics Type I markers are the protein-coding genes, Type II markers are the highly polymorphic microsatellites and Type IIIs are SNPs. ▶RFLP, ▶RAPD, ▶AFLP, ▶ladder, ▶microsatellite, ▶minisatellite, ▶SNIPs, ▶linkage, ▶association test; Schlötterer C 2004 *Nature Rev Genet* 5:63; plant markers: <http://markers.btk.fi/>.

Marker-Assisted Selection: Used for animal and plant breeding once linkage has been established between physical markers (RFLP, microsatellite loci) and others, economically desirable traits (e.g., disease resistance, productivity) that have low expressivity and/or poor penetrance because of the substantial environmental influences can be better identified. The physical markers should not have ambiguity of expression and thus may facilitate much faster progress in breeding. ▶RFLP, ▶microsatellite, ▶expressivity, ▶penetrance, ▶QTL; Hospital EF 2001 *Genetics* 158:1363; Davierwala AP et al 2001 *Biochem Genet* 39(7–8):261; Hayes B, Goddard ME 2001 *Genet Sel Evol* 33(3):209.

Marker Effect: Theoretically, by generalized transduction, any bacterial gene should be transferred by the transducing phage. In fact some genes are transduced 1,000 fold better than others. The differences have been attributed to the distribution of *pac* sites in the bacterial chromosome. Also recombination by transduction may vary along the length of the bacterial chromosome. Marker effects have been observed also in eukaryotic recombination. ▶generalized transduction, ▶*pac* site

Marker Exchange Mutagenesis: ▶targeting genes

Marker Exclusion: Occurs upon joint infection of bacteria by phages T4 and T2. In the progeny, T2 genes are recovered in about 30% rather than 50% as expected. The apparent basis of the bias is that T4 harbors 13 sequence-specific endonucleases that selectively eliminate particular tracts from the other phage. ▶homing endonucleases; Edgell DR 2002 *Current Biol* 12:R276.

Marker Panels: DNA probes or genes that cover reasonably well portions of the genome regarding linkage. ▶probe, ▶linkage

Marker Rescue: The integration of markers into normal DNA phage from mutagen-treated (irradiated) phage during mixed infection of the host; it is similar to cross

reactivation where from defective phages by recombination normal phages can be obtained. Alternatively, a wild type DNA fragment can be inserted by recombination into a mutant one and the mutation can thus be mapped. Marker rescue is the most commonly used method of mapping in phages. ▶reactivation, ▶multiplicity reactivation, ▶Weigle reactivation; Barricelli NA, Doermann AH 1961 *Virology* 13:460; Thompson CL, Condit RC 1986 *Virology* 150:10.

Marker Transfer: Gene replacement by recombination.

Markov Chain Monte Carlo Algorithm: It applies Bayesian inference for evaluation of the posterior distribution. It is used also in classical likelihood calculation. (See Gilks WR et al (Eds.) 1996 *Markov Chain Monte Carlo in Practice*. Chapman and Hall, London, UK; Larget B, Simon DL 1999 *Mol Biol Evol* 16:750; ▶Monte Carlo method, ▶Bayes' theorem).

Markov Chain Statistics: A sequence $x_1, x_2 \dots$ of mutually dependent random variables constitutes a Markov chain if there is any prediction about x_{n+1} . Knowing $x_1 \dots x_n$ may without loss be based on x_n alone. Among others, it is used in physical mapping of genomes, for ascertaining frequency distributions in populations. The *hidden Markov model* (HMM) type analysis—seeks the probabilities of an event occurring also prior to and after another event—permits the identification of protein domains in peptide chains or in nucleotide sequences and frequency distribution through time. ▶TB-parse, ▶alignment; Stephens DA, Fisch RD 198 *Biometrics* 54:1334.

Marmosets: New World Monkeys. In marmoset (*Callithrix kuhlii*) twins all somatic tissue types sampled were found to be chimeric by the use of microsatellite DNA (see Fig. M21). Chimerism was present in hematopoietic tissues and also in germ-line tissues, an event never before documented as naturally occurring in a primate. Chimeric marmosets often transmit sibling alleles acquired in utero to their own offspring. Thus, an individual that contributes gametes to an offspring is not necessarily the genetic parent of that offspring. Chorions of the twins'

Figure M21. Marmoset

placentas begin to fuse on day 19 and the process is complete by day 29, forming a single chorion with anastomoses connecting the pre-somite stage embryos. The fusion of the chorions and a delay in embryonic development at this stage allows the exchange of embryonic stem cells via blood flow between the twins. As a result, the infants are genetic chimeras with tissues derived from self and sibling embryonic cells (Ross CN et al 2007 Proc Natl Acad Sci USA 104:6278). ▶ *Callithrichidae*, ▶ *Chimera*

Marmota (groundhog, woodchuck): Squirrel-like rodents; *Marmota marmota* 2n = 38; *Marmota monax* 2n = 38 (see Fig. M22).

Figure M22. Marmota

Maroteaux-Lamy Syndrome: ▶ *mucopolysaccharidosis*

Marquo Syndrome: ▶ *mucopolysaccharidosis*

Marriage: In every state of the United States and many other countries marriages between parent and child, grandparent-grandchild, aunt-nephew, uncle-niece and brother-sister are illegal. In about half of the states first cousin and half sibling unions are also prohibited. In some societies, consanguineous marriages are legal. ▶ *consanguinity*, ▶ *miscegenation*

Marry-in: A member of a pedigree without his parents being members of the pedigree. ▶ *pedigree*

Mars Model: Developed to interpret the fate of mitochondria during the development of an organism. The acronym is derived from (i) accumulation of defective mitochondria, (ii) accumulation of aberrant proteins, (iii) effect of oxygen-free radicals and antioxidant enzymes, (iv) turnover of proteolytic scavengers. ▶ *mitochondria*, ▶ *aging*

Mars Shield: A symbol of male; in pedigrees usually squares are used (see Fig. M23). ▶ *venus mirror*

Figure M23. Mars shield

Marshall Syndrome: ▶ *Stickler syndrome*

Marsupial: A mammalian group of animals that carry their undeveloped offspring in a pouch, e.g., the kangaroos and other Australian species, also the North-American opossum. The organization of the genetic material of marsupials differs in several ways from other placental mammals. Ohno's law is not entirely complied with inasmuch as genes in the short arm of the eutherian X chromosomes are dispersed in three autosomes. Marsupial Y chromosomes are extremely small yet they contain testis-determining and other sequences homologous to other mammals although the Y chromosome is not critical for sex determination. Their sex chromosomes also carry a pseudoautosomal region at their tip but do not form synaptonemal complex and do not recombine. ▶ *Eutheria*, ▶ *Monotreme*, ▶ *Ohno's law*, ▶ *SRY*, ▶ *pseudoautosomal*, ▶ *vomeronasal organ*; Marshall Graves JA 1996 Annu Rev Genet 30:233; Zenger KR et al 2002 Genetics 162:321.

MART-1 (Melan-A): ▶ *MAG*

Marten (*Martes americana*): 2n = 38.

Martin-Bell Syndrome: ▶ *Fragile Xq27.3*

Martsof Syndrome: An apparently autosomal recessive cataract-mental retardation-hypogonadism. ▶ *cataracts*, ▶ *hypogonadism*, ▶ *mental retardation*, ▶ *Cerebro-oculo-facio-skeletal syndrome*; Hennekam RC et al 1988 Eur J Pediatr 147:539.

MaRX: A method of isolation of mammalian cells of a certain type. A DNA library is introduced into a packaging cell line (linX cells) with the aid of retroviral vectors. The virus-infected cells are subjected then to selection for the desired phenotype. Provirus are recovered and used for the production of virus and further screening. ▶ *DNA library*, ▶ *retroviral vectors*, ▶ *provirus*, ▶ *packaging cell line*; Hannon GJ et al 1999 Science 283:1129.

MAS: ▶ *Marker-assisted selection*

MAS Oncogene: MAS1 was assigned to human chromosome 6q27-q27; it encodes a trans-membrane protein. ▶ *transmembrane protein*, ▶ *oncogenes*

MASA Syndrome (Xq28): Involves mental retardation, aphasia, shuffling gate, adducted and/or clasped thumb, etc. The basic defect is in L1 CAM cell adhesion molecule of 143 molecular mass of 1,256 amino acids. MASA is allelic to X-linked hydrocephalus (prevalence: $\sim 3 \times 10^{-4}$). ▶ *aphasia*, ▶ *hydrocephalus*, ▶ *CAM*

Masculinization: ▶ *sex reversal*

MASDA (multiplex allele-specific diagnostic assay): A mutation detection test capable of simultaneous detection of up to 100 nucleotide changes in multiple genes concerned with disease. ▶ *single strand*

conformation polymorphism, ►peptide nucleic acids; Shuber AP et al 1997 Hum Mol Genet 6:337.

MASH2: A mammalian helix-loop-helix transcription factor controlling extraembryonic trophoblast development but not that of the mouse embryo. ►MYF-3, ►DNA-binding protein domains

Mask: A computer program that produces ambiguous files in order to protect confidential DNA sequences in EcoSeq programs. ►EcoSeq

Masked mRNA: It is present in eukaryotic cells in such a form and cannot be translated until a special condition is met. ►mRNA; Spirin AS 1996 p 319. In: Hershey JWB et al (Eds.) Translational Control, Cold Spring Harbor Lab. Press, Cold Spring Harbor, NY.

Masked Sequences: Masked sequences of nucleic acids are associated with either proteins or other molecules to protect them from degradation.

Masking DNA Sequences: It is replacing nucleotide regions with certain properties with 'N' characters, or by converting the nucleotides within the region to lower-case letters. The program called RepeatMasker most frequently used to mask repeats: <http://www.repeatmasker.org/>. Repeats around SNPs may cause failure of assay or give mixed signals from different genomic regions. Variations may cause biased signal due to allele-specific binding of primers. Automatic masking tool: <http://bioinfo.ebc.ee/snpmasker/>.

Maspin: A protease inhibitor of the serpin family; maspin sequences are frequently lost from advanced cancer cells. Maspin is an inhibitor of angiogenesis. ►serpin, ►angiogenesis; Maass N et al 2000 Acta Oncol 39:931; Futscher BW et al 2002 Nature Genet 31:175.

Mas6p: ►mitochondrial import

Mass-Coded Abundance Tagging (MCAT): A method of protein characterization for proteomic studies. It is based on differential guanidination of the C-terminal lysine residues in tryptic peptides and followed by capillary liquid chromatography–electrospray tandem mass spectrometry. ►capillary electrophoresis, ►electrospray MS, ►proteomics, ►trypsin; Cagney G, Emili A 2002 Nature Biotechnol 20:163.

Mass Spectrum: When in the mass spectrometer molecules are exposed to energetic electrons they are ionized and fragmented. Each ion has a characteristic mass to charge ratio, m/e or m/z . The m/e values are characteristic for particular compounds and provide the mass spectrum for chemical analysis. Quantitative mass spectrometry uses the incorporation of a stable isotope (N^{15}) derivative that shifts the mass of the peptides in a known extent. The ratio

between the derivatized and underivatized target can be measured. Shotgun mass spectrometry identifies components of a protein mixture by first identifying the mass of peptide fragments. ►laser desorption mass spectrum, ►electrospray mass spectrum, ►affinity-directed mass spectrometry, ►genomics, ►proteomics, ►MALDI, ►MS/MS, ►quadrupole, ►electrospray; Oda Y et al 1999 Proc Natl Acad Sci USA 96:6591; Mann M et al 2001 Annu Rev Biochem 70:437; Figeys D et al 2001 Methods 24:230; Cohen SL 2001 Annu Rev Biophys Biomol Struct 30:67; Aebersold R, Mann M 2003 Nature [Lond] 422:198; OMSSA, for protein structure: Sharon M, Robinson CV 2007 Annu Rev Biochem 76:167; virtual lab exercises: <http://mass-spec.chem.cmu.edu/VMSL>; Ms/Ms peptide spectra search: <http://pubchem.ncbi.nlm.nih.gov/omssa>.

Massively Parallel Signature Sequencing (MPSS): The method permits large-scale analysis of transcription templates of an entire genome without physical separation of the DNA fragments. The 16–20 base fragments were generated by repeated digestion with restriction endonucleases and ligated by appropriate adaptors. Complex DNA mixtures are cloned in vitro onto glycidyl methacrylate microbeds in quantities sufficient for biochemical and enzymatic analyses using fluorescent probes. The template-containing microbeads are assembled in a flow cell in a close planar, fixed array while the sequencing reagents are pumped through. The sequencing is monitored with the aid of the fluorescent signals. The procedures facilitate the early recognition of gene products involved in the development of disease and may permit intervention. The improved system is capable of sequencing 25 million bases within four hours in picoliter size wells 1.6 million on a 6.4-cm² slide, using a modified pyrophosphate-based method (pyrosequencing). It is about two-order magnitude faster than the standard Sanger method and has an accuracy of >99%. It does not require subcloning of the DNA in bacteria. Although it seems very convenient for relatively small (microbial) genomes, it is not yet practical with large (mammalian) systems (Margulies M et al 2005 Nature [Lond] 437:376). ►gene expression, ►microfluidics, ►small RNA, ►DNA sequencing, ►pyrosequencing; Brenner S et al 2000 Nature Biotechnol 18:630; Reinartz J et al 2002 Brief Funct Genomic Proteomic 1:95; Hood L et al 2004 Science 206:640; <http://www.massivelyparallel.com/>.

Mass-to-Charge (m/e , m/z): ►mass spectrum

Mast Cells: They reside in the connective or hemopoietic tissues and play an important role in natural and acquired immunity. They release TNF- α (tumor

necrosis factor), histamines and attract eosinophils (special white blood cells) and destroy invading microbes especially if they have IgE or IgG (immunoglobulins) on their surface. They are responsible for the inflammation reactions in allergies and susceptibility to bee and snake venoms by facilitating vascular permeability. On the other hand, they release carboxypeptidase A and probably other proteases, which can degrade the venoms (Metz M et al 2006 Science 313:526). Mast cells are essential for regulatory T-cell controlled immune tolerance. ▶IL-10, ▶IL-9, ▶immune system, ▶TNF, ▶immunoglobulins, ▶carboxypeptidase, ▶venome, ▶T cell regulatory, ▶immune tolerance

Mast Syndrome: A recessive (15q22.31) brain developmental disorder (paraplegia, dementia) caused by premature termination of transcription of the maspardin protein gene due to single nucleotide pair insertion. The protein is situated in the endosomal/trans-Golgi transport vesicles. ▶paraplegia, ▶endosome, ▶Golgi; Simpson MA et al 2003 Am J Hum Genet 73:1147.

Master Chromosome: The large circular genome within the mitochondria. ▶mtDNA

Master Genes: They have major role in a range of functions. (See Prior HM, Walert MA 1996 Mol Med 2:405; Silver LM 1994 Mamm Genome 5:S291).

Master molecule: Regulates series of reactions in differentiation, involving several genes. ▶morphogenesis in *Drosophila*, ▶neuron-restrictive silencer factor

Master-Slave Hypothesis: The hypothesis interpreted redundancy in the genomes by multiple copying 'the slaves' from the original 'master' sequences based on the structure of the loops of the lampbrush chromosomes of the newt *Triturus*. ▶redundancy, ▶Lampbrush chromosomes; Callan HG 1967 J Cell Sci 2:1.

MAT1: A RING finger protein subunit stabilizing cyclin H-CDK7 complex or CAK. ▶RING finger, ▶cyclin, ▶CDK, ▶CAK, ▶four-hybrid system; Devault A et al 1995 EMBO J 14:5027.

MAT Cassette: ▶mating type determination in yeast

MAT Locus: In yeast, it is involved in the determination of mating type in yeast. ▶mating type determination in yeast

Matched Pairs t-Test: Checks the equality of the means of paired observations. The difference between the matched pairs is tested by the formula: $t = \frac{\bar{d}}{s_d/\sqrt{n}}$
 \bar{d} = the mean of the differences, s_d = standard

deviation and t is determined at $n - 1$ degrees of freedom from a t table. The null hypothesis is that the means of the paired observations are true. ▶mean, ▶standard deviation, ▶Student's t table, ▶Null hypothesis

Mate Killer: mu particle. ▶symbionts hereditary

Mate Pairs: Randomly sequenced DNA fragments are fit together by their matching mate pair ends into a continuous sequence. DNA sequences read from opposite ends of fragments are the mate pairs. ▶WGS, ▶Human genome

Maternal Behavior: A very complex trait, it is regulated by hormones such as estradiol, progesterone, prolactin, oxytocin and β -endorphin. The Mest/Peg1 (mouse chromosome 6, human chromosome 7q32) is expressed only from the paternally transmitted allele and its defect leads to altered maternal behavior. ▶hormones under separate entries, ▶imprinting

Maternal Contamination: During amniocentesis, maternal cells may contaminate the sample withdrawn and may become a cause of genetic diagnostic error. ▶amniocentesis

Maternal Coordinate Genes: Expressed during oogenesis and determine positional information in the egg.

Maternal Effect Genes: Display delayed inheritance because only the offspring of the homozygous or heterozygous dominant females is affected; these females themselves may appear normal. Also, genes with products (RNA, protein) in the follicle and nurse cells that may diffuse into the oocytes and the embryo, and thus not just the zygotic genes, affect early development. After the initial phases, the maternal transcripts and proteins are destabilized. (See Fig. M24 of ▶morphogenesis, ▶delayed inheritance, ▶cadherin, ▶indirect epistasis, ▶trans-generational effect, ▶imprinting; Evans MMS, Kermicle JL 2001 Genetics 159:303; Tadros W et al 2003 Genetics 164:989.

Figure M24. The *Drosophila* egg chamber cysts are surrounded by follicle cells and inside the diploid primary oocyte is shown with the often polyploid nurse cells. These are connected by cytoplasmic bridges. The maternal genes affect oogenesis and the early development of the embryo

Maternal Embryo: Develops from an unfertilized egg.
 ▶apomixis, ▶parthenogenesis

Maternal Genes: ▶maternal effect genes, ▶*Limnaea*

Maternal Inheritance: Genetic elements (generally extranuclear) are transmitted only through the female.
 ▶mtDNA, ▶mitochondrial genetics, ▶doubly uniparental inheritance, ▶chloroplast genetics

Maternal Performance: A complex of physiological and behavioral traits of the mother that affects the wellbeing and survival of the offspring. It includes such maternal attributes as nursing, grooming, nest building, etc. The heritability of such traits is variable and generally low yet it contributes measurably to fitness. ▶maternal behavior; Peripato AC et al 2002 Genetics 162:1341.

Maternal Tolerance: The embryo expresses antigens that is supposed to be foreign to the maternal tissues yet usually the embryo does not suffer immunological rejection. The cause of the tolerance appears to be due to the secretion of corticotropin-releasing hormone (CRH) and the activation of the pro-apoptotic Fas ligand (FasL) resulting in killing of activated T lymphocytes. Some of the female infertility may be caused by lack of adequate level of CRH in the endometrium. ▶incompatibility, ▶corticotropin releasing factor, ▶FAS, ▶apoptosis, ▶T cell; Makrigiannakis A et al 2001 Nature Immunol 2:1018.

Maternity Verification: Rarely needed as the Romans held “mater certa” (mother is certain); in case of legal disputes, the methods of forensic genetics are available. ▶forensic genetics, ▶paternity testing

MATH (meprin and TRAF homology): The protein domain shared by metalloendopeptidases and TRAF proteins regulating the folding to activable forms of the molecules. ▶meprin, ▶TRAF

Mating Assortative: ▶assortative mating

Mating Bacterial: ▶conjugation (see Fig. M25).

Figure M25. Mating bacteria

Mating Controlled: ▶controlled mating

Mating Interrupted: ▶interrupted mating, ▶conjugation mapping

Mating Nonrandom: ▶inbreeding, ▶assortative mating, ▶autogamy (self-fertilization), ▶controlled mating

Mating, Physiological Consequences: In some species the male seminal fluid may contain substances toxic to the female. In contrast, the seminal fluid of the male cricket (*Gryllus lineaticeps*) increases the life expectancy of the female by about a third and multiple matings (common in this species) almost doubles the fertility of the female (Wagner WE Jr et al 2001 Evolution 55:994).

Mating Plug: A gelatinous material deposited at vulva after mating of hermaphroditic *Caenorhabditis*. During mating between some hermaphroditic males, plugs may be visible at the head. ▶vaginal plug

Mating Random: ▶random mating, ▶mating systems

Mating Success (K): Expressed as

$$\frac{\text{No. of females mated by mutants/No. of mutant male}}{\text{No. of females mated by wild types/No. of wild type males}}$$

Increasing success in mating in insect species may reduce the level of phenoloxidasases in both sexes. Thus, a major humoral immune component is weakened and the individuals become more susceptible to infection. Therefore, copulation may adversely influence fitness. (See Rolff J, Siva-Jothy MT 2002 Proc Natl Acad Sci USA 99:9916).

Mating Systems: It can be random mating, self fertilization, inbreeding, assortative mating or a combinations of these. ▶Hardy-Weinberg theorem

Mating Type: The designation of individuals with plus or *a* (“male”) and minus or *α* (“female”) labels when sex like in higher eukaryotes cannot be recognized yet genetically two types exist that do not “mate” within group but in between groups, and the diploid zygote subsequently undergoes meiosis and reproduces the mating types in 2:2 proportion. (See Ferris PJ et al 2002 Genetics 160:181).

Mating Type Determination in Yeast: *Saccharomyces cerevisiae* yeast can exist in homothallic and heterothallic forms. The heterothallic yeast cells are haploids and are either of *a* or *α* mating type. The homothallic yeast cells are diploid and heterozygous for the mating type genes (*a/α*). The diploid cells arise by fusion of haploid cells. Recognition of the

opposite mating type cells is mediated by pheromones, the α factor (13 amino acids) and the a factor (12 amino acids) peptide hormones, respectively. The two types of cells are equipped also by surface receptors for the opposite mating type pheromones. The diploid cells lack these factors and receptors and do not fuse but may undergo meiosis and sporulate by releasing both α and a haploid cells.

The two mating types are coded by genes in chromosome 3 on the left and right sides of the centromere, respectively. These genes are clustered within the so-called mating type cassettes and are silent at their positions named *HML α* and *HMR a* locations. They are expressed when transposed to the mating-type site, *MAT*. At *MAT*, either the left *HML α* or the right *HMR a* cassette can be expressed within a particular homologous chromosome. The *MAT* site is approximately 2-kb and it is about 187 kb from *HML α* and at about 93 kb from *HMR a* .

(See Fig. M26 for the overall structure of the regions). In the outline the *MAT* site is shown empty but in reality either the *HML α* or by the *HMR a* cassette occupies it. When one or the other silent complex is unidirectionally transposed to the *MAT* site, the expressed *MAT α* and *MAT a* , respectively, are generated. At the original (left and right) locations the *Y α* (747 nucleotides) and the *Y a* (642 nucleotides) are kept in place and silent by the product of the *SIR1–4* gene (Silent Information Regulator). Actually four Sir proteins exist, 1, 2, 3 and 4. Repression is mediated also by the autonomous replication sequences (ARS) and the pertinent enhancer (E) elements. The transposition activity of a *MAT* cassette requires also the presence of nuclease hypersensitive sites in the flanking regions. The transposition at the *MAT* sites is initiated when the HO endonuclease makes a staggered cut at the *YZI* junction-generating strands with four base overhangs:

The *HO* gene is expressed only in the haploid cells but not in the diploids, and only at the end of the G1 phase of the cell cycle and both new cells have the same mating type and can transpose their mating type gene only after the completion of the next cell cycle. The product of gene *SIN1–5* represses the function of *HO* and the expression of gene *SWI–5* is required for the expression of *HO*. Mother cells selectively transcribe *HO*. In daughter cells, Ash1p suppressor

of *HO* may accumulate as a result of asymmetric mRNA distribution. For the actual mating the function of other (sterility, *STE*) genes are also needed. *STE2* and *STE3* are cell type-specific receptors of G proteins. *GPA1* encodes the $G\alpha$ subunit, *STE4* the $G\beta$ subunit and *STE18* the $G\gamma$ subunit. The $G\beta G\gamma$ subunits, after activation, regulate further downstream units of the pheromone-signaling pathway, including the kinases *STE20*, a series of MAP kinases (encoded by *STE11*, *STE7* and *FUS/KSS* genes). The Ste5p protein (encoded by *STE5*) is presumed to be a scaffold for organizing all the kinases.

Transposition involves pairing with the homologous *Z* sequences, followed by an invasion of a double-stranded receiving *Y* site and degradation of these *Y* sequences. Subsequently the *X* site is invaded. New DNA synthesis then takes place using as template the sequences of the invader molecule that is replacing the old DNA tract. Integration is mediated in the pattern of a gene conversion mechanism as suggested by the Holliday model of recombination.

The α mating type gene has two elements $\alpha 1$ (transcribed from right to left) that induces the α mating functions and $\alpha 2$ (transcribed in left to right similarly to *a*) that keeps in check the expression of the *a* mating type expression. The simultaneous expression of $\alpha 1$ and $\alpha 2$ represses also *SIR* and other haploid-specific genes. These processes recruit also proteins PRTF (Pheromone Receptor Transcription Factor) and GRM (General Regulator of Mating type) that recognize specific nucleotide sequences within the haploids and diploids. The $\alpha 2$ protein also interacts the MCM1 DNA binding and the MADS box proteins. The binding of *MAT $\alpha 2$* with MCM1 represses α -specific genes in haploids but in diploid cells *MAT $\alpha 2$* heterodimerizes with *MAT $\alpha 1$* and thus haploid-specific genes are repressed (see Nature [Lond] 391:660 for the structural interactions of these proteins). In *Candida albicans* (and some other fungi) an apparently evolutionarily more ancient regulation operates the basically identical mating type determination system (Tsong AE et al 2006 Nature [Lond] 443:415).

Whether *HML* or *HMR* switching occurs depends on the surrounding sequences and it is not intrinsic to the elements. *Mat a* cells recombine with *HML* almost an order of magnitude more frequently than

Figure M26. Mating type region in yeast

5'-GCTTT↓CGGCAACAGTATA-3' *MATa*
 3'-CGAAAGGCG↑TTGTCATAT-5'

5'-ACTTCGCGC AACA↓GTATA-3' *MATr*
 3'-TGAAGCGCG↑TTGTCATAT-5'

Figure M27. Nucleotide sequences in the *MAT* loci

with *HMR* (see Fig. M27). *MATa* cells recombine in 80–90% of the cases with *HMR*. The switching is controlled by 700-kb element 17-kb proximal to *HML* by a recombinational enhancer.

The expression of the mating type genes involves a complex cascade of events. The mating type protein factors interact with G protein-like receptors situated in the cell membrane. These G proteins then transduce the mating signals through a series of phosphorylation reactions to transcription factors that control the turning on/off genes mediating the cell cycle, cell fusion and conjugation. The industrial strains of yeast are frequently diploid or polyploid and may be heterozygous for mating type. In such a case, they fail to mate. If they are plated on solid medium, they may sporulate and the chromosome number will be reduced. ▶*Holliday model*, ▶*signal transduction*, ▶*cell cycle*, ▶*silencer*, ▶*HML* and *HMR* sex determination, ▶*Candida albicans*, ▶*pheromones*, ▶*MCM1*, ▶*MADS box*, ▶*homothallic*, ▶*heterothallic*, ▶*rare-mating*, ▶*regulation of gene activity*, ▶*Ty*, ▶*Schizosaccharomyces pombe*, ▶*ORC*, ▶*RAP1*, ▶*Abf*; Haber JE 1998 Annu Rev Genet 32:561; Dohlgan HG, Thorner JW 2001 Annu Rev Biochem 70:703; Rusche LN et al 2003 Annu Rev Biochem 72:481; Tsong AE et al 2003 Cell 115:389.

Matrilineal: Descended from the same maternal ancestor, e.g., the mtDNA. ▶*mtDNA*

Matrix: Solutes in cells, organelles or chromosomes, etc.; the *extracellular matrix* fills the space among the animal cells and it is composed of a meshwork of proteins and polysaccharides, secreted by the cells. The viral matrix connects the genomic core with the envelope. ▶*nuclear matrix*

Matrix Algebra: It deals with elements that are arranged as shown in the figure. A matrix with r rows and c columns is of order $r \times c$ or an $r \times c$ matrix. If $r = c$, it is a *square matrix* (see Fig. M28). A matrix with 1 row is *row vector* and a matrix with only 1 column is a *column vector*. A *weight matrix* can be generated for a particular motif by the use of Bayes' theorem. Each column in the matrix represents one position of the motif. Each row of the matrix corresponds to the probability that a corresponding, e.g., nucleotide, occurs at a position in the motif. Matrix algebra can be used for correlations, in numerical taxonomy, evolution, comparative genomics, etc. ▶*motif*,

Figure M28. Matrix arrangements

▶*Bayes's theorem*; Hays WL, Winkler RL 1970 Statistics: Probability, inference and decision. Holt, Rinehart and Winston, New York.

Matrix Attachment Region: ▶*MAR*

Matrix-Assisted Laser Desorption Ionization/Time of Flight/Mass Spectrometry (MALDI-TOF): A procedure for separation of DNA fragments mixed with a carrier that is painted subsequently on the surface of a solid face target. Laser desorbs and ionizes the fragments and acceleration in a mass spectrometer is used to determine fragment length. The MALDI-TOF procedure may detect as small as a nucleotide change in the length of a DNA sequence (ca. 100 perhaps 1,000 bp) or changes in the microsatellite numbers. This technique can be utilized in DNA sequencing, discrimination among mutations of a gene, for identification of STS. It may eventually be used also for clinical and diagnostic procedures. ▶*laser*, ▶*mass spectrum*, ▶*laser desorption mass spectrum*, ▶*microsatellite*, ▶*SNIPs*, ▶*proteomics*, ▶*STS*, ▶*TOFMS*, ▶*MALDI-TOF*; Shahgholi M et al 2001 Nucleic Acids Res 29:E91; Chu J et al 2001 Clin Chim Acta 311:95; Nordhoff E et al 2001 Electrophoresis 22:2844.

Matrix Diseases: These diseases periodically/seasonally reoccur, frequently in a somewhat different form such as the annual influenza epidemics or the occasional pandemics.

Matroclinous: The offspring resembles the mother because it developed either from an unfertilized egg or from an egg that underwent nondisjunction and carries two X chromosomes or from a female with attached X-chromosomes or by imprinting or dauermodification or due to sets of dominant genes or the failure of transmission of a particular chromosome through the sperm or caused by non-nuclear (mitochondrial, plastid) genes. ▶*Rosa canina*, ▶*chloroplast genes*, ▶*mtDNA*, ▶*mitochondrial genetics*

Matthiola (garden stock, wallflower): A cruciferous ornamental ($2n = 14$). Lethal factor (*l*), is tightly

linked to the simple flower character (*S*), has been of special interest (see Fig. M29). This causes the appearance of the “ever-segregating “full-flower” trait (*s*) in 1:1 proportions rather than in 3:1. By sophisticated breeding techniques and seed selection in trisomic offspring, the commercially available seed germinates and develops into nearly 100% full-flower/double flower plants that are, however, completely sterile due to the recessive lethal factor. Thus, the seed supply is entirely dependent on commercial sources. (See Kappert H 1937 Ztschr Ind Abst- Vererb-lehre 73:233; Roeder AHK, Yanofsky MF 2001 Dev Cell 1:4).

Figure M29. Matthiola

Maturases: Proteins that mediate a conformational change in the pre-mRNA transcript and cooperate in the splicing reactions. ▶introns, ▶mitochondrial genetics

Maturation Divisions: Same as meiosis.

Maturation of DNA: Phage proteins cut the linear, continuous DNA into pieces that can be accommodated by the phage capsids.

Maturation Promoting Factor: ▶MPF

Maurice of Battenberg: A hemophiliac grandson of Queen Victoria of England; son of carrier daughter Beatrice. ▶hemophilias

Mauriceville Plasmid: ▶*Neurospora* mitochondrial plasmids

MAVS: ▶RIG oncogene

MAX: A b/HLH/LZ (basic helix-loop-helix/leucine zipper) protein hetero-oligomerizes with the MYC oncoproteins, and this state is required for malignant transformation by c-MYC. MAX alone lacks the transactivator domain of MYC. Its DNA recognition site is CACGTG. MAX may be orchestrating the biological activities of b/HLH/LZ transcription factors. The basic α helices follow the major groove of the DNA in a *scissors grip*. ▶MYC, ▶helix-loop-helix, ▶RFX, ▶leucine zipper, ▶Mxi/Max, ▶major groove

Maxam-Gilbert Method: ▶DNA sequencing

Maxicells: Bacterial cells that lost most or their entire chromosomal DNA because of heavy irradiation by UV light. Therefore, they do not replicate their DNA. The plasmid they contain may have escaped the irradiation, and represents an appropriate replicon, and can carry on replication of that plasmid and direct the synthesis of plasmid-coded proteins. This makes such cells ideal for the expression of the plasmid-born protein without a background of cellular proteins. Especially useful are those maxi cells containing lambda vectors, which have sufficient expression of the phage repressor and thus do not permit λ protein expression. ▶mindless, ▶lambda phage, ▶replicon, ▶plasmids; Jemiole DK et al 1988 Methods Enzymol 164:691.

Maxicircle: The large mitochondrial genome. ▶mtDNA; Carpenter LR, England PT 1995 Mol Cell Biol 15 (12):6794.

Maximal Equational Segregation: It takes place when a gene is segregating independently from the syntenic centromere. It has particular significance in polyploids because it facilitates an increase of double (or multiple) recessive gametes and thus affects segregation ratios as a function of the map distance between gene and centromere. ▶autopolyploids, ▶trisomic analysis, ▶syteny, ▶polyploidy; Mather K 1935 J Genet 30:53; Rédei GP 1982 Genetics. Macmillan, New York.

Maximal Parsimony: ▶evolutionary tree

Maximal Permissive Dose: ▶radiation hazard assessment

Maximization of Gene Expression: It can be achieved by the selection or modification of optimal promoters or in prokaryotes by varying the bases immediately after the Shine-Dalgarno sequence or manipulation of the triplet preceding the first methionine codon. ▶regulation of gene expression, ▶regulation of protein synthesis, ▶Shine-Dalgarno

Maximum Likelihood Method Applied to Recombination Frequencies: The justification for the use of the maximum likelihood principle in estimating recombination frequencies is that the value obtained has the smallest variance among all procedures. The estimation is based on the maximization of:

$$\frac{n!}{a_1!a_2!\dots a_t!} (m_1)^{a_1} (m_2)^{a_2} \dots (m_t)^{a_t}$$

where n is the population size, $a_1\dots a_t$ stand for the number of individuals in the different phenotypic or genotypic classes, $m_1\dots m_t$ represent the expected proportions of individuals in classes $1\dots t$. After maximizing the logarithm of the likelihood (L)

expression with respect to the recombination fraction (p), we have:

$$L = C + a_1 \log m_1 + a_2 \log m_2 + \dots a_t \log m_t,$$

where C is a constant of the maximum likelihood that is eliminated upon differentiation:

$$\frac{dL}{dp} = a_1 \frac{d \log m_1}{dp} + a_2 \frac{d \log m_2}{dp} + a_t \frac{d \log m_t}{dp} = 0$$

For the coupling experiment (Table M3) below:

$$L = 4032 \log\left(\frac{1}{2} - \frac{1}{2}p\right) + 149 \log\left(\frac{1}{2}p\right) + 152 \log\left(\frac{1}{2}p\right) + 4035 \log\left(\frac{1}{2} - \frac{1}{2}p\right)$$

After maximization and differentiation:

$$\frac{dL}{dp} = \frac{4032}{1-p} + \frac{149}{p} + \frac{152}{p} - \frac{4035}{1-p} = 0 \text{ and } p = \frac{149 + 152}{8368} \cong 0.03597$$

The standard error s_p is calculated:

$$-\frac{1}{V_p} = S\left(mn \frac{d^2 \log m}{dp^2}\right)$$

Since

$$a \frac{d \log m}{dp}$$

was defined earlier, after a second differentiation and substitution (mn) for (a), we obtain:

$$-\frac{1}{V_p} = -\frac{n}{2} \times \frac{1}{1-p} + \frac{1}{p} + \frac{1}{p} + \frac{1}{1-p} = \frac{n}{p(1-p)} \cong \frac{8368}{0.034676} \cong 241,319$$

and hence

$$V_p = 0.000004143$$

and

$$s_p = \sqrt{V_p} \cong 0.00204$$

or by the general formula

$$s_p = \sqrt{\frac{p[1-p]}{n}}$$

Recombination in F_2 can also be estimated with the aid of the maximum likelihood principle and a coupling phase progeny will exemplify it (see Table M4):

Table M3. Hypothetical test cross examples

| | Parental | Recombinant | Recombinant | Parental | |
|-----------------------------|---------------------|---------------------|---------------------|---------------------|--------|
| Gametic genotypes → | AB | Ab | aB | ab | Σ |
| Observed in coupling | 4032 | 149 | 152 | 4035 | 8368 |
| Expected coupling | $\frac{1}{2}n(1-p)$ | $\frac{1}{2}n(p)$ | $\frac{1}{2}n(p)$ | $\frac{1}{2}n(1-p)$ | n |
| | Recombinant | Parental | Parental | Recombinant | |
| Gametic genotypes → | AB | Ab | aB | ab | Σ |
| Observed repulsion | 638 | 21,379 | 21,096 | 672 | 43,785 |
| Expected repulsion | $\frac{1}{2}n(p)$ | $\frac{1}{2}n(1-p)$ | $\frac{1}{2}n(1-p)$ | $\frac{1}{2}n(p)$ | n |

Table M4. Recombination in F_2 coupling

| | Parental | Recombinant | Recombinant | Parental | |
|--------------------|--------------------|--------------------|--------------------|----------------|---------|
| Phenotypic classes | AB | aB | Ab | ab | Σ |
| Expectation | $\frac{n}{4}(2+P)$ | $\frac{n}{4}(1+P)$ | $\frac{n}{4}(1-P)$ | $\frac{n}{4}P$ | n (1) |
| Observed | 663 | 36 | 40 | 196 | 935 |

$$L = 663 \log\left(\frac{1}{2} + \frac{1}{4}P\right) + 36 \log\left(\frac{1}{4} - \frac{1}{4}P\right) + 40 \log\left(\frac{1}{4} - \frac{1}{4}P\right) + 196 \log\left(\frac{1}{4}P\right) \quad (2)$$

Upon maximization:

$$\frac{dL}{dP} = \frac{663}{2+P} - \frac{36}{1-P} - \frac{40}{1-P} + \frac{196}{P} = 0 \quad (3)$$

This can be reduced:

$$\frac{663(1-P(P))}{2P-P^2-P^3} - \frac{76(2+P)(P)}{2P-P^2-P^3} + \frac{196(2+P-2P-P^2)}{2P-P^2-P^3} \quad (4)$$

Common denominator omitted and multiply

$$663(P-P^2) - 76(2P+P^2) + 196(2+P-2P-P^2) \quad (5)$$

Multiplication completed:

$$663P - 663P^2 - 152P - 76P^2 + 392 + 196P - 392P - 196P^2 \quad (6)$$

Terms summed up: $392 + 315P - 935P^2 = 0.0001585$
(close to zero)

$$\begin{array}{ccc} \uparrow & \uparrow & \uparrow \\ \text{(Designate terms)} & c & b & a \end{array} \quad (7)$$

The right side of eq. (7) can be determined only after solving the quadratic equation below:

$$\begin{aligned} P &= -b \pm \frac{\sqrt{b^2 - 4ac}}{2a} = 315 \pm \frac{\sqrt{99225 + 1466080}}{1870} \\ &= -315 \pm \frac{\sqrt{1565305}}{1870} = -315 \pm \frac{1251.1215}{1870} = \frac{-1566.1215}{1870} \\ &= -0.837498; \text{ after changing sign, } P = 0.837498 \end{aligned}$$

Thus $P = 0.837498$, and $\sqrt{P} = 0.9151492 = 1 - p$, and hence the recombination fraction $p = 1 - 0.9151492 = 0.0848508$.

The variance of P ,

$$V_P = \frac{2P[1-P][2+P]}{n[1+2P]} = 0.0004495,$$

where $n (= \Sigma) = 935$ and the variance of p ,

$$V_p = \frac{VP}{4P} = 0.0001342$$

and the standard error

$$s_p = \sqrt{V_p} = \sqrt{0.0001342} = 0.01158$$

Thus, the frequency of recombination between the two genes is $\sim 0.085 \pm 0.012$. Data may be entered at

step (6) to expedite routine calculations. ▶ [maximum likelihood principle](#), ▶ [recombination frequency](#), ▶ [F₂ linkage estimation](#), ▶ [information](#); Mather K 1957 The Measurement of Linkage in Heredity. Methuen, London, UK; Wu R, Ma C-X 2002 Theor Population Biol 61:349.

Maximum Likelihood Principle: It provides a statistical method for estimating the optimal parameters from experimental data. The best statistics for the computations is that it provides the smallest variance., E.g., the variance of the median of a sample is $\frac{\pi a^2}{2n}$ which is $\frac{\pi}{2} = 1.57$ times the size of the variance of the mean (\bar{x}). Therefore the mean is a much better characteristic of the population than the median. The binomial probability is expressed as: $\binom{n}{r} p^r (1-p)^{n-r}$ giving the probability (p) that (r) events occur in a sample of (n).

The relative probability of r/n events for different values of (p) is called the *likelihood*. The procedure that facilitates finding a population parameter (θ) that maximizes the likelihood of a particular observation is a *maximum likelihood procedure*. If the dispersion of a population follows the normal distribution, the variance $V = \sigma^2$, is a maximum likelihood estimator of the distribution of that population. All other methods need to be compared with and tested against this method before their results can be accepted and used.

Naturally, all statistics provide only predictions and not direct proof regarding the biological mechanism concerned. Therefore, careful collection of data, replications, sufficient sample sizes, etc., are indispensable for accuracy and predictability. The maximum likelihood mandates that the choice of the parameter (θ) makes the likelihood, $L(X_1, X_2, \dots, X_n | \theta)$ the largest value. Example: a random sample of 20 is obtained and among them, say 12 belongs to a particular class. We can hypothesize that the true frequency of this class is either (I): $p = 0.6$ or (II): 0.5 or (III): 0.7 . According to the normal distribution then:

$$\begin{aligned} \text{(I)} \binom{20}{12} (0.6)^{12} (0.4)^8 &= \frac{20!}{12!8!} (0.6)^{12} (0.4)^8 \\ &= 125.970 \times 0.002176782 \\ &\quad \times 0.00065536 \\ &\cong 0.17971 \end{aligned}$$

$$\begin{aligned} \text{(II)} \binom{20}{12} (0.5)^{12} (0.5)^8 &= \frac{20!}{12!8!} (0.5)^{12} (0.5)^8 \\ &= 125.970 \times 0.000244140 \\ &\quad \times 0.00390625 \\ &\cong 0.12013 \end{aligned}$$

$$\begin{aligned}
 \text{(III)} \binom{20}{12} (0.7)^{12} (0.3)^8 &= \frac{20!}{12!8!} (0.7)^{12} (0.3)^8 \\
 &= 125.970 \times 0.013841287 \\
 &\quad \times 0.00006561 \\
 &\cong 0.11440
 \end{aligned}$$

Obviously, hypothesis (I) has the maximum likelihood to be applicable to this case. After this simple demonstration, we can generalize the likelihood function as:

$$L(X_1, X_2, \dots, X_N | p) = \binom{N}{r} p^r (1-p)^{N-r}$$

where X are the samples, N = population size, p = probability, and $r = 0, 1, \dots, N$. The maximized likelihood is conveniently expressed by the logarithm of the likelihood function:

$$\log L = \log \binom{N}{r} + (r) \log(p) + (N-r) \log(1-p)$$

After differentiation to (p) and equating it to zero:

$$\frac{d}{dp} \log L = \frac{r}{p} - \frac{N-r}{1-p} = 0.$$

After bringing it to the common denominator:

$$\frac{r(1-p) - (N-r)p}{p(1-p)} = 0$$

The denominator omitted:

$r(1-p) - (N-r)p = 0 = r - rp - Np + rp$, and hence $p = r/N$ and this is the *maximum likelihood estimator* of p . Similarly, it can be shown that for a population in normal distribution the arithmetic mean of the sample $\left(\frac{\sum x_i}{N}\right)$ is the maximum likelihood estimator of the μ . The probability P for a multinomial distribution is: $\frac{N!}{x_1!x_2! \dots x_r!} p^x q^y r^z$ where p, q, r, \dots are the probabilities of X, Y, Z, \dots classes. Although we may not know these probabilities but we may have experimentally observed the classes (genotypes, alleles, etc.), and we can derive the likelihood function which permits the estimation of the parameters of p, q , etc. If in a random mating population the proportion of A is p^2 , that of B is $2pq$ and that of C is q^2 , we can write the likelihood function as:

$$L = \frac{N!}{A!B!C!} (p^2)^A (2pq)^B (q^2)^C$$

from which after logarithmic conversion and differentiation we can obtain the value of $p = \frac{2A+B}{2N}$ and $q = \frac{2C+B}{2N}$ and the variance $V_p = \frac{pq}{2N}$.

For an in-depth treatment of maximum likelihood, mathematical statistics monographs should be consulted. The maximum likelihood method is widely used in decision-making theory. In genetics, it is most commonly used for the estimation of recombination and allelic frequencies. (See maximum likelihood method applied to recombination frequencies, probability, information)

Maximum Parsimony: same as maximal parsimony.
▶evolutionary tree

Maximum Tolerated Dose (MTD): It does not cause more than 10% weight loss, does not cause clinical toxicity, death or disease that would shorten life span.

Maxizyme: A dimeric ribozyme

May-Hegglin Anomaly (Dohle leukocyte inclusions with giant platelets): An asymptomatic dominant granulocyte and platelet disorder resulting often in thrombocytopenia located to chromosome 22q12.3-q13.1. The locus is about 0.7 megabase DNA. In the granulocytes, spindle-shaped cytoplasmic inclusions have been observed that appear to be the depolarization relics of ribosomes. The Fechtner syndrome and the Sebastian syndrome share the major characteristics and the chromosomal location (22q13.3-q13.2). The non-muscle myosin heavy chain IIA (MYH9) mutations appear to account for the three diseases. The Alport syndrome shares some of the symptoms also although that is a different disease.
▶hemostasis, ▶platelet anomalies, ▶giant platelet; Martignetti JA et al 2000 Amer J Hum Genet 66:1449; Kelley MJ et al 2000 Nature Genet 26:106.

Maytansinoids: The extract of tropical trees or shrubs with an LDLo of 190 $\mu\text{g/kg}$ as intravenous dose for humans (see Fig. M30). Related compounds are rifamycin, streptovaricin, macrolides, etc.
▶magic bullet, ▶LDLo

Figure M30. Maytansin

MBD (methyl-binding domain): MBD proteins are members of the histone deacetylase complex and bind to DNA and remodel the chromatin resulting in

gene silencing. *Mbd2*⁻ homo or heterozygous mice displayed fewer intestinal tumors than the wild type for the gene. ▶[histone deacetylase](#), ▶[5-azacytidine](#); Sansom OJ et al 2003 Nature Genet 34:145.

MBF: ▶[Mbp1](#), ▶[Swi](#)

MBP: Maltose binding protein, encoded by gene *malE* (91 min) of *E. coli*.

Mbp: Megabase pair, 1 million base pair.

Mbp1 (mitotic binding protein): The components of the MBF (microtubule-binding factor) with Swi6, mediate S phase expression of the cell cycle. ▶[cell cycle](#), ▶[SBF](#), ▶[Swi](#); Iyer VR et al 2001 Nature [Lond] 409:533.

μC (microcurie): 3.7×10^4 dps [disintegration/second]. ▶[Curie](#), ▶[isotopes](#)

MCA (metabolic control analysis): The study of complex enzyme systems in response to any changes in substrate(s). It may facilitate the detection of thresholds potentially leading to disease. It may permit the classification of genes and protein regarding their role in metabolic networks and thus may help drug discovery. ▶[proteomics](#); Cascasnte M et al 2002 Nature Biotechnol 20:243.

McArdle's Disease: ▶[glycogen storage disease type V](#)

McCune-Albright Syndrome (MAS, GNAS1, 20q13.2): A pituitary neoplasia resulting from excessive secretion of growth hormone, caused by mutation and constitutive expression of the GTP-binding subunit (*G_s*) of a G-protein. It is characteristically a polyostotic fibrous dysplasia, café-au-lait skin lesion, and gonadotropin-independent gonadal precocious activation. MAS is generally not inherited, probably because germline *G_s*-activating mutations are lethal. It is believed that the somatic mutation in MAS patients occurs early in development, and therefore the clinical spectrum in each individual is determined by the tissue distribution of mutant-bearing cells (Rey RA et al 2006 Hum Mol Genet 15:3538). ▶[pituitary gland](#), ▶[pituitary tumor](#), ▶[G-proteins](#), ▶[securin](#), ▶[Albright hereditary osteodystrophy](#), ▶[pseudohypoparathyroidism](#), ▶[gonadotropin](#), ▶[café-aut-lait](#)

McDonald-Kreitman Hypothesis: The excess of replacement substitutions in the amino acids in proteins indicates that they are the consequences of selectively advantageous mutations. Reduction in non-synonymous mutations indicates that they are selected against. ▶[mutation neutral](#), ▶[amino acid replacement](#), ▶[Ka/Ks](#), ▶[selection inferred from DNA sequences](#); McDonald JH, Kreitman M 1991 Nature [Lond] 354:114.

MCF Oncogene (synonymous with DBL, ROS): The human mammary carcinoma proto-oncogene was assigned to human chromosome Xq27. It encodes a serine-phosphoprotein (p66). ▶[oncogenes](#), ▶[ROS](#)

MCH (melanin-concentrating hormone): MCH reduces appetite and increases metabolic rate. It encodes a neuropeptide precursor at 12q23 and PMCHL1 at 5p14 and PMCHL2 at 5q13 are truncated versions of MCH. ▶[obesity](#), ▶[leptin](#), ▶[melanin](#)

Mch: ICE-related proteases. ▶[ICE](#), ▶[apoptosis](#)

MCK: A muscle-specific kinase. ▶[MyoD](#)

MKusick-Kaufman Syndrome (MKKS, 20p12): A recessive developmental anomaly including accumulation of fluids in the uterus and vaginal area (hydrometrocolpos), extra finger at the area of the little finger (postaxial polydactyly), heart disease, etc. Several other genes map apparently to the same chromosomal location, e.g., that of the Bardet-Biedl (BBS) syndrome. The distinction between MKKS and BBS is by the three criteria named above. Some of the symptoms are shared also the Ellis-van Creveld syndrome that is at another chromosomal location. The critical protein appears to be a chaperonin. ▶[Bardet-Biedl syndrome](#), ▶[Ellis-van Creveld syndrome](#); David A et al 1999 J Med Genet 36:599; Slavotinek AM et al 2000 Nature Genet 26:15.

McLeod Syndrome (XK): A recessive human Xp21 region deficiency of the Kx blood antigen precursor. The symptoms vary because of overlapping defect with closely linked genes, particularly CGD (chronic granulomatous disease). It may be associated with acanthocytosis, characteristic for abetalipoproteinemia. ▶[abetalipoproteinemia](#), ▶[granulomatous disease chronic](#), ▶[Kell-Cellano blood group](#), ▶[contiguous gene syndrome](#)

MCM1 (licensing complex): A yeast DNA-binding protein, product of the minichromosome maintenance gene also involved in the regulation of mating type; it controls the entry into mitosis. All eukaryotes have apparently at least six different MCMs assisting in DNA replication. MCM 2–7—a putative helicase—appears to become activated in telophase before the exit cell cycle (Dimitrova DS et al 2002 J Cell Sci 115:51). Some have helicase and DNA-dependent ATPase function. Mcm10 is a component of the replication fork and apparently is required for the function of DNA polymerase-α (Ricke RM, Bielinsky A-K 2004 Mol Cell 16:173). The licensing actually means that the chromatin must be subject to quality control to qualify for replication after mitosis. MCM also prevents the re-entry into S phase. ▶[mating type determination in yeast](#), ▶[MCM3](#), ▶[ARS](#), ▶[Cdc45/Cdc46/Mcm5](#), ▶[cell cycle](#), ▶[CDC19](#), ▶[CDC21](#),

►Cdc6, ►Cdc18, ►Cdt1, ►geminin, ►reinitiation of replication, ►DNA polymerases, ►sex hormones; Tye BK 1999 Annu Rev Biochem 68:649; Lee J-K, Hurwitz J 2000 Proc Natl Acad Sci USA 98:54; Nishitani H et al 2001 J Biol Chem 276:44905.

MCM3: It is apparently the same as the replicational licensing factor (RLF), that appears in tight binding to DNA during interphase but released during S phase. This factor assures that within a cell just one cycle of DNA replication occurs. This protein belongs to the family of MCM1 to MCM5 factors detected in yeast. ►MCM1, ►replication licensing factor, ►cell cycle

MCP (membrane cofactor protein, CD46): MCP regulates (along with other proteins such as DAF, factor H and C-4 binding protein) complement functions and protects the cells from attacks by their own defense system. MCP and DAF control also reproductive functions (spermatozoa, extrafetal tissues) besides infectious diseases and xenografts. These functions are encoded in human chromosome 1q3.2 region. MCP (14 exons) has four isoforms generated by alternative splicing of a single transcript. MCP shares a 34 amino acid signal peptide with DAF (11 exons). The signal sequence is followed by *complement control protein repeats* (CCPR) where C3b and C4b complement components bind. Glycosylated and serines, threonines, prolines (STP) residues follow the CCPR sequences. The other regions of MCP and DAF are different. ►complement, ►decay accelerating factor, ►xenotransplantation, ►signal sequence, ►atherosclerosis; Kemper C et al 2001 Clin Exp Immunol 124(2):180.

MCP-1 (monocyte chemoattractant protein): It controls (along with IL-8) adhesion of monocytes to the vascular epithelium. It is inducible by the platelet-derived growth factor (PDGF). Mice lacking these receptors are more prone to atherosclerosis. ►atherosclerosis, ►chemokines, ►monocytes; Yamamoto T et al 2001 Eur J Immunol 31:2936.

MCR (mutation cluster region): A segment of a gene where mutations occur at high frequency.

mcr: ►methylation of DNA

MCS: Multiple cloning sites. ►polylinker

M-CSF: ►macrophage colony stimulating factor, ►macrophage

MDA (multiple displacement amplification): MDA can be carried out from crude whole blood or tissue culture cell. As small as 1–10 copies of human genomic DNA can be amplified to 20–30 microgram. It has been used for analysis of the entire genome of single microbial cells. The product is suitable for various genetic analyses such as SNP, Southern blots,

and various diagnostic purposes. ►amplification, ►SNP, ►Southern blot; Dean FB et al 2002 Proc Natl Acad Sci USA 99:5261.

Mda-7 (IL24): Encodes a cytokine, which selectively inhibits human melanoma cancer cells without conspicuous side effects. ►IL24; Fisher PB et al 2003 Cancer Biol Ther 2 Suppl 1:S23.

MDC1: A mediator of DNA checkpoint control. ►checkpoint, ►histone variants; Lou Z et al 2003 Nature [Lond] 421:957.

mdg: ►copia

mDIP (methylated DNA immunoprecipitation): It uses antibodies specific for 5-methylcytosine residues and the procedure can distinguish between some cancerous and normal tissues (Keshet I et al 2006 Nature Genet 38:149). ►landmark genomic scanning

Mdl1: A mitochondrial export protein of the AAA transporter family. ►AAA proteins

MDM2 (murine double-minute homolog, MDM2 is at 12q14.3-q15): A cellular oncoprotein that can bind and downregulate p53 tumor suppressor, attach to the retinoblastoma suppressor, and can stimulate transcription factors E2F1 and DP1, and thus may promote tumorigenesis. MDM2 is an E3 ubiquitin ligase that assists in the degradation of p53. The cis-imidazole analogs (nutlins) are antagonists of MDM2 and can activate the p53 pathway, leading to cell cycle arrest, apoptosis (see Fig. M31) and inhibition of tumor growth (Vassilev LT et al 2004 Science 303:844). Nutlin prevents the interaction of MDM2 with p53, and the growth of half of the cancers by the normal tumor suppressor function of p53 is restored (Harris C 2006 Proc Natl Acad Sci USA 103:1659; Tovar C et al 2006 Proc Natl Acad Sci USA 103:1888).

MDM2 can suppress TGF- β effect also without the inactivation of p53. MDM2 is regulated by RASA through the Raf/Mek/Map kinase pathway. Raf also activates p19^{ARF}, an inhibitor of MDM2. MDM2 involves TGF resistance in various tumor cell lines. MDM2 prevents transcriptional activation by Sp1 but the retinoblastoma protein displaces Sp1 from MDM2 and restores Sp1 transcriptional activity. The RING

Figure M31. MDM2 functions

domain of MDM2 may stimulate ubiquitins (Minsky N, Oren M 2004 Mol Cell 16:631). Loss of MDM2 or MDM4 leads to lethality in p53-dependent manner in the mouse. Mice lacking MDM2 in the central nervous system develops hydranencephaly after 14.5 days of pregnancy whereas lacking MDM4 results in porencephaly (cerebrospinal fluid-filled cavities of the brain) after 17.5 days of embryonic development. Both mutations can be rescued by inhibition of p53 (Xiong S et al 2006 Proc Natl Acad Sci USA 103:3226). Similar diseases are known also in humans that are encoded in different chromosomes. ►[oncogenes](#), ►[transcription factors](#), ►[retinoblastoma](#), ►[E2F](#), ►[DP1](#), ►[p53](#), ►[TGF](#), ►[cyclin G](#), ►[ubiquitins](#), ►[ARF](#), ►[apoptosis](#), ►[anencephaly](#), ►[endocytosis](#), ►[Zinc finger](#); Johnson-Pais T et al 2001 Proc Natl Acad Sci USA 98:2211.

MDR: ►[multidrug resistance](#)

MDS (macronuclear destined sequences): From the germline DNA during vegetative development of ciliates internal sequences are eliminated by the process of chromosome diminution and only the MDS is retained in the macronucleus. ►[chromosome diminution](#), ►[Paramecium](#), ►[macronucleus](#); Prescott DM 1997 Curr Opin Genet Dev 7:807.

Meal Worm (*Tenebrio molitor*): A larger X and a smaller Y chromosome in this insect determine sex. ►[anti-freeze protein](#)

Mealybug: A member of the coccidian taxonomic group of animals with the name reflecting the “mealy” appearance of the wax coat of the body of the insects and the mealy appearance of their colonies on the surface of plants (see Fig. M32). They received attention by the peculiarity of their chromosome behavior. During the cleavage divisions immediately after fertilization, all the chromosomes are euchromatic. After blastula one-half of the chromosomes ($2n = 10$) becomes heterochromatic in the embryos which develop into males. At interphase these heterochromatic chromosomes clump into a chromocenter. By metaphase, the heterochromatic and euchromatic sets are no longer distinguishable. In the males, the first meiotic division is equational and during the second division the two types of chromosomes go to opposite poles. Two of the four nuclei are heterochromatic and two euchromatic. The heterochromatic nuclei then disintegrate and the euchromatic cells proceed to

Figure M32. Mealybug

spermiogenesis. The euchromatic set of the fathers becomes later the heterochromatic chromosomes of the sons. This was verified by X-raying the females and males. Only 3% of daughters of males irradiated by 16,000 R survived but the sons were unaffected even after 30,000 R. Some sons survived even after 90,000 R exposure of the fathers. Thus, sex appears to be determined developmentally in these insects. ►[chromosomal sex determination](#); Nur U 1967 Genetics 56:375; Palotta D 1972 Can J Genet Cytol 15:809.

Mean: The *arithmetic mean* \bar{x} is equal to the sum (Σ) of all measurements (x) divided by the number (n) of all measurements, or $\bar{x} = \frac{\sum x}{n}$. The *geometric mean* (G) is the n th root of the product of all measurements: $G = \sqrt[n]{x_1 \cdot x_2 \cdot \dots \cdot x_n}$. The *harmonic mean* (H) is the inverse average of the reciprocals of the measurements $H = \frac{n}{\sum 1/x}$.

Examples:

$$\bar{x} = \frac{2 + 8}{2} = 5, G = \sqrt[3]{2 \times 8 \times 4} = \sqrt[3]{64} = 4,$$

$$H = \frac{2}{[1/2] + (1/8)} = 3.2.$$

The *weighted mean* is the calculated mean multiplied by the pertinent frequency of the groups in a population. (See variance)

Mean Lethal Dose: Mutagens or toxic agents are denoted by LD_{50} . ►[LD₅₀](#), ►[LDLo](#), ►[LC50](#)

Mean Squares: The average of the squared deviations from the mean; it is obtained by dividing the sum of the squared deviations by the pertinent degrees of freedom. Basically, this is the estimated variance. ►[variance](#), ►[variance analysis](#), ►[intraclass correlation](#)

Meander: When two consecutive β -sheets of a protein are adjacent and antiparallel. ►[protein structure](#)

Measles: An infectious viral disease, practically eliminated in the USA since compulsory vaccination was introduced in the 1960s. Sporadically—after importation from a foreign country—local measles outbreaks have however occurred (Parker AA et al 2006 N Engl J Med 355:447).

Measurement Units: Length: 10 ångström (Å) = 1 nanometer (nm), 1000 nm = 1 micrometer (µm), 1000 µm = 1 millimeter (mm), 10 mm = 1 centimeter (cm), 100 cm = 1 m.

Volume: 1000 microliter (µL or λ = 1 milliliter (mL), 1000 mL = 1 liter (L);

Weight: 1000 picogram (pg) = 1 nanogram (ng), 1000 ng = 1 microgram (µg), 1000 µg = 1 milligram (mg), 1000 mg = 1 gram (g), 10 g = 1 dekagram (dg), 100 dg = 1 kilogram (kg).

Generally: milli = 10^{-3} , micro = 10^{-6} , nano = 10^{-9} , pico (p) = 10^{-12} , fempto (f) = 10^{-15} , atto (a) = 10^{-18} and kilo (k) = 10^3 , mega (M) = 10^6 , giga (G) = 10^9 and tera (T) = 10^{12} . ▶*M_i*, ▶dalton, ▶agricultural measures; Unit Converter: [http:// mypage.bluewin.ch/berthod/vuc/](http://mypage.bluewin.ch/berthod/vuc/).

MEC: ▶degenerin, ▶ion channels

MEC1: A kinase locus of yeast (member of the PIK family); its phosphorylates RAD53 and RAD9, signal transducers of DNA damage. Mec3 protein seems to regulate telomere length. Mec1 and Rad53 are also involved in the G1, S and G2 checkpoint control. Tel1 can carry out the Mec1 function also. The homologs are *SAD3*, *ESR1*, and the human gene is homologous to AT, responsible for ataxia telangiectasia. ▶ataxia, ▶RAD, ▶signal transduction, ▶DNA replication, ▶cell cycle, ▶checkpoint, ▶double-strand break, ▶PIK, ▶telomeric silencing; Tercero JA, Diffley JFX 2001 Nature [Lond] 412:553; Lopes M et al 2001 Nature [Lond] 412:557.

Mechanism-based Inhibition: ▶regulation of enzyme activity

Mechanosensory Genes: These are involved in the neurobiological control of proprioceptive sensations. The proprioceptive nerve terminals are located in the muscles, joints, tendons and the ears and perceive the information about movements, touch, balance and hearing. The process converts mechanical forces into electrical signals through special ion channels. ▶zona pellucida

Mecillinam: A β -lactam type antibiotic, which targets the penicillin-binding protein 2 (PBP2) required for the elongation of the bacterial cell wall. ▶ β -lactamase

Meckel Syndrome (MKS): A rare complex recessive syndrome (MKS1, 17q22-q23) with most specific characteristics are the brain defects, cystic kidneys and polydactyly. MKS1 is also called the Meckel-Gruber syndrome. In Finnish populations, it may occur however in the near 10^{-4} range. The mouse homolog is at chromosome 11; similar genes occur in the majority of organisms and appear to have ciliary functions (Kyttälä M et al 2006 Nature Genet 38:155). MKS genes were located also at 11q13, and at 8q21.13-q22.1. The latter encodes a 995-amino acid seven-transmembrane receptor protein (meckelin) of unknown function (Smith UM et al 2006 Nature Genet 38:191). ▶neural tube defects, ▶polydactyly, ▶kidney diseases, ▶cilia, ▶Joubert syndrome

MeCP1 (methyl-CpG binding protein, MBD1): It binds methylated CpG sequences in the DNA and is part of a transcriptional repression complex along with histone deacetylase. It is encoded at human chromosome 18q21. ▶CpG, ▶islands, ▶histone deacetylase, ▶methylation of DNA

MeCP2: methyl-CpG binding protein encoded at Xq28 and it is involved with the Rett syndrome autism. It seems to be involved in brahma-containing SWI/SNF chromatin remodeling system (Harikrishnan KN et al Nature Genet. 38:964). ▶autism, ▶brahma, ▶Rett syndrome; Chen WG et al 2003 Science 302:885.

MED-1: ▶null promoter

Medaka (*Oryzias latipes*): A small, fertile fish (see Fig. M33) well suited for developmental studies because it is genetically pigment-free (due to four recessive genes). Transparent stock is available that permits the direct visualization through a stereoscopic microscope, the major internal organs (heart, spleen, blood vessels, liver, gut, gonads, kidney, brain, spinal cord, eye lens, air bladder, etc.) in live animals. Medaka draft genome (700 megabases), is less than half of the zebrafish genome and 20,141 genes are predicted (Kasahara M et al 2007 Nature [Lond] 447:714). ▶zebrafish; Wakamatsu Y et al 2001 Proc Natl Acad Sci USA 98:10046; ▶pufferfish; [http:// medaka.utgenome.org](http://medaka.utgenome.org).

Figure M33. Medaka female (courtesy of Dr. Yuko Wakamatsu)

Medea Factor (maternal effect dominant embryonic arrest): A lethality factor transmitted through the egg cytoplasm, which kills the offspring, in, e.g., *Tribolium*, unless it inherits from either parent a rescuing M factor. ▶killer genes, ▶*Tribolium*; Beman RW, Fries KS 1999 Heredity 82:529; Grossniklaus U et al 1998 Science 280:446.

Median: A statistical concept that indicates that equal numbers of (variate) observations are on its sides at both minus and plus directions. ▶mean, ▶mode

Median-Joining Networks: A statistical procedure for reconstructing phylogenies from intra-specific data. The difficulties are in the large required sample sizes and small genetic differences and a network of potential evolutionary paths overcomes these obstacles to construct simple evolutionary trees. It proved useful for the analysis of mitochondrial DNA phylogenies (Bandelt HJ et al 1999 Mol Biol Evol 16:37).

Mediator: Assembly factors of RecA and like recombinases and single-strand DNA binding proteins. The mediator of the GAL gene of yeast is associated with

the upstream activator sequences and not with the core promoter or with TBP or TFIID (Kuras L et al 2003 Proc Natl Acad Sci USA 100:13887). ►[RecA](#), ►[core promoter](#), ►[UAS](#), ►[TBP](#), ►[transcription factors](#); Gasior SL et al 2001 Proc Natl Acad Sci USA 98:8411.

Mediator Complex (Meds): A group of ~20 or more proteins involved in the facilitation of transcription by RNA polymerase II in yeast and other eukaryotes (see Bjorklund S et al 1999 Cell 96:759). The mediator complex is a co-activator, co-repressor and a general transcription factor. These proteins share subunits and participate in a large variety of different complexes, which have different functions in gene expression and developmental control. They may mediate chromatin remodeling, interact with various proteins (activators), general transcription factors and directly or indirectly with RNA polymerase II. One form of RNA polymerase II includes an additional polypeptide, Gdown1 and it is called Pol II(G). The latter type of polymerase definitely requires the Mediator for efficient transcription (Hu X et al 2006 Proc Natl Acad Sci USA 103:9506). The yeast Mediator proteins interacting with Med17(Srb4) as a 223 kDa complex is called a *mediator head module*. It interacts with an RNA polymerase II-TFIIF complex, but not with the polymerase or TFIIF alone. This interaction is lost in the presence of a DNA template and associated RNA transcript, recapitulating the release of Mediator that occurs upon the initiation of transcription (Takagi Y et al 2006 Mol Cell 23:355). MSA specifically restricts PIC (preinitiation complex) function in the absence of the Mediator. This function is fully restored in the presence of the Mediator, indicating that Mediator dependency in the metazoan cell is imparted, at least in part, through factors that negatively modulate unregulated PIC function. That one such activity resides in a complex containing hSpt5 and hSpt4, which were previously identified as components of the transcription elongation factor DRB sensitivity-inducing factor DSIF (Malik S et al 2007 Proc Natl Acad Sci USA 104:6182). ►[Srb](#), ►[DRIP](#), ►[NAT](#), ►[chromatin remodeling](#), ►[activator proteins](#), ►[transcription factors](#), ►[TBP](#), ►[TAF](#), ►[co-activator](#), ►[re-initiation](#), ►[elongator](#), ►[preinitiation complex](#), ►[DRB](#), ►[DSIF](#), ►[PIC](#); Svejstrup JQ et al 1997 Proc Natl Acad Sci USA 94:6075; Gustafsson CM et al 1998 J Biol Chem 273:30851; Myers LC, Kornberg RD 2000 Annu Rev Genet 69:729; Gustafson CM et al 2001 Mol Microbiol 41:1; Boube M et al 2002 Cell 110:143; Conaway RC et al 2005 Trends Biochem Sci 30:250.

Medicago: ►[alfalfa](#)

Medical Error: It kills 44,000 to 98,000 people in US hospitals annually (Hayward RA, Hofer TP 2001 J Am Med Assoc 286:415).

Medicine: ►[diseases in humans](#), ►[preventive medicine](#); history and encyclopedia of medicine: <http://www.mic.ki.se/History.html>.

Medicinal Chemistry: It is involved with drug design and development.

Mediterranean Fever, Familial (FMF): A human chromosome-16p13 recessive disease with recurrent spells of fever, pain in the abdomen, chest and joints and red skin spots (erythema). It is a type of amyloidosis. The basic defect involves a 781-amino acid protein, pyrin. In some populations the prevalence, gene frequency and carrier frequency may be 0.00034, 0.019, and 0.038, respectively. ►[amyloidosis](#); Schaner P et al 2001 Nature Genet 27:318.

Medline: A medical bibliographic system of the National Library of Medicine USA. It can be reached on-line as part of the MEDLARS database, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?DB=pubmed>. ►[BITOLA](#)

MedMiner: It extracts and organizes relevant sentences in the scientific literature based on a gene, gene-gene or gene drug query. (See <http://discover.nci.nih.gov/textmining/main.jsp>).

medRNA: mini-exon-dependent RNA. ►[Trypanosoma brucei](#)

Medulla: The inner part of organs, the basal part of the brain connecting with the spinal chord. ►[brain human](#)

Medullary Bone: An ephemeral tissue inside the long bones of female birds. It is formed during ovulation by the increased level of estrogen. Its role is to accumulate calcium that is mobilized for the building of eggshells.

Medulloblastoma (17p13.1-p12, 10q25.3-q26.1, 1p32): A brain cancer of childhood. Its frequency in adenomatous polyposis increases by about two orders of magnitude. Dysregulation of the sonic hedgehog signaling may lead to the disease. ►[Gardner](#)

syndrome, ►nevoid basal cell carcinoma, ►squamous, ►sonic hedgehog

Meekrin-Ehlers-Danlos Syndrome: A connective tissue disorder.

MEF: A series of myocyte enhancer binding factors that specifically potentiate the transcription of muscle genes and thus differentiation of various types of muscles and myoblasts. The MEF group belongs to the family of MADS domain protein. MEF2 is a Ca^{2+} -regulated transcription factor and it is actively transcribed during development of the central nervous system. MEF2 is activated when it dissociates from histone deacetylase in response MAPK signals. Nur77 and Nor1 steroid receptors mediate apoptosis of T cell receptors controlled by MEF2. Mutation in MEF-2 may lead to coronary heart disease and myocardial infarction (Wang L et al 2003 Science 302:1578). The MEF2C is involved in inflammation responses and it is stimulated by lipopolysaccharides of Gram-negative bacteria. MEF2C transactivation is regulated through phosphorylation by p38. ►MADS box, ►MAPK, ►MyoD, ►MYF5, ►MRF4, ►myocyte, ►p38, ►Gram-negative, ►Nur77, ►Nor1, ►apoptosis, ►coronary heart disease, ►myocardial infarction, ►T cell; Mora S et al 2001 Endocrinology 142:1999; Han A et al 2003 Nature [Lond] 422:730; regulation of excitatory synapses: Flavell SW et al 2006 Science 311:1008.

Megabase (Mb): 1,000,000 nucleic acid bases.

Megablast: ►BLAST; <http://genopole.toulouse.inra.fr/blast/megablast.html>.

Megabyte (MB): 1 megabyte is 1024 K (1 K= 1024 bytes [2^{10}]; 1 byte = 8 bits [binary digits]). Conversion of pages into MB may be affected substantially by font size, formatting, size of the window, illustrations included, etc.

Megadalton (Mda): Mda is 10^6 dalton; 1 da (or Da) = 1.661×10^{-24} g.

Megalencephalic Leukoencephalopathy (MLC, 22qtel): The recessive enlargement of the brain, defective motor functions (ataxia, spasms) and mental deterioration caused by defects in a transmembrane protein. Onset is within a year of birth and a slow progressive realization of the symptoms follows.

Megaevolution: The process and facts of descent of higher taxonomic categories. ►evolution, ►macroevolution

Megagametophyte: One of the four, the functional, haploid products of female meiosis (megaspores) in

plants, it develops into embryo sac. Its origin and most prevalent developmental paths are outlined in a figure at gametophyte. ►gametophyte [female]

Megakaryocytes: Large cells in the bone marrow with large lobed, polyploid nuclei; their cytoplasm produces the platelets. Megakaryocyte formation from stem cells is regulated by surviving, the cytokine receptor cMpl and its ligand the megakaryocyte lineage-specific growth factor (meg-CSF), which is homologous to erythropoietin and has both meg-CSF and thrombopoietin-like activities. ►erythropoietin, ►thrombopoietin, ►platelet, ►survivin

Megalin: A cell surface apolipoprotein-B receptor. Its deficiency may lead to holoprosencephaly. There is some disagreement concerning megalin-mediated pathway of sex steroid movement (Rosner W 2006 Cell 124:455; Willnow TE, Nykjaer A 2006 Cell 124:456). ►holoprosencephaly, ►cholesterol, ►apolipoprotein; Barth JL, Argraves WS 2001 Trends Cardiovasc Med 1:26.

Megaloblast: Large, nucleated, immature cells giving rise to abnormal red blood cells.

Megaloblastic Anemia: The autosomal dominant (human chromosome 5q11.2-q13.2) deficiency of dehydrofolate reductase (involved in the biosynthetic path of purines and pyrimidines) resulting in hematological and neurological anomalies. Megaloblastic anemia 1 (MGA1, 14q32) is a vitamin B12 absorption defect. The symptoms may be alleviated by 5-formyltetrahydrofolic acid. A rare recessive type (10p12.1) is caused by intestinal malabsorption of vitamin B₁₂, due to defects in cubilin, the intrinsic factor (IF)-B₁₂ receptor. In the Imerslund-Grasbeck syndrome (11q12) the vitamin 12 deficiency is not corrected by cubilin alone but with co-administration of B12 it is effective (Tanner SM et al 2005 Proc Natl Acad Sci USA 102:4130).

Another form (TRMA, Rogers syndrome, 1q23.2-q23.3) responds favorably to thiamin. In chromosome 5p15.3-p15.2 methyl-cobalamine and methionine synthase reductase have been located. Megaloblastic anemia may be found in several other syndromes too. ►phosphatase [ACPI], ►megaloblast, ►folic acid, ►thiamin, ►anemia, ►transcobalamine deficiency; Tanner SM et al 2003 Nature Genet 33:426.

Megalocytosis: Induction of gradually increasing cell size.

Megaspore: ►megagametophyte, ►gametogenesis, ►megasporocyte

Megaspore Competition: It determines which of the four products of meiosis (megaspore) in the female (plant)

becomes functional (see Fig. M34). It occurs only in a few species such as *Oenotheras*. ►certation, ►pollen, ►gametogenesis

Figure M34. Megaspore competition in the *Oenotheras* where normally the top spore of the tetrad is functional but in case there is a deleterious gene in the top spore, the basal spore may compete with it successfully. (After Renner O. from Goldschmidt R 1928 Einführung in die Vererbungswissenschaft. Springer-Vlg. Berlin, Germany)

Megaspore Mother Cell: A diploid cell that produces the haploid megaspores through meiosis in the female plant (see Fig. M35). ►gametophyte [female]

Figure M35. Megaspore mother cell

Megasporocyte: The same as megaspore mothercell. ►gametogenesis, ►gametophyte

MEI41: A 270-kDa *Drosophila* phosphatidylinositol kinase. When inactivated meiotic recombination is reduced. ►PIK

Meiocyte: The cell that undergoes meiosis. ►meiosis

Meiosis: The two step-nuclear divisions, which reduce somatic chromosome number ($2n$) to half (n) and is usually followed by gamete formation. (See Fig. M36). Meiosis is genetically the most important step in the life cycle of eukaryotes. Meiosis proceeds

from the 4C sporocyte (in diploids) and includes one numerically reductional and one numerically equational chromosome divisions.

Synapsis takes place at prophase I to metaphase I. Chiasmata may be visible by the light microscope during prophase I. Centromeres do not split at anaphase I and the sister-chromatids are held together at the centromeres during the separation of the bivalents at anaphase I. At the completion of meiosis I the chromosome number is reduced to half ($2C$) and by the end of meiosis II, the C-value of each of the 4 haploid daughter cells is 1. The major stages of meiosis are shown in the diagram. These stages are rather transitional than absolutely distinct. The nucleolus is not shown. The nuclear membrane is generally not discernible by the light microscope from metaphase to anaphase but reappears at telophase. Dashed and solid thin lines represent the spindle fibers. The genetic consequences of the meiotic behavior of the chromosomes are best detected in ascomycete fungi with linear tetrads.

The duration of meiosis generally much exceeds that of mitosis and the longest is the prophase stage. In the majority of plants, the completion of mitosis requires 1–3 hours whereas meiosis may need from 1–8 days. In yeast, meiosis takes place in about 7 hours. The stages most revealing for the cytogeneticist, pachytene (2–8), diplotene (0.5–1), metaphase I (1.5–2), and anaphase I (0.5–1) require generally the number of hours indicated in parenthesis (see Fig. M37). In human females meiosis begins at the early embryonic stage (in mice ovaries it is microscopically detectable by day 12.5) and it stalls at the late prophase stage, at dictyotene, and the subsequent divisions take place only before the onset of ovulations (and following fertilization), a period repeated approximately 13 times annually during about 40 years. In males, meiosis is initiated in the testes only after birth. In both ovaries and testes, the onset of meiosis is under the control of gene *Stra8* (*stimulated by retinoic acid gene 8*). Retinoic acid is key regulator of the initiation of meiosis in both sexes (Koubova J et al 2006 Proc Natl Acad Sci USA 103:2474).

The activation of meiosis requires C_{29} sterols in both male and female. In *Schizosaccharomyces pombe* starvation initiates the switch from mitosis to meiosis. Starvation stimulates the expression of the *ste11* gene through cAMP-dependent protein kinase. Ste11 protein activates many genes, including *mei2*, which produces an RNA-binding protein. The meiRNA is transcribed from gene *sme2*. Mutant *ste11* cannot support meiosis. The Mmi1 RNA-binding protein is required for the elimination of RNA conducive to meiosis. Actually, a larger number of mRNAs must be blocked for meiosis to proceed

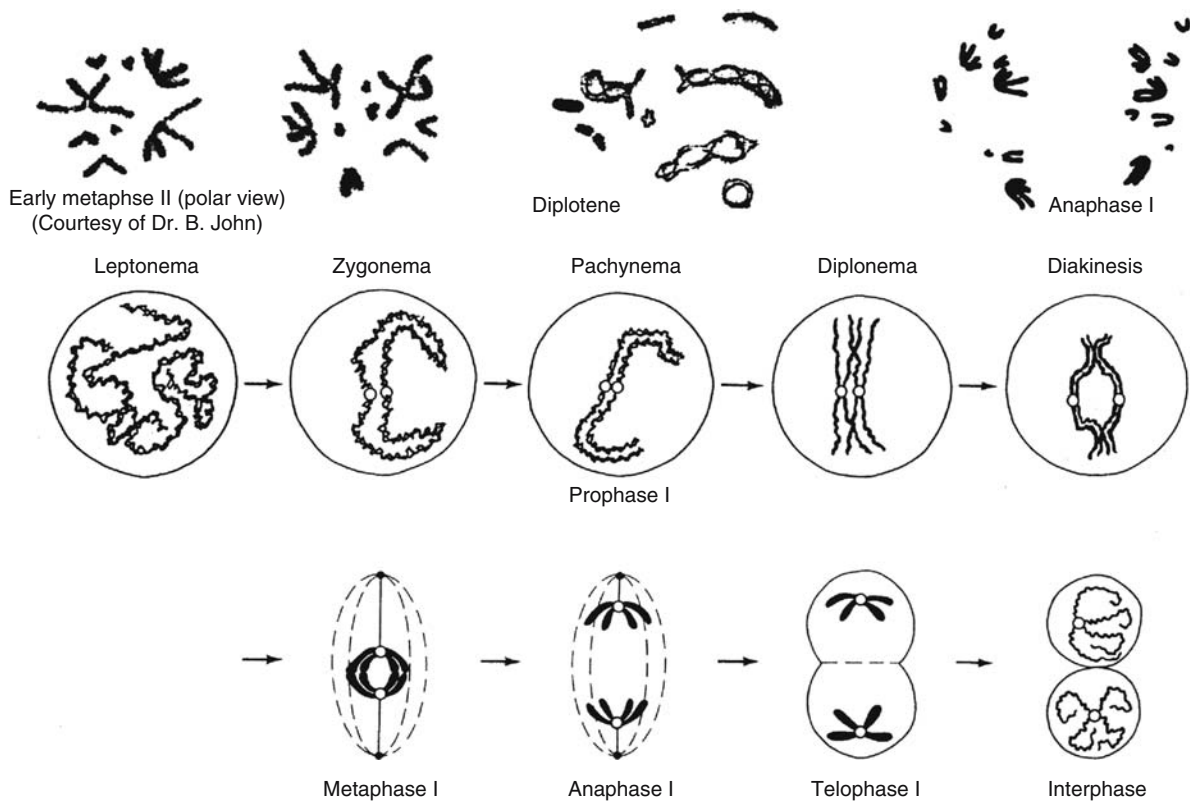

Figure M36. A generalized course of meiosis represented by only one pair of chromosomes with characteristic photomicrographs of the male grasshopper *Chortippus paralellus*

Figure M37. The four male meiotic products in plants

(Harigaya Y et al 2006 Nature [Lond] 442:45). Under such conditions protein kinase Pat1/Ran1 is inactivated by the expression of the *mei3⁺* gene. The substrate of this kinase is the RNA-binding protein Mei2. Dephosphorylation of Mei2 protein also causes a change from mitosis into meiosis. Mei2 is required for premeiotic DNA synthesis and the polyadenylated meiRNA promotes the first nuclear division. Mei2 is localized in the cytoplasm in mitotic cells but during meiotic prophase, it has been visualized in the microtubule-organizing center. Meiosis in budding yeast is controlled by about 150 genes but meiosis affects the expression of over ten times more loci.

Maternal mRNA is transmitted and stored in the egg and it is selectively translated after fertilization during the early stages of embryogenesis. Testicular mRNA is present in the sperm and it is translated postmeiotically. The translation is developmentally regulated, depending on the nature of the genes concerned (Iguchi N et al 2006 Proc Natl Acad Sci USA 103:7712). ▶leptotene, ▶zygotene, ▶pachytene, ▶diplotene, ▶diakinesis, ▶metaphase, ▶anaphase, ▶cohesin, ▶separin, ▶shugoshin, ▶interphase, ▶tetrad analysis, ▶mitosis, ▶dictyotene, ▶nucleolus, ▶cell cycle, ▶gametophyte, ▶C amount of DNA, ▶Ran1, ▶Pat1, ▶Cdc28, ▶sister chromatid cohesion, ▶monopolin, ▶recombination; Zickler D, Kleckner N 1998 Annu Rev Genet 32:619; Zickler D, Kleckner N 1999 Annu Rev Genet 33:603; Rabitsch KP et al 2001 Curr Biol 11:1001; Davis L, Smith GR 2001 Proc Natl Acad Sci USA 98:8395; Forsburg S 2002 Mol Cell 9:703; Nakagawa T, Kolodner RD 2002 J Biol Chem 277:28019; Nakagawa T, Kolodner RD 2002 J Biol Chem 277:28019; Lemke J et al 2002 Am J Hum Genet 71:1051, general and species-specific features of meiosis: Gerton JL, Hawley RS 2005 Nature Rev Genet 6:477.

Meiosis I: It is the first stage of meiosis when through reduction of the chromosome number the 4C amount of DNA in the meiocyte takes place and each of the two daughter nuclei has 2C amounts of DNA. During meiosis I, the sisterchromatids are held together at the centromere by the protective action of the shugoshin proteins until meiosis II. Shugoshins are localized to the centromere by the kinase Bub1 (Vaur S et al 2005 Curr Biol 15:2263). The cohesin protein complex mediates the cohesion of the sisterchromatids. This complex includes protein Scc1. During meiosis, Rec8 replaces Scc1 and Rec8 persists until metaphase II. Anaphase promoting complex (APC) mediates the degradation of securin, which releases Esp1 endopeptidase and that in turn cleaves Scc1 and leads to the termination of the cohesion (Kitajima TS et al 2004 Nature [Lond] 427:510). ▶meiosis, ▶C amount of DNA, ▶cohesin, ▶securin, ▶cohesin, ▶separin, ▶shugoshin, ▶Esp1, ▶Bub1, ▶Scc, Fig. M36.

Meiosis II: It follows meiosis I, and is basically an equational division of the chromosomes resulting in four daughter nuclei of the meiocyte that each have only 1C amount of DNA. Mes1 protein is essential for the completion of meiosis II but it is non-essential for mitosis. ▶meiosis, ▶cohesin, ▶separin, ▶shugoshin, ▶C amount of DNA, ▶CDC13

Meiotic Drive: It results in unequal proportions of two alleles of a heterozygote among the gametes in a population because certain meiotic products are not or less functional and consequently the proportion of other gametes increases. In spite of the preferential transmission of the segregation distorters, the various populations display fewer carriers of the distorter than expected. Meiotic drive usually requires the *drive locus* (with driving and non-driving alleles) and the *target locus* (with sensitive and resistant alleles). These two loci are usually tightly linked in repulsion. Coupling the drive and sensitive alleles is expected to eliminate the system. These loci are usually within inversions and they involve the sex chromosomes more commonly than the autosomes probably because the two sex chromosomes (X and Y) in *Drosophila* do not recombine, except in pseudoautosomal region. Meiotic drive may become a microevolutionary factor because it may alter gene frequencies. Meiotic drive may favor selectively disadvantageous gene combinations and thus may contribute to the genetic load of a population. Meiotic drive may be subject to genetically determined modification. Meiotic drive operates in the males or in the females but not in both. In the mouse, cytoplasmic factors may affect meiotic drive and it has been attributed also to the effect of the paternal allele of the *Om (ovum)* locus by inducing the maternal allele to go preferentially to the polar body after fertilization. Meiotic drive may be caused by

deletions from the pericentromeric heterochromatin of the X chromosome and Y chromosome—autosome translocations. X-linked insertions containing the 240-bp rRNA intergenic spacer or the rRNA genes may restore the normal conditions. The failure of pairing in the pseudoautosomal region causes meiotic drive and XY nondisjunction. Meiotic drive may be detected by sperm typing. ▶segregation distorter, ▶preferential segregation, ▶spacer DNA, ▶rRNA, ▶pseudoautosomal, ▶polarized segregation, ▶certation, ▶megaspore competition, ▶genetic load, ▶transmission, ▶polycystic ovarian disease, ▶symbionts hereditary, ▶killer strains, ▶brachyury, ▶sexual dimorphism, ▶sexual selection, ▶sex-ratio, ▶sperm typing, ▶mitotic drive; Hurst GD, Werren JH 2001 Nature Rev Genet 2:597; Jaenike J 2001 Annu Rev Ecol Syst 32:25.

meiRNA: The polyadenylated meiotic RNA cooperates with meiotic non-phosphorylated protein Mei2 to promote premeiotic DNA synthesis and nuclear division. ▶meiosis, ▶Pat1, ▶Ran; Ohno M, Mattaj IW 1999 Curr Biol 9:R66.

Meisetz: A meiosis-induced factor containing a PR/SET and a zinc-finger domain is a histone methyltransferase required for the progression of early meiotic prophase. The PR/SET domain is the catalytic domain of histone methyltransferases. It only trimethylates lysine 4 of histone H3. It is important for the formation of sex body, fertility, homologous chromosome pairing and double-strand DNA repair. ▶histone methlyltransferases, ▶sex body; Hayashi K et al 2005 Nature [Lond] 438:374.

MEIV (multilocus exchange with interference and viability): A statistical model of recombination and achiasmate segregation in tetrads. (See Zwick ME et al 1999 Genetics 152:1615).

MEK: A member of the extracellular signal-regulated kinase (ERK) family. About 30% of human cancers have activated MEK1 and MEK2 tyrosine/threonine protein kinase activity. The similar structures have a pocket that binds inhibitors, causes conformational changes in the unphosphorylated proteins and inhibition (Ohren JF et al 2004 Nature Struct Mol Biol 11:1192). ▶signal transduction, ▶BRAF, ▶MAPK, ▶MP1, ▶Cranio-facio-cutaneous syndrome; Widmann C et al 1999 Physiol Rev 79:143.

MEKK (196-kDa protein serine/threonine kinase): MEK kinase (i.e., a kinase kinase). ▶MEK, ▶signal transduction; Yujiri T et al 1998 Science 282:1911.

MEL Oncogene: Isolated from human melanoma although its role in melanoma is unclear; it was assigned to the broad area of human chromosome 19p13.2-q13.2). ▶melanoma, ▶oncogenes, ▶p16^{INK4}

Melancholy: Severe depression (seeing the world bitter dark; melano: dark, chole: bile). Increased level of norepinephrin appears in the cerebrospinal fluid and increases the chances for heart failure (Gold PW et al 2005 Proc Natl Acad Sci USA 102:8303). ▶depression, ▶animal hormones

Melandrium (synonymous with *Lychnis*, *Silene*): A dioecious plant (see Fig. M38) ($2n = 22 + XX$ or $22 + XY$). *Caryophyllaceae*. ▶intersex, ▶*Lychnis*; Lardon A et al 1999 Genetics 151:1173; Lebel-Hardenack S et al 2002 Genetics 160:717.

Figure M38. *Melandrium*

Melanin: ▶albinism, ▶pigmentation of animals, ▶piebaldism, ▶agouti, ▶hair color, ▶melanosome

Melanie: A computer software package that can match two-dimensional protein gel data to information in database. ▶databases, ▶annotation; <http://www.expasy.org/melanie/>.

Melanism: Increased production of the dark melanin pigment. ▶melanin, ▶industrial melanism, ▶*Biston betularia*

Melanocortin: Synthesized as a complex pre-pro-opiomelanocortin, which by processing contributes to the formation of the adrenocorticotropin hormone (ACTH), melanocyte-stimulating hormone (MSH) and β -endorphin. UV-induction of POMC/MSH under the control of p53 regulates the response of the cells to ultraviolet light by tanning (Cui R et al 2007 Cell 128:853). MSH regulates the brain melanocortin-4-receptor (MC4R) and thereby leptin. Haplo-insufficient, morbid autosomal (18q29) mutation in MC4R leads to obesity in the carriers. The agouti and related gene products are natural antagonists of the MC4R ligand MSH. In many fair-skinned individuals melanocortin 1 receptor (MC1R) is not functional and therefore lack protection against UV light that would be secured by tanning. In this case melanocyte-stimulating hormone fails to stimulate pigmentation in the keratinocytes (see Fig. M39). In red/blonde mice forskolin application can restore pigmentation even in the absence of UV and functional MC1R. This information indicates the

Figure M39. Mice pigmentation

topical application of this chemical can protect against skin damage and cancer (D'Orazio JA et al 2006 Nature [Lond] 2006 443:340). ▶opiocortin, ▶ACTH, ▶melanocyte stimulating hormone, ▶POMC, ▶p53, ▶leptin, ▶endorphin, ▶agouti, ▶pigmentation of animals, ▶nociceptor, ▶haplo-insufficient, ▶hyperphagia, ▶melanoma, ▶forskolin, ▶keratin, ▶tanning, ▶ultraviolet light; Huszar D et al 1997 Cell 88:131; Kistler-Heer V et al 1998 J Neuroendocrinol 10:133; Chen AS et al 2000 Nature Genet 26:97.

Melanocyte: Produces melanin. ▶melanin

Melanocyte Stimulating Hormone (MSH): MSH exists in forms α -MSH, β -MSH and γ -MSH. These adenocortical hormones regulate melanization and also energy utilization. ▶opiocortin, ▶agouti, ▶pigmentation of animals, ▶leptin, ▶syndecan; Haskell-Luevano C et al 2001 J Med Chem 44:2247.

Melanoma (CMM1, 1p36; CMM2, 9p21): Forms of cancer arising in the melanocytes or other tissues. The most prevalent form appears as a mole of radial growth of reddish, brown and pink color with irregular edges that penetrate, as they progress, into deeper layers. It may originate in dark freckles on the head or other parts of the body. Excessive exposure to sunlight may condition its development although autosomal dominant genes determine susceptibility to melanoma. Three alleles of the melanocortin receptor (MC1R, 16q24.3) double the cutaneous malignant melanoma in MC1R variants (CMM1) risk for red-haired individuals. Mutations in BRAF strongly increase the incidence of melanoma among Caucasians who are not exposed chronically to sun-induced skin damage (Landi MT et al 2006 Science 313:521). Melanoma may be one of the most aggressively metastatic cancers. The development of melanoma is regulated by the melanoma mitogenic polypeptide, encoded by GRO human gene in chromosome 4q21. The melanoma-associated antigen, ME49 appears in the early stages of this cancer, and it is coded by an autosomal dominant locus (MLA1) in human chromosome 12q12-q14. Melanoma-associated

antigen, MZ2-E, is coded for by another autosomal dominant locus. The melanoma-associated antigen p97, a member of the iron-binding transferrin protein family, is coded by an autosomal dominant gene, MAP97 (MF12) at human chromosome 3q28-q29. An autosomal dominant gene in human chromosome 15 encodes the melanoma-specific chondroitin sulfate proteoglycan, expressed in melanoma cells. In cultured melanoma and metastatic tissues a mutant CDK4/CDKN2A (p21 protein) was found that was unable to bind the p16^{INK4a} protein and thereby interferes with normal regulation of the cell cycle inhibitor. The ERK growth factor is hyperactivated in up to 90% of melanomas. RAS-ERK and phosphoinositide-3-OH kinase signal to its development. The microphthalmia-associated transcription factor (MITF, 3p14.1-p12.3) is a regulator of melanomas. Therapies may involve several drugs targeted to various kinases in the melanoma development pathways (Gray-Schopfer V et al 2007 Nature [Lond] 445:851).

In human chromosome 11 several presumptive melanoma suppressors have been found. Many of the hereditary melanomas are attributed to G→34T mutation at this locus. Because of this mutation an AUG initiation codon is created at site -35 and the resulting 4-kDa translation-product shows no homology to CDKN2A/p16. Deletions of p16 may frequently be responsible for malignant melanoma. Catenin seems to be a transcriptional coactivator of Tcf and Lef and seems to affect melanoma progression. Approximately 5 to 10% of the melanoma patients have at least one afflicted family member. Non-melanoma skin cancer in fair skinned redheads may be associated with the melanocortin-1 receptor (MCR1). The *fat-1* mutation in mice can convert n-6 fatty acids into n-3 and it reduced melanoma development in melanoma transgenic animals and establish a favorable balance between the two groups of fatty acids. In *fat-1* mice prostaglandin E3 and PTEN were upregulated (Xia S et al 2006 Proc Natl Acad Sci USA 103: 12499). Genetic hybrids between the species of the platyfishes (*Xiphophorus*) are prone to develop melanoma. Melanoma is frequently an aggressive cancer and is refractory to anticancer drugs. Cisplatin is sequestered into subcellular organelles of melanosomes and thus hindered from accessing the nucleus (Chen KG et al 2006 Proc Natl Acad Sci USA 103:9903). ▶**MEL oncogene**, ▶**p16**, ▶**melanocyte**, ▶**cancer**, ▶**catenins**, ▶**Tcf**, ▶**Lef**, ▶**MAGE**, ▶**metastasis**, ▶**freckles**, ▶**cisplatin**, ▶**Apaf**, ▶**survivin**, ▶**CDKN2A**, ▶**skin cancer**, ▶**mole**, ▶**BRAF**, ▶**fatty acids**, ▶**obesity**, ▶**prostaglandin**, ▶**PTEN**; Mellado M et al 2001 Curr Biol 11:691; van der Velden P et al 2001 Am J Hum Genet 69:774; melanoma statistics database: <http://www.pcab.cupmc.edu/main.cfm?dis=statmel>.

Melanoma Growth-Stimulatory Factor (GROα): An interleukin-related protein like SDF. ▶**IL-8**, ▶**SDF**, ▶**CXCR**, ▶**chemokines**; Wang et al 2000 Oncogene 19:4647.

Melanopsin: A sensory retinal photopigment in mammals and other species (Bellingham J et al 2006 PLoS Biol 4(8):e254).

Melanosomes: Specialized pigment-containing organelles of animals produced by the melanocytes. They include tyrosinase, and related proteins, GP100, etc. and bear resemblance in function to lysosomes. ▶**melanocyte**, ▶**albinism**, ▶**pigmentation of animals**, ▶**lysosomes**, ▶**skin color**, ▶**amyloids**; Kishimoto T et al 2001 Proc Natl Acad Sci USA 98:10698; Marks MS et al 2001 Nature Rev Mol Cell Biol 2:738.

Melas Syndrome: ▶**mitochondrial disease in humans**

Melatonin: Hormone synthesized in the pineal gland and is controlling reactions to light, diurnal changes, seasonal adjustment in fur color, aging, sleep, and reproduction. It is a scavenger of oxidative radicals and it protects from ionizing radiation without substantial side effects. It is synthesized from serotonin by serotonin N-acetyltransferase and regulated by cAMP. ▶**serotonin**, ▶**sulfhydryl**, ▶**radio-protectors**, ▶**circadian rhythm**; Reiter RJ et al 2007 World Rev Nutr Diet 97:211.

MELD: Overlapping, Merged DNA fragments.

MELD₁₀ (mouse equivalent lethal dose): ▶**LD50**

Melibiose (galactopyranosyl-glucose): A fermentable disaccharide (see Fig. M40).

Figure M40. Melibiose

MELK (multi-epitope-ligand-‘Kartographie’): Technology capable of analyzing the pattern, topological arrangement and interaction of proteins within single cells rather than cell homogenates. It thus detects single combinatorial protein patterns (s-CCP) and combinatorial protein pattern motifs. The pattern may provide specific signatures of cell types, cell states in health and disease and response to drugs. It provides information in parallel also on carbohydrates nucleic acids and lipids and reveals their interaction networks the topome. ▶**genetic networks**; Schubert W 2003 Adv Biochem Engin/Biotechnol 83:189.

Melnick-Needles Syndrome (xq28): A hereditary bone defect due to mutation in filamin A. ► [filamin](#)

Melt-and-Slide Model: The dual functions of DNA polymerase I are carried out by pol I occupying the duplex primer-template site for the polymerase action, and for the editing reaction the DNA melts (strands separate), unwinds and the single-strand DNA is transferred to the exonuclease site of the polymerase enzyme. ► [DNA repair](#), ► [DNA replication](#)

Meltdown, Mutational: Can occur when the mutation rate is high, the genetically effective population size is small and genetic drift is high. It may lead to extinction. ► [effective population size](#), ► [genetic drift](#), ► [extinction](#); Zeyl C et al 2001 *Evolution* 55:909.

Melting: The breakdown of the hydrogen bonds between paired nucleic acid strands (► [Denatur-A-tion](#), ► [breathing of DNA](#), ► [Watson and Crick model](#)).

Melting Curve of DNA: Higher temperatures cause progressively higher disruption of the hydrogen bonds between DNA strands; it is affected also by the base composition of the DNA because there are three hydrogen bonds between G≡C and two between A=T. ► [re-naturation](#), ► [C₀t curve](#), ► [hydrogen pairing](#), ► [melting temperature](#)

M

Melting Temperature: The temperature where 50% of the molecules is denatured (T_m); the DNA strands may be separated (depending on the origin of the DNA, G≡C content, solvent, and homology of the strands) generally above 80° C and melting may be completed below 100°. ► [C₀t curve](#), ► [hyperchromicity](#), ► [melting curve of DNA](#)

Meltrins: Metalloproteinase proteins mediating the fusion of myoblasts into myotubes. ► [myotubes](#), ► [metalloproteinase](#), ► [ADAM](#); Inoue D et al 1998 *J Biol Chem* 273:4180.

Memapsins: Cloned and sequenced aspartic proteases with β secretase activity. ► [secretase](#)

Membrane: Lipid protein complexes surrounding cells and cellular organelles and forming intracellular vesicles. Synthetic membranes can now be engineered on polymer surfaces and their functions studied along with associated proteins using semiconductor technology. The function of membranes is important for many physiological mechanisms, including screening for pathogens and drugs. ► [cell membranes](#), ► [semiconductor](#); Tanaka M, Sackmann E 2005 *Nature [Lond]* 437:656.

Membrane Attack Complex (MAC): C5b can be converted to C5b6 and then to C5b67 by binding to C6 and C7 complement components and then with C8 and C9 resulting in the formation of MAC.

This complex can protect the cells against certain foreign, intruder cells but it must be regulated to protect the cells own membrane system. The so-called homologous restriction factor (HRF) is a 65-kDa glycoprotein bound to cell membranes through glycosylphosphatidylinositol (GPI) can perform this task. A smaller (20-kDa) immunoglobulin G (IgG1) called also HRF20 (CD59), and MIRL (membrane inhibitor of reactive lysis) function in a similar manner. In paroxysmal nocturnal hemoglobinuria is a mutational defect in GPI anchoring of HRF20 to the hematopoietic membrane. ► [complexment](#), ► [paroxysmal nocturnal hemoglobinuria](#), ► [phosphoinositides](#), ► [immunoglobulins](#), Linton S 2001 *Mol Biotechnol* 18:135.

Membrane Channels: These permit passive passing of ions and small molecules through membranes. ► [cell membrane](#), ► [ion channel](#)

Membrane Filters: Used for clarification of biological or other liquids, trapping macromolecules, for exclusion of contaminating microbes, for Southern and Northern blotting, etc. The filters may be cellulose, fiberglass, nylon and might have been specially treated to best fit for the purpose.

Membrane Fusion: Maintains sub cellular compartments. The process requires ATPases (NSF), accessory proteins (SNAP), integral membrane receptors of SNAP (SNARE) and GTPases (RAB) and additional proteins. The SNARE function may be transient. Vacuoles Ca^{2+} /calmodulin regulates membrane bilayer mixing in the final steps (see Fig. [M41](#)). Protein phosphatase 1 (PP1) has essential role in membrane mixing. Infection by viral pathogens—penetration of the egg by the sperm, vesicular transport, etc.—involves fusion of membranes.

► [ATPase](#), ► [RAB](#), ► [SNAP](#), ► [SNARE](#), ► [protein phosphatases](#); Eckert DM, Kim PS 2001 *Annu Rev Biochem* 70:777; Jahn R, Grubmüller H 2002 *Current Opin Cell Biol* 14:488; Ostrowski SG et al 2004 *Science* 305:71.

Membrane Potential: Eelectromotive force difference across cell membranes. In an average animal cell inside it is 60 mV relative to the outside milieu. It is caused by the positive and negative ion differences between the two compartments.

Membrane Proteins: These may be *integral* parts of the membrane structure and cannot be released. The *transmembrane* proteins are single amino acid chains folded into (seven) helices spanning across the membrane containing lipid layers. The latter have a hydrophobic tract that passes through the lipid double layer of the membrane and their two tails, one pointing outward from the membrane and the other

Figure M41. Fusion of viral membranes with the cell membrane during infection. The several subunits of the fusion protein complex draws the membranes together. This is an oversimplified representation. (See Modis Y et al 2004 Nature [Lond] 427:313; Gibbons DL et al 2004 Nature [Lond] 327:320)

Figure M42. 1. Globular protein is attached to the outer surface by a glycosyl-phosphatidyl inositol anchor. 2. The protein is attached to the outer layer of the lipid bilayer by a thioether linkage between the sulfur of cysteine and a farnesyl molecule. 3. Amino acid and myristil anchor join a protein to the outer surface of the membrane. 4. Prenyl residue anchors the protein to the inner part of the membrane. 5. Transmembrane protein chain passes through the membrane three or seven times. 6. Transmembrane protein anchors another protein without covalent linkage

reaching into the cytosol, are hydrophilic. Some of the membrane proteins are attached only the outer or to the inner layer of the membrane lipids and they are called *peripheral membrane proteins*. The topology of >50,000 prokaryotic and ~15,000 eukaryotic membrane proteins have been determined and there is a remarkable similarity between these two groups (Kim H et al 2006 Proc Natl Acad Sci USA 103:11142). The membrane proteins regulate not just the cell membranes but cell morphology by anchoring to cytoskeleton, pH, ion channels and general physiology of the cell. The structure of membranes can now be analyzed with the aid of membrane mutants, available in several organisms. Method has been developed for the computational design of peptides that target (TM) transmembrane helices in a sequence-specific manner. The designed peptides specifically recognized the TM helices of two closely related integrins in micelles, bacterial membranes, and mammalian cells (Yin H et al 2007 Science

315:1817). (See Fig. M42, ►prenylation, ►farnesyl pyrophosphate, ►myristic acid, ►cell membranes, ►cytoskeleton, ►integrins; Dalbey RE, Kuhn A 2000 Annu Rev Cell Dev Biol 16:51; Sachs JN, Engelman DM 2006 Annu Rev Biochem 75:707; membrane protein structure: Elofsson A, von Heijne G 2007 Annu Rev Biochem 76:125.

Membrane Segment: Antigen receptor immunoglobulins possess a membrane-bound segment at the C-end of their heavy chains. The transmembrane part is composed of 25–26 highly conserved amino residues and the intracellular portion is of 25-amino acids in IgG and 14 in IgE and IgA in mouse. Membrane bound IgG, IgE and IgA are involved in the stimulated B cell receptors whereas IgM and IgD are parts of the naive (immature) B cell receptors. ►immunoglobulins

Membrane-Spanning Helices: ►membrane proteins, ►seven membrane proteins

Membrane Transport: The movement of polar solutes with the aid of a transporter protein through cell membranes. ► [cell membrane](#), ► [ABC transporters](#), ► [major facilitator superfamily](#); Kaback HR et al 2001 *Nature Rev Mol Cell Biol* 2:610, membrane traffic: Pfeiffer SR 2007 *Annu Rev Biochem* 76:629; membrane transport proteins: <http://www.membrane-transport.org/>.

MEME: A unit of cultural transmission (imitation), which bears some similarities to the gene that it is “transmitted” horizontally and not vertically from generation to generation as cultural inheritance and not as a biological entity. (See Boyd R, Richerson PJ 2000 *Sci Amer* 283(4):70).

MEME: Replicator functions of organisms that also control co-evolution of genes and organisms. (See Bull L et al 2000 *Artif Life* 6(3):227; motif alignment tool: <http://meme.nbcr.net/meme/intro.html>).

Memory: Information storage in the brain or in a computer. The mammalian brain deals with synaptic strength as memory. If synapses are used repeatedly, the strength is improved and long-term potentiation (LTP) takes place. Arc/Arg3.1 regulates endophilin 3 and dynamin 2, two components of the endocytosis machinery. Genetic ablation of *Arc/Arg3.1* in mice or overexpression in culture suggests that Arc/Arg3.1 regulates AMPA receptor trafficking and synaptic plasticity (See *Neuron* 52(3):445–474 2006). The opposite of LTP is LTD (long-term depression). The latter may erase the effect of LTP. Acetylcholine, dopamine and norepinephrine mediate different memory signals acting in the prefrontal cortex of the brain. Both of these mechanism are triggered by the inflow of Ca^{2+} , regulated by an ion channel (NMDAR), glutamate-activated N-methyl-D-aspartate receptor channel. Multiple protein kinases (adenylate cyclase, CREB) appear to be involved in extremely complex manners. It is not entirely clear how discrimination between LTP and LTD is accomplished. Nerve growth factor (NGF) gene transfer to basal forebrain of rats resulted in recovery from age-related memory loss. There are some indications that memory is controlled by positive and negative signals. LTP seems to require protein synthesis but long-term memory (LTM) may not. Long-term memory seems to require synthesis of new proteins in the dendrites (Sutton MA, Schuman EM 2006 *Cell* 127:49). Modern neurobiology uses a variety of techniques for exploring the mechanisms of memory and learning, including mutations, knock-outs, transgenes, tomography, magnetic resonance imaging, etc. Unwanted memories are eliminated by increased dorsolateral prefrontal activation

and reduced hippocampal activation in the brain (Anderson MC et al 2004 *Science* 303:232). *Explicit* (declarative) *memory*: the remembrance of facts, resides in the hippocampal region of the brain. *Implicit* (non-declarative) *memory* involves perceptual and motor skills (based on basal ganglia) that may be more widely distributed; memory of conditional fear appears to be in the corpus amygdaloideum (an almond-shaped part in the temporal lobe of the brain with connections to the hippocampus, thalamus and hypothalamus). The *working memory* functions during the period when a mental task is performed. *Social memory* (parental care, etc.) in mice is based on olfactory functions controlled by oxytocin in the brain. *Drosophila* mutants *dunce* (encoding cAMP phosphodiesterase) and *rutabaga* (encoding adenylate cyclase) appear to have an ability to learn yet display short memory. The mutant *amnesiac* is defective in a pituitary peptide required for activation of adenylate cyclase, and mutation *linotte* is affected in a helicase-like function. In *Aplysia* and mice CREB affects long-term memory but not the short-term memory. All these pieces of information point to the role of cAMP in memory. Ca^{2+} /calmodulin dependent protein kinase (CaMKII) is an important signaling molecule for memory. Dynamin, a microtubule-associated GTPase is important for synaptic vesicle recycling. Protein phosphatase 1 seems to be a suppressor of learning and memory (Genoux D et al 2002 *Nature [Lond]* 418:970). Single amino acid substitutions in brain derived neurotrophic factor (BDNF) in rats seem to effect long-term potentiation of memory (Egan MF et al 2003 *Cell* 112:257). Recalling olfactory memory in *Drosophila* requires the function of the mushroom bodies although this organelle is not necessary for learning or storage of information. In *Drosophila*, the most central part of the brain—in the so-called fan-shaped body (FB)—stores short-term memory of visual pattern recognition. Memories of different shape patterns are localized in groups of neurons in different, parallel, horizontal branches of FB. In the flies the rutabaga protein (an adenylate cyclase regulated by Ca^{2+} /calmodulin and G_α protein) is required for conditioned and unconditioned memory. For the experiment *rut⁻* mutants were employed. Then the investigators looked for neurons where transgenic *rut⁺* restored learning. Using sophisticated genetic regulatory system and well-controlled environment providing behavioral (and memory) control permitted mapping the visual memory pattern in the brain (Liu G et al 2006 *Nature [Lond]* 439:551).

Diacylphosphatidyl ethanol (present in fish oil) in the diet may significantly increase learning capacity of young rats but not the old ones (Barceló-Coblijn G et al 2003 *Proc Natl Acad Sci USA* 100:11321). Age

in humans generally reduces memory and may result in Alzheimer disease. In mice, which express human amyloid- β protein precursor (APP), a variant of 56-kDa amyloid- β plaques accumulate in the neurons by aging and cause memory loss (Lesné S et al 2006 *Nature [Lond]* 440:352). ►brain, ►human, ►mushroom body, ►ARC, ►AMPA, ►dynammin, ►endophilin, ►synaps, ►ion channels, ►long-term potentiation, ►NMDAR, ►flyn, ►hebbian mechanism, ►synapse, ►adenylate cyclase, ►oxytocin, ►dopamine, ►acetylcholine, ►norepinephrine, ►C/EBP, ►CREB, ►long-term potentiation, ►knock-out, ►transgene, ►tomography, ►nuclear magnetic resonance spectroscopy, ►Alzheimer disease; Silva AZ et al 1997 *Annu Rev Genet* 31:527; Zars T et al 2000 *Science* 288:672; Sweatt JD 2001 *Curr Biol* 11: R391; Waddell S, Quinn WG 2001 *Science* 293:1271; Wadell S, Quinn WG 2001 *Annu Rev Neurosci* 24:1283; maintenance of long-term memory: Bailey CH et al 2004 *Neuron* 44:49.

Memory, Epigenetic: ►epigenetic memory

Memory, Immunological: Immunological memory rests with the lymphocytes and this is the basis of vaccination. There are three phases in its development: (i) activation and expansion of the CD4 and CD8 T cells, (ii) apoptosis, and (iii) stability (memory). During phase (i), lasting for about a week the antigen selects the appropriate cells and an up to 5,000-fold expansion of the specific cells takes place. They also differentiate into effector cells. Between a week and a month's time, as the antigen level subsides, the T cells die and effector function declines. This is called activation-induced cell death (AICD). THE AICD is a defense against possible autoreactive function. The memory stage may then last for many years and they respond to low exposure of the reintroduced antigen and respond very rapidly. A certain level of antigen maintenance seems to be required to keep memory cell at high level but it appears that memory cells can be saved even in the absence of the antigen (Maruyama M et al 2000 *Nature [Lond]* 407:636). The conditions for CD4 and CD8 cell maintenance appear different. Memory B and T cells do not provide immediate protection against infection but after infection they start rapid formation of effectors. The duration of the memory depends on the strength of immunization. The protection against peripheral re-infection is antigen-dependent. The long-term success of immunization depends on the presence of memory cells. Therefore there is much significance in selecting T cells that may become memory cells. The division of CD8⁺ memory T cells is slow and it can be increased by IL-15 but IL-2 has the opposite effect. T-bet and

omesodermin transcription factors facilitate cytokine-dependent memory T cell and natural killer cell formation. These two transcription factors enhance the expression of CD122, which mediates interleukin-15 (IL-15) responsiveness (Intlekofer AM et al 2005 *Nature Immunol* 6:1236). Eomesodermin (Eomes) is a T-box transcription factor homologous to T-bet. Thus these memory T cells are under the control of interleukin balance. The 'central memory cells' have CCR7⁺ receptors whereas the 'effector memory T cells' are CCR7⁻. ►immune system, ►apoptosis, ►CD4, ►CD8, ►lymphocytes, ►germinal center, ►T cell, ►B cell, ►T-bet, ►omesodermin, ►killer cell, ►immunization, ►vaccines, ►immunotherapy active specific, ►and affinity maturation, ►IL-15, ►IL-12, ►CCR, ►effector, ►CD8; Mackay CR, von Andrian UH 2001 *Science* 291:2323; Sprent J, Tough DF 2001 *Science* 293:245; Fearon DT et al 2001 *Science* 293:248; Sprent J, Surh CD 2002 *Annu Rev Immunol* 20:551.

Memory, Molecular: Heritable specific pattern of gene expression.

Memory, Transcriptional: Maintains transcriptional state and transmits it epigenetically to cell progeny. In yeast the ATP-dependent SWI/SNF chromatin-remodeling system is essential for the GAL1 gene and it antagonizes the ISWI system (Kundu S et al 2007 *Genes & Dev* 21:997). ►ISWI, ►SWI/SNF, ►Gal

MEN (multiple endocrine neoplasia): MEN1 (dominant) was located to human chromosome 11q13, responsible for the production of a 610 amino acid protein, Menin, encoded by 10 exons predisposing to pancreatic islet cell tumors. Menin is both a tumor suppressor and a cofactor of mixed lineage leukemia (MLL) oncoprotein (Yokoyama A et al 2005 *Cell* 123:207). MEN1 homozygosity is lethal. MEN2 is encoded at 10q11.2 and puts individuals at risk of thyroid cancer. The RET tyrosine kinase is defective. ►endocrine neoplasia, ►p27, ►ganglioneuromatosis, ►RET oncogene; Crabtree JS et al 2001 *Proc Natl Acad Sci USA* 98:1118; Krapp A et al 2004 *Current Biol* 14:R722.

MEN (mitotic exit network): Includes cyclin-dependent kinase (CDK) inactivators, CDC15, CDC14, CDC5, DBF, TEM1, etc. (See factors named, ►mitotic exit, ►FEAR; Asakawa K et al 2001 *Genetics* 157:1437).

Menaquinone (vitamin K₂): Synthesized by bacteria and is an electron carrier. ►vitamin K

Menarche: The first menstruation event, followed by a period of about three years of no ovulations before the regular menstruation begins and continues until menopause. ►menstruation, ►menopause

Mendelian Laws: The term was first used by Carl Correns (1900), one of the rediscoverers of these principles, which he named (1) Uniformitäts- und Reziprozitätsgesetz, (2) Spaltungsgesetz, (3) unabhängige Kombination). *First law:* uniformity of the F_1 (if the parents are homozygous) and the reciprocal hybrids are identical (in the absence of cytoplasmic differences). *Second Law:* independent segregation of the genes in F_2 (in absence of linkage). *Third law:* independent assortment of alleles in the gametes of diploids. Thomas Hunt Morgan (1919) also recognized three laws of heredity: (1) free assortment of the alleles in the formation of gametes, (2) independent segregation of the determinants for different characters, (3) linkage-recombination. In some modern textbooks only two Mendelian laws are recognized but this is against the tradition of genetics that the first used nomenclature is upheld. Mendel himself never claimed any rules as such to his credit. He did not observe any linkage among the 7 factors he studied in peas although he had less than 1% chance for all factors segregating independently. This was called “Mendel’s luck”. If he had found the linkage it would have in all probability been recorded in his notes. Unfortunately after his death, his successor at the abbey, Anselm Rambousek, disposed most of the records. After he experimented with *Hieracium*, an apomict (unknown that time), he developed some doubt about the general validity of his discoveries. Yet, before ending his career he stated: “My scientific work has brought me a great deal of satisfaction, and I am convinced that I will be appreciated before long by the whole world”. That appreciation began in 1900, 16 years after his death and continues since. In 1936, the famous statistician and geneticist Ronald Fisher (Annals of Sci. 1:115) questioned the authenticity of Mendel’s observations on the basis

that the data were ‘too good to be true’. Fisher’s criticism has been widely touted by many without thoroughly studying the original paper of Mendel or that of Fisher. The statistician F. Weiling (1966 Züchter 36:359) pointed out that Fisher misunderstood some of the experiments and erred in his analysis too. More recently Hartl & Fairbanks (2007 Genetics 175:975) concluded, “Fisher’s allegation of deliberate falsification can finally be put to rest, because on closer analysis it has proved to be unsupported by convincing evidence.” The experimental data accumulated during the one and a half century since the publication of Mendel’s paper convincingly prove that Mendel was right and honest (Rédei GP 2002 p 1. In: Quantitative Genetics, Genomics and Plant Breeding. Kang MS (Eds.) CABI Publishing, New York). ►Mendelian segregation, ►epistasis, ►modified Mendelian ratios

Mendelian Population: A collection of individuals, which can share alleles through interbreeding. ►population, ►genetics

Mendelian Segregation: Mendelian segregation for independent loci can be predicted on the basis of the Table M5. Mendelian segregation ratios may show only apparent deviations in case of epistasis (see Fig. M43). Reduced penetrance or expressivity may also confuse the segregation patterns and in such cases it may be necessary to determine the difference between male and female transmission. The wrinkled/shrunken seeds shown in Fig. M43 accumulate water-soluble sugars at the expense of complex starch and when the seed dries it shows the wrinkled phenotype. ►epistasis, ►penetrance, ►expressivity, ►segregation distorter, ►certation, ►modified Mendelian ratios

Table M5. Mendelian expectations

| | | | | | |
|--|---|----|----|-----|-------|
| Number of different allelic pairs | 1 | 2 | 3 | 4 | n |
| Kinds of gametes and number of phenotypes in case of dominance | 2 | 4 | 8 | 16 | 2^n |
| Number of phenotypes (in case of no dominance) and number of genotypes | 3 | 9 | 27 | 81 | 3^n |
| Number of gametic combinations | 4 | 16 | 64 | 256 | 4^n |

Figure M43. Segregation for smooth and wrinkled within a pea pod

Mendelizing: Segregation corresponds to the expectations by Mendelian laws. ▶ [Mendelian laws](#), ▶ [Mendelian segregation](#)

Ménière Disease (COCH, 14q12-q13): A late-onset, dominant non-syndromic deafness although in some cases vertigo (dizziness-like sensation of whirling of the body or the surroundings) and tinnitus (ringing inside the ears) may occur periodically. In the majority of cases mutation at nucleotide position C-T²⁰⁸ results in proline⁵¹→serine substitution in the COCH protein. ▶ [deafness](#)

Menin1: A tumor suppressor protein (binding JunD) encoded at 11q13 by the gene responsible for multiple endocrine neoplasia. ▶ [endocrine neoplasia](#), ▶ [Jun](#); Guru SC et al 2001 Gene 263:31.

Meninges: The three membranes (pia, arachnoid, dura maters) surrounding the brain and the spinal cord.

Meningioma: A slow proliferating brain neoplasias classified into different groups on the basis of anatomical features. Generally meningiomas involve the loss of human chromosome 22 (hemizygosity) or part of its long arm or some lesions at 22q12.3-q13 where the SIS oncogene, responsible for a deficit of the platelet derived growth factor (PDGF) is located. Chromosomes 1p, 14q, and 17 have also been implicated. ▶ [SIS](#), ▶ [cancer](#), ▶ [neurofibromatosis](#), ▶ [meninges](#), ▶ [ERM](#)

Meningocele: ▶ [spina bifida](#)

Menkes Syndrome (MNK, kinky hair disease): The gene is situated in the centromeric area of the human X-chromosome (Xq12-q13). The phenotype involves hair abnormalities, mental retardation, low pigmentation, hypothermia and short life span. Apparently, the defect is in the malabsorption of copper through the intestines resulting in copper deficiency of the serum. The prevalence is in the 10⁻⁵ range or less. It is detectable prenatally and the heterozygotes can be identified although its inheritance is apparently recessive. Lysyl oxidase and other copper-dependent enzyme levels (tyrosinase, monoamine oxidase, cytochrome c oxidase, ascorbate oxidase) are reduced in the afflicted individuals. In the mouse homolog, Mottled-Bridled, the non-exported copper is tied up by metallothionein and the afflicted individual dies within a few weeks after birth. The Occipital Horn Syndrome may be an allelic variation of MNK and of cutis laxa. ▶ [mental retardation](#), ▶ [Wilson disease](#), ▶ [acrodermatitis](#), ▶ [hemochromatosis](#), ▶ [Ehlers-Danlos syndrome](#), ▶ [Cutis laxa](#), ▶ [collagen](#), ▶ [metallothionein](#)

Menopause: The end of the periodic ovulation (menstruation) and fertility around age 50 in human females. Animals in the wild usually stay fertile in old age. The evolutionary cause of menopause is not

known but it has been hypothesized it is a protection against the increase of chromosomal aberrations in old egg cells. An alternative hypothesis assumes that life beyond menopause may aid the rearing of the last offspring or grandchildren and this conveys fitness by kin selection. ▶ [menstruation](#), ▶ [menarche](#), ▶ [andropause](#), ▶ [age-specific birth and death rates](#), ▶ [kin selection](#), ▶ [dictyotene stage](#), ▶ [porin](#)

Menses: Same as menstruation

Menstruation: The monthly discharge of blood from the human (primate) uterus in the absence of pregnancy. If the egg is not fertilized, it dies and the endometrial tissue of the uterus is removed amidst the bleeding. Fertilization takes place within the oviduct. About three days are required for the egg to reach the uterus through the oviduct where it is implanted within a day or two, and about a week after being fertilized. Fertilization may occur if the coitus takes place in period about two weeks after the beginning of the last monthly menstruation. The calendar rhythm method of birth control relies on knowledge of this receptive period. Unfortunately, its effectiveness is not very high. ▶ [hormone receptors](#), ▶ [sex hormones](#), ▶ [ovulation](#), ▶ [menarche](#)

Mental Retardation: A collection of human disabilities caused by direct or indirect genetic defects and acquired factors such as diverse types of infections (syphilis, toxoplasma coccidian protozoa), viruses (rubella, human immunodeficiency virus, cytomegalovirus, herpes simplex, coxsackie viruses), bacteria (*Haemophilus influenzae*, meningococci, pneumococci, mechanical injuries to the brain pre-, peri- and postnatally, exposure to lead, mercury, addictive drugs, alcoholism or deprivation of oxygen during birth, severe malnutrition, deficiency of thyroid activity, social and psychological stress, etc. An estimated 2 to 3% of the population is suffering from mild (IQ 50–70%) or more or less severe (IQ below 50%) forms of it. Special education programs can help an estimated 90% of the cases. Approximately 10% of the human hereditary disorders have some mental-psychological debilitating effects.

Autosomal dominant type hemoglobin H disease associated mental retardation due to a lesion in the α -globin gene cluster with chromosomal deletion and without it have been observed. Other cases of mental retardation were also observed involving autosomal dominant inheritance caused by breakage in several chromosomes. Autosomal recessive inheritance was involved in mental retardation associated with head, face, eye, and lip abnormalities, hypogonadism, diabetes, epilepsy, heart and kidney malformations, phenylketonuria. X-chromosome linked mental retardation was observed as part of the syndromes involving the development of large heads, intestinal

defects, including anal obstructions, seizures, short statures, weakness of muscles, obesity, marfanoid appearance, etc. In some cases the “kinky hair” syndrome (Menkes syndrome), caused apparently by abnormal metabolism of copper and zinc, also involved mental retardation. A fragile site in the X chromosome (Xq27-q28) apparently based on a deficiency of thymidine monophosphate caused by insufficient folate supply is associated with testicular enlargement (macroorchidism), big head, large ears, etc. A defect in the IL-1 receptor accessory protein, encoded at Xp22.1–21.3, affects learning ability and memory. The transmission of the fragile X sites (FRAX) is generally through normal males. The carrier daughters are not mentally retarded and generally do not show fragile sites. In the following generation, about a third of the heterozygous females display fragile sites and become mentally retarded. This unusual genetic pattern was called the Sherman paradox and it is interpreted by some type of a pre-mutational lesion. The pre-mutation ends up in a genuine mutation only after being transmitted by a female, which already had a microscopically undetectable rearrangement.

The risk of the sons was estimated to be 50% from mentally retarded heterozygous females, 38% from normal heterozygous mothers, and 0% from normal transmitting fathers. The probability of these sons being a mentally sound carrier was estimated as 12, 0 and 0%, respectively. The risk of the daughters of the same mothers to become a mentally affected carrier was calculated to be 28, 16 and 0%, and being a mentally normal carrier was estimated 22, 34 and 1%, respectively. The chance of mental retardation for the brother of a proband whose mother has no detectable fragile X site, may vary from 9–27% and among first cousins this is reduced to 1–5%. It was proposed (Laird 1987 Genetics 117:587) that the expression of the fragile X syndrome is mediated by chromosomal imprinting. The imprinting can, however, be erased by transmission through the parent of the other sex. The fragile X syndrome is apparently caused by localized breakage and methylation of CpG islands at the site (Bardoni B, Mandel J-L 2002 Current Op Genet Dev 12:284). Currently, the most reliable diagnosis of this condition is based on DNA probing. Submicroscopic deletions (1.5–2.9 Mb) associated with mental retardation can be detected by microarray hybridization (Vissers LELM et al 2003 Am J Hum Genet 73:1261). In addition, the fragile X syndrome autosomal and sex-chromosomal trisomy and chromosome breakage associated with translocations may be contributing factors of mental retardation. Human chromosome 17q21.31 microdeletions accompanied mental retardation and face morphology as detected by fluorescence in situ hybridization (Koolen DA et al 2006 Nature Genet

38:999). Further, mutations causing metabolic disorders (phenylketonuria, homocystinuria), defects in the branched-chain amino acid pathway (maple syrup urine disease) anomalies in amino acid uptake (Hartnup disease), defects involving mucopolysaccharids (Hunter, Hurler and Sanfilippo syndromes), gangliosidoses and sphingolipidoses (most notably the Tay-Sachs disease, Farber’s disease, Gaucher’s disease, Niemann-Pick disease, etc.), galactosemias, failure of removal of fucose residues from carbohydrates (fucosidosis), defects in acetyl-glucosamine phosphotransferase (I-cell disease), defects in HGPRT (Lesch-Nyhan syndrome), hypothyroidism, a variety of defects of the central nervous system, and other genetically determined conditions may be responsible for mental retardation. The incidence, establishment of genetic risks and possible therapies are as variable as the underlying causes.

Mental retardation is defined as borderline: IQ \approx 70–85, mild in case of IQ \approx 50–70, moderate: IQ \approx 35–50, severe: IQ \approx 25–35 and profound: IQ \leq 20.

In utero radiation exposure may cause mental retardation; 140 rad during the first 8–15 weeks may result in such damage in 75% of the fetuses and in 46% of the irradiated at any stage. (For more specific details see ►Huntington’s disease, ►biotinidase deficiency, ►myotonic dystrophy, ►muscular dystrophy, ►hydrocephalus, ►craniofacial dysostosis, ►spina bifida, ►tuberous sclerosis, ►neurofibromatosis, ►Menke’s syndrome, ►Smith-Lemli-Opitz syndrome, ►Smith-Magenis syndrome, ►Seckel’s dwarfism, ►Laurence-Moon syndrome, ►Noonan syndrome, ►Lowe’s syndrome, ►mental retardation X linked, ►Apert syndrome or Apert-Crouzon disease, ►Prader-Willi syndrome, ►Rubinstein syndrome, ►cerebral gigantism, ►Langer-Giedion syndrome, ►Miller-Dieker syndrome, ►Walker-Wagner syndrome, ►Wilms tumor, ►Roberts syndrome, ►Russel-Silver syndrome, ►Opitz-Kaveggia syndrome, ►De Lange syndrome, ►Bardet-Biedl syndrome, ►focal dermal hypoplasia, ►ceroid lipofuscinosis, ►autism, ►dyslexia, ►human intelligence [IQ], ►psychoses, ►aspartoacylase deficiency, ►glutamate formiminotransferase deficiency, ►CADASIL, ►Cohen syndrome, ►Coffin-Lowry syndrome, ►Juberg-Marsidi syndrome, ►fragile sites, ►FMR1 mutation, ►trinucleotide repeats, ►human intelligence, ►human behavior, ►head/face/brain defects, ►craniosynostosis, ►double cortex, ►periventricular heterotopia, ►oligophrenin, ►heritability, ►QTL, ►PAK, ►neurodegenerative diseases, ►neurotrypsin, ►IL-1, ►serpines, ►tetraspanin, ►microdeletion; Shea SE 2006 Semin Pediatr Neurol 13(4):262).

Mental Retardation X-Linked (MRX): These hereditary defects occur in a variety of forms: (i) MRXS with

diplegia (bilateral paralysis), (ii) associated with psoriasis (skin lesions), (iii) with lip deformities, obesity and hypogonadism, (iv) Renpenning type with short stature and microcephaly, (v) with seizures (EFMR), (vi) with Marfan syndrome-like habitus, (vii) with fragile X-chromosome sites among others. Altogether more than a dozen different types have been characterized. Translocation involving chromosome 7 results in nonsyndromic cognition deficit due to a defect in a zinc-finger protein (ZNF41). Several of the MRX disorders map in the human Xq28 region and in this general area apparently 12 genes are located. At Xp22.1–21.3 there is the IL1RAPL (IL-1 receptor accessory protein) gene, expressed in the hippocampus. Translocations involving Xq26 and 21p11 (ARHGEF6) involve defects in a guanine exchange factor for Rho GTPases. Some of the sequences observed at Xp22 are found also at Yq11.2 where infertility and azoospermia factors are situated. ▶ [Marfan syndrome](#), ▶ [fragile X-chromosome](#), ▶ [Juberg-Marsidi syndrome](#), ▶ [Lowe's syndrome](#), ▶ [Coffin-Lowry syndrome](#), ▶ [Rett syndrome](#), ▶ [West syndrome](#), ▶ [Partington syndrome](#), ▶ [mental retardation](#), ▶ [oligophrenin](#), ▶ [tetraspanin](#), ▶ [non-syndromic](#); Fukami M et al 2000 Am J Hum Genet 67:563; Chelly J, Mandel J-L 2001 Nature Rev Genet 2:669; Shoichet SA et al 2003 Am J Hum Genet 73:1341; review: Skuse DH 2005 Human Mol Genet 14 (1):R27.

Mentalizing: The ability to read the mental states of others and self in the process. It engages many neural processes (Frith CD, Frith U 2006 Neuron 50:531).

Menthos: A group of dicotyledonous species of plants of various (frequently aneuploid) chromosome numbers. *M. arvensis*: 2n = 12, 54, 60, 64, 72, 92; *M. sylvestris*: 2n = 24, 48; *M. piperita*: 2n = 34, 64. They were the source of menthol (peppermint camphor) and other oils used in cough drops, nasal medication, anti-itching ointments, candy, liquors, etc. Menthol appeared non-carcinogenic although doses above 1 g/kg may cause 50% death in laboratory rodents when administered subcutaneously or orally.

Mentor Pollen Effect: The simultaneous application of dead or radiation damaged compatible (mentor) pollen with incompatible pollen may in some instances help to overcome the incompatibility of the latter and fertilization may result. ▶ [incompatibility alleles](#); Stettler RF 1968 Nature [Lond] 219:746.

Menu: In a computer, menu lists the various functions to choose. The menu bar on top of the screen of the monitor displays the titles of the menus available.

Meprin: A metalloendoprotease with α and β subunits. The β subunit is a kinase-splitting membrane protease. The α subunit stays in the endoplasmic

reticulum until its transmembrane and cytoplasmic domains are cleaved off and then it moves out. (See Ishmael FT et al 2001 J Biol Chem 276:23207).

MEPS (minimal efficient processing segment): The identical nucleotide tract length required for efficient initiation of recombination. ▶ [recombination mechanisms in eukaryotes](#)

MER (from the Greek μέρος, part): It is used as, e.g., octamer, indicating it is built of 8 units (octomer would be a Latin-Greek hybrid to be avoided even by geneticists).

MER: Medium reiteration frequency sequence; ~35 copies/human genome. ▶ [redundancy](#)

Mer: Human T cell protooncogene encoded receptor tyrosine kinase. It mediates phagocytosis and apoptosis of thymocytes. ▶ [TCR](#), ▶ [thymocytes](#), ▶ [phagocytosis](#), ▶ [apoptosis](#), ▶ [receptor tyrosine kinases](#)

Mer⁻ Phenotype: Mammalian cell defective in methyl-guanine-O⁶-methyltransferase.

Mercaptoethanol: Keeps SH groups in reduced state and disrupts disulphide bonds while proteins are manipulated in vitro. ▶ [DTT](#), ▶ [thiol](#)

Mercaptopurine: A purine analog inhibiting DNA synthesis and is therefore cytotoxic. The drug 6-mercaptopurine (6-MP) is effective against acute lymphoblastic leukemia (see Fig. M44). The enzyme thiopurine-S-methyltransferase (TPMT, 245 amino acids, encoded at human chromosome 6p22.3) catalyzes S-methylation of 6-MP and inactivation. The dominant allele (frequency ~0.94) determines high activity whereas the recessive (frequency ~0.06) conveys no detectable activity in the homozygotes and in the heterozygotes a low intermediate level occurs. At low or no TPMT activity 6-MP treatment may be fatal to the patients (about 1% of the population). The testing for TPMT may help to adjust the dosage yet some physicians do not favor it because delaying the treatment may also be risky. ▶ [leukemia](#), ▶ [TPMT](#)

Figure M44. Mercaptopurine

Merge: Merged images.

Merged Sequence Contig: The overlapping initial sequence contigs are merged. ▶ [initial sequence contig](#), ▶ [contig](#)

Mericlinal Chimera: The surface cell layers are different from the ones underneath just like in the periclinal chimeras but the difference is that the different surface layer does not cover the entire structure but only a segment of it (see Fig. M45). ▶[chimera](#), ▶[periclinal chimera](#); Jørgensen CA, Crane MB 1927 J Genet 18:247.

Figure M45. Mericlinal chimera

Meristem: Undifferentiated plant cells capable of production of various differentiated cells and tissues, functionally similar to the *stem cells* of animals. (See Fig. M46, ▶[stem](#), ▶[cells](#), ▶[flower differentiation](#), ▶[Seed germination](#), ▶[Arabidopsis mutagen assay](#); Weigel D, Jürgens G 2002 Nature 415:751; Nakajima K, Benfey PN 2002 Plant Cell 14:S265; axial patterning of shoot meristem: Grigg SP et al 2005 Nature [Lond] 437:1022.

Figure M46. Apical meristem

Meristemoid: For example, stomatal precursor cell. ▶[stoma](#)

Meristic Traits: Quantitative traits that can be represented only by integers, e.g., the number of kernels in a wheat ear or the number of bristles on a *Drosophila* body. ▶[quantitative traits](#)

7mer-9mer: Seven or nine base long conserved sequences in the vicinity of the V-D-J (variable, diversity, junction) segments of immunoglobulin genes in the germline DNA. ▶[immunoglobulins](#)

Merit, Additive Genetic: The same as the breeding value of an individual.

MERLIN (moesin, ezrin, radixin-like protein): The same as schwannomin. ▶[neurofibromatosis](#), ▶[ERM](#);

Bretscher A et al 2000 Annu Rev Cell Dev Biol 16:113.

MeRNA: Metal-binding RNA is required for proper folding of the molecule: <http://merna.lbl.gov/>.

Merodiploid: ▶[merozygous](#)

Merogenote: ▶[merozygous](#)

Merogone: A fragment of an egg.

Meromelia: ▶[limb defects in humans](#)

Merosin: ▶[muscular dystrophy](#)

Merosome: Parasite-filled transport vehicles of malaria that mediate migration in the bloodstream of the host and thus evade immunity. ▶[malaria](#); Sturm A et al 2006 Science 313:1287.

Merotelic Attachment: The capture of single kinetochores by microtubules from both centrosomes, i.e., the kinetochore is attached to both spindle poles. It may cause aneuploidy. ▶[kinetochore](#), ▶[centrosome](#), ▶[aneuploidy](#), ▶[spindle pole](#); Stear JH, Roth MB 2002 Genes & Development 16:1498.

Merozoite: ▶[Plasmodium](#)

Merozygous: A prokaryote, diploid for part of its genome (merogenote). Prokaryotes are functionally haploid but transduction or plasmid may add another gene copy into the cell. ▶[transduction](#), ▶[conjugation](#); Wollman E L et al 1956 Cold Spring Harbor Symp Quant Biol 21:141.

MERRF: ▶[mitochondrial diseases in humans](#)

MERRY: ▶[M genes causing developmental defects of the germ cells in the offspring](#)

MES (maternal effect sterility): MES occurs due to recessive genes causing developmental defects of the germ cells in the offspring.

Meselson-Radding Model Of Recombination (1975 Proc Natl Acad Sci USA 72:358): Explains gene conversion (occurring by asymmetric heteroduplex, symmetric heteroduplex DNA) and crossing over occurring from one initiation event as indicated by the data of *Ascobolus* spore octads. In yeast the aberrant conversion tetrads arise mainly from asymmetric heteroduplexes as suggested by the Holliday model ▶[Holliday model](#)). Symmetric heteroduplex covers the same region of two chromatids whereas asymmetric heteroduplex means that the heteroduplex DNA is present in only one chromatid. The heteroduplexes can be genetically detected very easily in asci containing spore octads. In the absence of heteroduplexes, the adjacent (haploid) spores are identical genetically. If the heteroduplex area carries different alleles the two neighboring spores may

become different after post-meiotic mitosis. Actually heteroduplexes may be detectable also in yeast (that forms only 4 ascospores) by sectorial colonies arising from single spores. Branch migration indicates that the exchange points between two DNA molecules can move and eventually they can reassociate in an exchanged manner in both DNA double helices involved in the recombination event. Rotary diffusion indicates that the joining between single strands can take place by movement of the juncture in either direction, thus making the heteroduplex shorter or longer. See Fig. M47, ►recombination models, ►recombination molecular mechanisms

Meselson-Stahl Model: Proved that in bacteria DNA replication is semi-conservative. See Fig. M48 ►semi-conservative replication; Meselson M, Stahl FW 1958 Proc Natl Acad Sci USA 44:671; Hanawalt PC 2004 Proc Natl Acad Sci USA 101:17894.

Mesenchyma: Unspecialized early connective tissue of animals that may give rise also to blood and lymphatic vessels. The epithelial–mesenchymal transition is mediated by transcription factors that repress E-cadherin expression. As a consequence embryonic morphogenesis can proceed. The transition also plays a part in the initiation of metastasis.

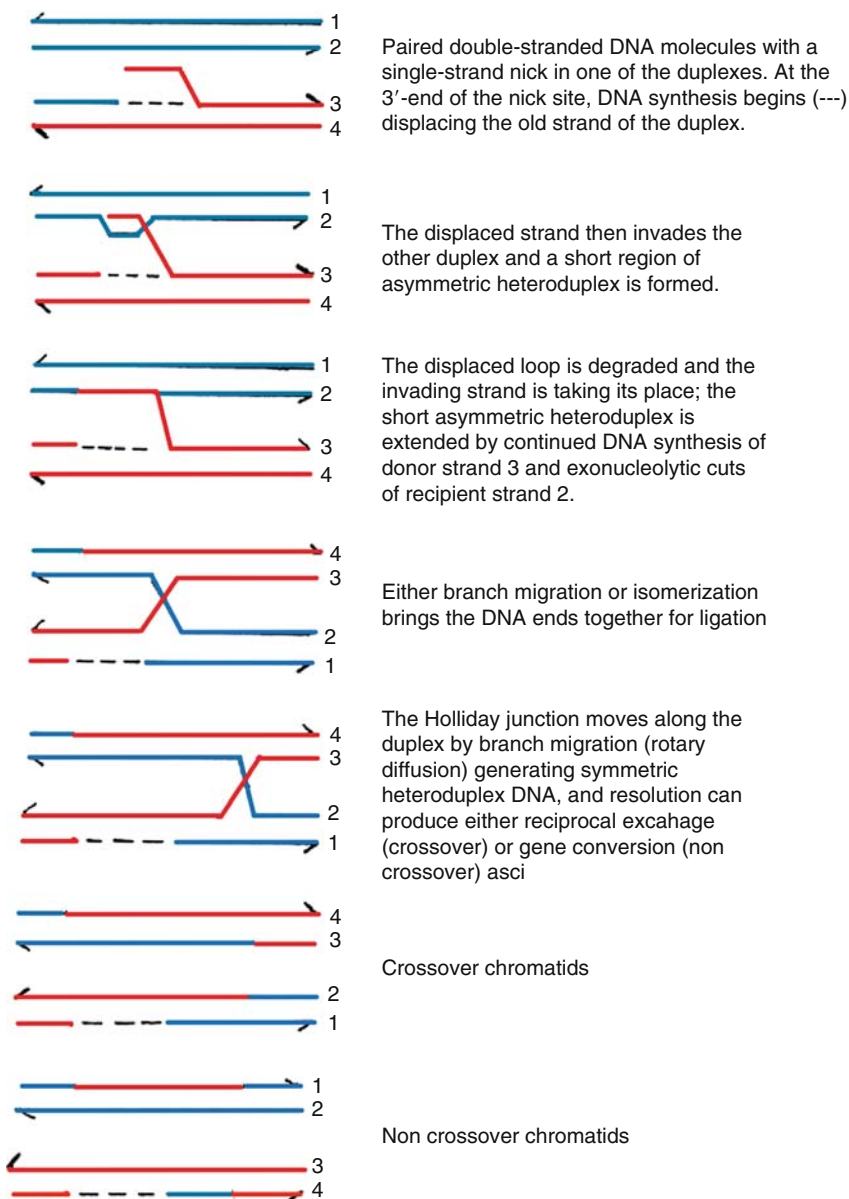

Figure M47. Meselson and Radding model of recombination

Figure M48. Density labeling was used (open box light DNA single strands), colored box (heavy strands). At left: the original double-stranded DNA molecule, in the middle: the first generation after one replication, at right: the second generation daughter molecules. This experiment thus indicated semi-conservative replication rather than conservative one in the absence of recombination

Mesenchymal stem cells are pluripotent and a balance between Runx2 and PPAR γ determine whether osteoblasts or adipocytes develop from the stem cells. The transcriptional activator with PDZ-binding domain (TAZ), a 14–3–3-binding protein coactivates Runx-dependent gene transcription and represses PPAR and functions like a rheostat (Hong J-H et al 2005 Science 309:1074). ▶osteoblast, ▶adipocyte, ▶RUNX, ▶PPAR, ▶PDZ, ▶mesoderm, ▶metastasis, ▶cadherins, Kang Y, Massagué J 2004 Cell 118:277.

MeSH: Database for information retrieval using certain MEDLINE terminologies. (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=mesh&cmd=search&term=>).

Mesocarp: The middle part of the fruit wall. ▶exocarp, ▶endocarp

Mesoderm: The middle cell layer of the embryo developing into connective tissue, muscles, cartilage, bone, lymphoid tissues, blood vessels, blood, notochord, lung, heart, abdominal tissues, kidney and gonads. Members of the transforming growth factor (TGF β) family of proteins regulate mesoderm development. ▶morphogenesis, ▶TGF, ▶eomesoderm, ▶endomesoderm, Furlong EEM et al 2001 Science 293:1629; Kimelman D 2006 Nature Rev Genet 7:360.

Mesogen (liquid crystal): Some compounds may exhibit transitions between crystalline and liquid forms and can be manipulated by rotation or external electric fields causing rotation. They have various applications (in cellular phones, pocket computers, etc) and because of these properties they may also be used for detection of binding of ligands to specific molecules. Heat responding mesogens may generate optical anisotropy and thus may transduce optical signals and thus facilitate molecular diagnostics without invasive procedures.

Mesokaryote: Organism(s) that occupy some kind of a middle position between prokaryotes and eukaryotes.

They are endowed with cytoplasmic organelles like plant cells but their nuclear structure reminds of prokaryotes. The amount of chromosomal basic proteins in the nucleus is low, the chromosomes are attached to the membrane yet they develop a nuclear spindle apparatus. Several microtubules pass through the nuclear membranes and in the majority of the species then pull the chromosomes to the poles with the membrane and without being attached to the chromosomes. In the dinoflagellate *Cryptocodinium cohnii* 37% of the thymidylate is replaced by 5-hydroxymethyluracil. More than half of the DNA is repetitious. The vegetative cells appear to be haploid and thus mutations can be readily detected. Both homo- and heterothallic species are known. ▶prokaryote, ▶eukaryote, Hamkalo BA, Rattner JB 1977 Chromosoma 60:39.

Mesolithic Age: Period about 12,000 years ago when domestication of animals and agriculture started. ▶paleolithic, ▶neolithic

Mesomere: A blastomere of about medium size. ▶blastomeres

Mesonephros: Secretory tissue of the embryo along the spinal axis supporting the development of the gonads.

Mesophyll: The parenchyma layers of the leaf blade (see Fig. M49) (below cuticle and epidermis).

Figure M49. Mesophyll

Mesophyte: Plants avoiding extreme environments such as wet, dry, cold or warm.

Mesosome: An invaginated membrane within a bacterial cell.

Mesothelin (MSLN/MPF, human chromosome 16): A 33kDa protein expressed in the lung and other organs. Various monoclonal antibodies have been developed that react with ovarian cancer (Chang F, Pastan I 1996 Proc Natl Acad Sci USA 93:136). ▶ovarian cancer, ▶monoclonal antibody, ▶humanized antibody

Mesothorax: The middle thoracic segment of insects, bearing legs and possibly wings (see Fig. M50). ▶Drosophila

Figure M50. Mesothorax

Mesozoic: Geological period in the range of 225 to 65 million years ago; age of the life and extinction of dinosaurs and several other reptiles. ► [geological time periods](#)

Messenger Polypeptides: Extracellular signaling molecules that can pass the cell membrane, enter the cell nucleus, recognize in the DNA a special sequence motif and activate then transcription. These messengers are different from hormones or other signaling molecules because they do not need membrane receptors or special ligands or series of adaptors or phosphorylation to be activated and becoming nuclear co-activators of gene expression. ► [lactoferrin](#)

Messenger RNA: ► [mRNA](#)

Mestizo: Offspring of Hispanic and American Indian parentage. ► [miscegenation](#), ► [mulatto](#)

MET Oncogene: Hepatocytic growth factor receptor gene in human chromosome 7q31. Its α subunit is extracellular and its β subunit is an extra- and transmembrane protein. It is a tyrosine kinase as well as a subject for tyrosine phosphorylation. The receptor of HGF-SF (hepatocyte growth factor/scatter factor) is the product of Met. Expression of the MET oncogene in the liver leads to hepatocarcinogenesis after blood coagulation and internal hemorrhages. The pathogenesis involves the upregulation of plasminogen activator inhibitor type 1 (PAI-1) and cyclooxygenase (COX-2) genes (Boccaccio C et al 2005 Nature [Lond] 434:396). An engineered decoy for MET inhibits its binding to the hepatocyte growth factor receptor; interferes with tumor proliferation, angiogenesis, suppresses or prevents metastasis synergizes with radiotherapy without affecting the physiological functions in mice (Michielli P et al 2004 Cancer Cell 6:61). ► [tyrosine kinase](#), ► [oncogenes](#), ► [hepatocyte growth factor](#), ► [papillary renal cancer](#), ► [cyclooxygenase](#), ► [plasminogen activator](#);

Birchmeier C et al 2003 Nature Rev Mol Cell Biol 4915.

$$\chi^2_{2m} = -2 \sum_{i=1}^m \ln(P_i)$$

Meta-Analysis of Linkage: Used when the information in an experiment is inadequate for drawing definite conclusions. In such cases, data from other comparable experiments are pooled the best possible way. Usually the formula of R.A. Fisher (Statistical Analysis for Research Workers) is used where the P = the probability of obtaining as or more extreme information under the assumption that there is no linkage, m = the data sets. The χ^2 is calculated by 2 degrees of freedom. Meta-analysis may be used for other synthetic purposes when the information available is inconclusive. Its conclusions, therefore, may have to be regarded with some reservations. Meta-analysis may reveal substantial variation/heterogeneity in the genetic association of disease symptoms. ► [linkage](#), ► [chi square](#), ► [association test](#), ► [GSMA](#); Allison DB, Heo M 1998 Genetics 148:859; Wise LH et al 1999 Ann Hum Genet 63 (Pt 3):263; Ioannidis JPA et al 2001 Nature Genet 29:306.

Metabolic Block: A non-functional enzyme (due to mutation in a gene, or to an inhibitor) prevents the normal flow of metabolites through a biochemical pathway.

Metabolic Footprinting: Monitors extracellular metabolites in the culture medium during different physiological states of wild type and mutant cells with the aid electrospray ionization-mass spectrometry. (See Electrospray MS, Allen J et al 2003 Nature Biotechnol 21:692).

Metabolic Pathway: A series of sequential biochemical reactions mediated by enzymes under the control of genes. Genetic studies greatly contributed to their understanding along with the use of radioactive tracers. ► [radioactive tracer](#), ► [auxotrophy](#), ► [MCA](#); <http://expasy.ch>; <http://ecocyc.PangeaSystems.com/ecocyc>; <http://path-a.cs.ualberta.ca>; metabolic pathway annotation tool: <http://kobas.cbi.pku.edu.cn/>; pathway reconstruction tool: <http://bioinformatics.leeds.ac.uk/shark/>; pathway networking tools for downloading: <http://biocyc.org/download.shtml>.

Metabolic Syndrome (MetS): The syndrome develops through the interplay of obesity and metabolic susceptibility. It provides information and guidance on insulin signaling, intensity of drug therapy for elevated cholesterol, aspirin prophylaxis, blood pressure and glucose control in cardiovascular disease (Grundy SM 2007 J Clin Endocrinol Metab 92:399; Petersen KK et al 2007 Proc Natl Acad Sci USA 104:12587). ► [diabetes](#), ► [heart disease](#), ► [cholesterol](#)

Metabolism: Enzyme-mediated anabolic and catabolic reactions in cells. ►BRENDA, ►MetaCyc, ►EX-Prot, ►MCA; compound/enzymes/reactions: <http://www.genome.ad.jp/ligand/>.

Metabolite: The product of metabolism. ►metabolism; <http://metacyc.org/>.

Metabolite Connectivity: The number of reactions of a metabolite. ►pathway tools

Metabolite Engineering: The transformation of certain genes into a new host may lead to production of substances that the organisms never produced before. It can also synthesize larger quantities or different qualities of certain proteins. Examples include: production of indigo or human insulin in *E. coli* or novel antibiotics or expressing antigens of mammalian pathogens in plants or changing the pathway of diacetyl formation in yeast to acetoin production and thus shortening the lagering process in brewing beers, etc. ►genetic engineering, ►protein engineering; Kholodenko BN et al 2000 Metabol Eng 2(1):1.

Metabolome: A complete set of (low-molecular weight) intermediates in a cell or tissue metabolism. Plants produce about 200,000 metabolites. ►gene function; Tweeddale H et al 1998 J Bacteriol 180:5109; Fiehn O 2002 Plant Mol Biol 48:155; human metabolome: <http://www.hmdb.ca>.

Metabolon: A supramolecular-associated complex of sequential metabolic enzymes. (See Reithmeier RA 2001 Blood Cells Mol Dis 27:85).

Metabonomics: The study of the metabolic status in the biofluids of animals (urine, serum, tissues) by high-resolution nuclear magnetic resonance spectroscopy and appropriate statistics to reveal possible toxic effects of chemicals used for drug development. Metabonomic studies may make possible personalized drug treatment if predose phenotyping variations are considered before administration of drugs to which individual differences in response can be predicted. Besides the metabonomic state a number of other factor nutritional state, gut microbiota, age, disease and co- or pre-administration of other drugs may have great influence (Clayton TA et al 2006 Nature [Lond] 440:1073). ►nuclear magnetic resonance spectroscopy; Robosky LC et al 2002 Comb Chem High Throughput Screen 5:651.

Metabotropic Receptor: The binding of a ligand initiates intracellular metabolic events. Many have transmembrane regions and may respond to second messengers such as cAMP, cGMP or inositol triphosphate. ►ionotropic receptor; Ramaekers A et al 2001 J Comp Neurol 438(2):213.

Metacarpus: The area of the hand between the wrist and fingers (see Fig. M51). ►metatarsus

Figure M51. Metacarpus

Metacentric Chromosome: Chromosome whose two arms are nearly equal in length (see Fig. M52). ►chromosome morphology

Figure M52. Metacentric chromosome

Metachondromatosis: Autosomal dominant multiple exostoses particularly on hands, feet, knees and limb bones, without deforming the bones or joints and which disappears with time. ►exostosis, ►fibrodysplasia

Metachromasia: When the same stain colors different tissues in different hues.

Metachromatic Leukodystrophy (MLD): A sulfatide lipidosis. Two distinct forms have been identified that are due to two recessive alleles of a gene, mutations in *A* and *I*, in human chromosome 22q13.31-qter. Due to the deficiency arylsulfatase A, cerebroside sulfate accumulates in the lysosomes. The accumulation of galactoside-sulfate-cerebrosides in the plasma membrane and particularly in the neural tissues (myelin) causes a progressive and fatal degeneration in the peripheral nerves, liver and kidneys. As a consequence failure of muscular coordination (ataxia), involuntary partial paralysis, hearing and visual defects as well as lack of normal brain function arise after 18 to 24 months of age and usually causes death in early childhood. In the juvenile form of the disease the symptoms appear between age 4 and 10 years. There is also an adult type of the disease with an onset after age 16 and involves schizophrenic symptoms. The mutations involve either a substitution of tryptophan at amino acid residue 193, or at threonine 391 by serine or a defect at the splice donor site at the border of exon 2. MLD has been observed also in animals. The reduced activity of the enzyme can be identified also in cultured skin fibroblasts of heterozygotes and prenatally in cultured amniotic fluid cells of fetuses. ►arylsulfates, ►sphingolipidoses, ►sphingolipids, ►Krabbe's leukodystrophy, ►prenatal diagnosis, ►lysosomal storage diseases, ►saposin

Metacline Hybrids: In *Oenotheras*, called the exceptional progeny that occurred only in reciprocal crosses due to the difference in transmission through egg and sperm of the different complex translocations. ▶ **complex heterozygotes**, ▶ **certation**, ▶ **mega-spore competition**

MetaCyc: A database of more than 445 metabolic pathways involving more than 1,115 enzymes in >300 organisms. ▶ **pathway tools**; <http://metacyc.org/>; <http://www.pubmedcentral.nih.gov/articlerender.fcgi?artid=99148>; <http://bioinformatics.ai.sri.com/ptools/>.

Metacyclic Trypanosoma: Parasitic eukaryote that lives in the salivary gland of insects, which spread sleeping sickness. ▶ *Trypanosoma*

Metacyclogenesis: The differentiation of the promastigote of *Leishmania* into a highly infective form in the sandfly. ▶ *Leishmania*

Metadata: Data about the data, i.e., closer information regarding the methods of collection, analysis, etc., of data available in databases or in reviews or in other publications.

Metafemale: Having more than the usual dose of female determiners; it may be XXX (see Fig. M53). ▶ *Drosophila*, ▶ **triplo-X**, ▶ **euploid**

Figure M53. Euploid metafemale *Drosophila*

Metagene: Metagene has several meanings.

1. A gene-predicting commercial software.
2. Network of genes mediating certain physiological functions as revealed by joint expression in microarrays and which display similarities across evolutionary boundaries (Stuart JM et al 2003 Science 302:249).
3. A mystical, hypothetical RNA formed under exceptional conditions imparting superhuman qualities to individuals, which form it.

Metagenesis: Sexual and asexual generations alternate.

Metagenomics: The analysis of the genomes of groups of organisms in samples from the environment, including special environmental locations, such as deep sea, hospital waste, acid mine water, and

archeological remains. Generally nucleotide sequences and functions are used. Such studies yield valuable information on evolution, new genes, new functions and new antibiotics. The human intestinal microbiota is composed of 10^{13} to 10^{14} microorganisms and their collective genome contains at least 100 times as many genes as the human genome (Gill SG et al 2006 Science 312:1355). ▶ **genomics**, ▶ **microbiome**; Riesenfeld CS et al 2004 Annu Rev Genet 38:525; Green Tringe S, Rubin EM 2005 Nature Rev Genet 6:805.

Metal Metabolism And Disease: ▶ **Wilson syndrome**, ▶ **Menkes syndrome**, ▶ **Occipital horn syndrome**, ▶ **hemachromatosis**, ▶ **acrodermatitis enteropathica**, ▶ **hyperzincemia**, ▶ **selenium-binding protein**, ▶ **glutathione peroxidase**, ▶ **aceruloplasminemia**, ▶ **metalloproteinases**, ▶ **metallothionein**, ▶ **protoporphyrin erythropoietic**, ▶ **porphyria**, ▶ **coproporphyrin**; Thompson KH, Orvig C 2003 Science 300:936.

Metallo-Base Pairing: The nucleobases (e.g., hydroxy-pyridone) are modified and paired not by hydrogen bonds but by an interstrand metal such as copper. The metal-containing bases are incorporated into the DNA by phosphoramidite chemistry or by automated DNA synthesis. Such a duplex may have advantage for some applications because of higher thermal stability or for the construction of molecular magnets. ▶ **hydrogen pairing**, ▶ **phosphoramidates**, ▶ **DNA chemical synthesis**; Tanaka K et al 2003 Science 299:1212.

Metalloprotein: The prosthetic group of the protein is a metal, e.g., hemoglobin. ▶ **hemoglobin**, ▶ **zinc-finger**; Annotations and Structure: Shi W et al 2005 Structure 13:1473; <http://metallo.scripps.edu>.

Metalloproteinases (metalloproteases): Cell surface endopeptidase enzymes mediating the degradation of the extracellular matrix, cartilage formation, the release of tumor necrosis factor α , a cytokine involved in inflammatory reactions, in embryogenesis, and cell migration. Membrane-bound metalloproteinase (matrix metalloproteinase, MMP3, stromelysin 1, 11q13) deficiencies cause cranio-facial anomalies, arthritis, dwarfism and other defects due to collagen and connective tissue problems. MMP11 (stromelysin III, 22q11.2) is overexpressed in metastatic breast cancers. Cancer tissues are associated with increased protease activities and it is supposed that these activities facilitate the bursting out of the tumor from the normal cell milieu and increase angiogenesis. MMP-9 (gelatinase, 20q11.2-q13.1) is a contributor to skin carcinogenesis. MMP8 I is collagenase I (11q21-q22), MMP2 is collagenase type IV (16q13) mediating endometrial breakdown during menstruation and may facilitate carcinogenesis by promoting angiogenesis. MMP1 is also a collagenase (11q22-q23). MMP26 (matrilysin 2,

11p15) is involved in tissue healing and remodeling. MMP7 (11q21-q22) is a relatively short uterine matrilysin protein. MMP15 (16q13-q21) and MMP16 (8q21) are membrane enzymes with roles in normal physiological as well as pathogenic processes at special organs. Metalloproteinase inhibitors are explored for cancer therapy. ▶*tace*, ▶*meltrin*, ▶*stromelysin*, ▶*collagenase*, ▶*bone morphogenetic protein*, ▶*night blindness* [Sorsby syndrome], ▶*ADAM*, ▶*arthritis*, ▶*disintegrin*, ▶*extracellular matrix*; Nagase H et al 1992 Matrix Suppl 1:421; Bode W et al 1999 Cell Mol Biol Life Sci 55:639; Sternlicht MD, Werb Z 2001 Annu Rev Cell Dev Biol 17:463; Coussens LM et al 2002 Science 295:2387; Egeblad M, Werb Z 2002 Nature Rev Cancer 2:163; Saghatelian A et al Proc Natl Acad Sci USA 101:10000.

Metallothionein: It is an SH-rich metal-binding protein in mammals. Its main function is detoxification of heavy metals. The promoter is activated by the same heavy metal the protein product binds. This promoter is very useful for experimental purposes because structural genes attached to it can be turned on and off by regulating the amount of heavy metal in the drinking water of the transgenic animals. It is encoded in human chromosome 16q13. ▶*transgenic*, ▶*Menke's disease*, ▶*metals*; Vasák M, Hasler DW 2000 Curr Opin Chem Biol 4:177.

Metals: They may contribute oxidative damage to the DNA and may hinder repair and enhance radiation damage. Beryllium, chromium and lead salts may enhance radiation damage. ▶*metallothionein*

Metamale: ▶*supermale*, ▶*Drosophila*

Metamerism: Anterior–posterior segmentation of the body of annelids and arthropods (see Fig. M54). In chemistry it is rarely used for a type of structural isomerism when different radicals of the same type are attached to the same polyvalent element and give rise to compounds possessing identical formulas.

Figure M54. Metameric insect

Metamorphosis: The distinct change from one developmental stage to another, such as from larva to adult or from tadpole to toad. ▶*Drosophila*

Metanomics: The use of gas chromatography and mass spectrometry to trace metabolic changes upon mutation or environmental changes. ▶*gas-liquid chromatography*, ▶*mass spectrum*

Metaphase: A stage in mitosis and meiosis when the eukaryotic chromosomes have reached maximal condensation and spread out on the equator of the cell (metaphase plane) and their arm ratios and some other morphological features can be well recognized. In meiosis I the bivalent chromosomes may be associated at their ends if chiasmata had taken place during pro-phase. The ring bivalents indicate crossing over between both arms whereas rod bivalents are visible when crossing over was limited to only one of the two arms. Figure M55 shows a HeLa cell at metaphase stained with DAPI, anti-tubulin (green) and human anti-centromere autoantibody (red), chromatin (blue). Courtesy of Kevin F. Sullivan, Department of Cell Biology, The Scripps Research Institute, San Diego, California and Don W. Cleveland, Ludwig Institute for Cancer Research, University of California, San Diego, California. ▶*meiosis*, ▶*mitosis*, ▶*chromosome rosette*, ▶*ring bivalent*

Figure M55. A fluoro-chrome-stained metaphase of HeLa human cells

Metaphase Arrest: Can occur if toxic agents or two separate kinetochores joined by translocation block the nuclear division. Homologous recombination does not lead to metaphase arrest indicating kinetochore tension may be responsible for the event. ▶*meiosis*

Metaphase Plane: The central region of the cell where the chromosomes are located during metaphase. Often incorrectly called metaphase plate (but no plate is involved). ▶mitosis, ▶meiosis

Metamphetamine (ecstasy): A psychoactive, addictive drug. In the presence of white light and riboflavin it is photodegradable to the non-psychoactive enantiomer via a type I photooxidation process by monoclonal antibody derived from mouse (Xu Y et al 2007 Proc Natl Acad Sci USA 104:3681).

Metaplasia: One cell type gives rise to another and in the tissue the two may be adjacent. Normally these two cell types are not expected to occur together. The phenomenon is attributed to different activation of a particular cell(s). ▶stem cells; Tosh D, Slack JMW 2002 Nature Rev Mol Cell Biol 3:187.

Metapopulation: A large population composed of smaller, local populations. (See Coalescent F, Hanski I et al (Eds.) 1997 Metapopulation Biology: Ecology, Genetics, and Evolution. Academic Press, San Diego).

Metastable: A potentially transitory state; it can change to more or less stable form.

Metastasis: The spread of cancer cells through the blood stream and thus establishing new foci of malignancy in any part of the body although, e.g., breast cancer cells frequently metastase to the lung or to the liver. Metastasis has been attributed to epigenetic changes and/or mutation during cancer progression. Several genes have been identified that predispose lung cancer to metastase specifically or mainly to lung (Minn AJ et al 2005 Nature [Lond] 436:518). Three membrane-anchored proteases, type-1, type-2, and type-3 metalloproteinases, independently confer cancer cells with the ability to proteolytically open the basement membrane scaffolding, initiate the assembly of invasive pseudopodia, and propagate transmigration (Hotary K et al 2006 Genes Dev 20:2673). VEGFR1-positive hematopoietic bone marrow progenitor cells scout out

suitable niches where metastatic cells can attach and support the incoming lung tumor cells. The VEGFR1 (vascular endothelial growth factor receptor) cells also express integrin $\alpha 4 \beta 1$, which upregulate fibronectin, an integrin ligand and have essential role in establishment of cancerous growth of metastized cells (Kaplan RN et al 2005 Nature [Lond] 438:820).

The invasiveness of cancer cells requires an active state of the integrin system, cell surface gelatinases (collagenases, proteases) so they could penetrate the extracellular matrix of the target cells. On the cell surface actually precursors of the gelatinases are found that are proteolytically activated by metalloproteinases. Heatshock protein 90 α seems to an activator of the surface metalloproteinase 2 (Eustace BK et al 2004 Nature Cell Biol 6:507). The plasminogen activator proteases include urokinase and tissue type activators. Plasminogen activator inhibitor (PAI1) is also required. IL-18 and TNF- α may promote cell adhesion and metastases by upregulating vascular cell adhesion molecule (VCAM-1, 1p32-p31) synthesis. Also ICE may facilitate metastasis after processing the precursors of IL-1 β and IL-18 proinflammatory cytokines. The CCR gene product appears to suppress metastasis by apoptosis of small cell lung carcinoma and melanoma cells. CXCR4 and CCR7 are highly expressed in breast cancer cells and metastasis.

Migrastatin, a macrolide antibiotic produced by *Streptomyces* and their synthetic analogs inhibit 91–99% of migration of some tumor cells of mouse and human tumor cells but did not inhibit cell proliferation at relatively low toxicity. These compounds were highly selective in their effect on tumor cells compared to normal cells (see Fig. M56). (Shan D et al 2005 Proc Natl Acad Sci USA 102:3772).

It seems that these chemokine receptors and chemokines play important role in metastasis. The direction of invasiveness may depend on the organs/tissues where these receptors are expressed. TIP30 kinase, which appears to be the same as CC3, up-regulates some apoptotic genes by phosphorylating the C-terminal domain of the largest subunit of DNA-dependent RNA polymerase II. Some interfering RNAs

Figure M56. Migrastatin, Macroketone, Macrolactam

(RNAi) suppressed metastasis of ovarian cancer cell line (SKOV3) by affecting a cyclin-dependent kinase (CDK7), a dual-specificity tyrosine phosphorylation-regulated kinase (DYRK1B), mitogen-activated protein kinase (MAP4K4) and serpin (SCCA-1). Such a procedure may have therapeutic potential for cancer (Collins CS et al 2006 Proc Natl Acad Sci USA 103:3775).

Mucin-type glycoprotein precursor of the core 3 structure (GlcNAc β 1–3GalNAc α 1-Ser/Thr) is synthesized by the enzyme β 1,3-*N*-acetylglucosaminyltransferase 6. Core 3 structure is markedly reduced in gastric and colorectal carcinomas in comparison to the Core 1 structure (Gal β 1,3GalNAc α 1-Ser/Thr) and core 2 structure and metastasis occurs. When the Core 3 synthase activity is restored by transfection of the active gene, metastasis is suppressed (Iwai T et al 2005 Proc Natl Acad Sci USA 102:4572). Platelet-derived lysophosphatidic acid promotes the progression of breast and ovarian cancer metastasis to bone. Silencing its receptor by siRNA provided effective protection (Boucharaba A et al 2006 Proc Natl Acad Sci USA 103:9643).

Lysyl oxidase (LOX) expression is regulated by hypoxia-inducible factor (HIF) and the high level of LOX presents poor prognosis for breast cancer and other tumors in mice (Erler JT et al 2006 Nature [Lond] 440:1222).

In *Drosophila* cooperation between Ras^{V12} and one of the cell polarity genes results in metastasis of tumor cells (Pagliarini RA, Xu T 2003 Science 302:1227). Techniques have been designed for the identification of genes, which control/suppress metastasis. In a forward mutation test of mice, disulfide isomerases (thiol isomerases), which catalyze disulfide bond formation, reduction and isomerization, were found to mediate metastasis. Overexpression of ERp5 promotes both in vitro migration and invasion and in vivo metastasis of breast cancer cells. These effects were shown to involve activation of ErbB2 and phosphoinositide 3-kinase (PI3K) pathways through dimerization of ErbB2. Activation of ErbB2 and PI3K subsequently stimulates RhoA and β -catenin, which mediate the migration and invasion of tumor cells (Gumireddy K et al 2005 Proc Natl Acad Sci USA 104:6696).

Hammerhead ribozyme proteins are hooked to RNA helicases. Such a system may destroy the transcripts of metastasis suppressor genes and thus enhance cell migration and can be assayed by an in vitro system (Suyama E et al 2003 Proc Natl Acad Sci USA 100:5616). Metastasis of melanoma cells may be initiated by an increase in the expression of fibronectin, RhoC and thymosin β 4 as visualized by microarray hybridization. Microarray hybridization of primary tumor tissue transcripts may permit the prognostication of tumor progression and patient

survival. ▶CD44, ▶cancer, ▶oncogenes, ▶malignant growth, ▶organizer, ▶contact inhibition, ▶saturation density, ▶collagen, ▶extracellular matrix, ▶VEGF, ▶fibronectin, ▶Rho, ▶thymosin, ▶metallopotein, ▶DAP kinase, ▶intravasation, ▶KISS, ▶urokinase, ▶plasminogen activator, ▶TNF, ▶ICE, ▶IL-1, ▶IL-18, ▶apoptosis, ▶PRL-3, ▶anoikis, ▶RAGE, ▶CCR, ▶CXCR, ▶ACIS, ▶ADM, ▶FAST, ▶macrolide, ▶wound-healing assay, ▶lysophosphatidic acid, ▶ERBB1, ▶PIK, ▶catenins, Al-Mehdi AB et al 2000 Nature Genet 6:100; Müller A et al 2001 Nature [Lond] 410:50; Liotta LA, Kohn EC 2001 Nature [Lond] 411:375; Trusolino L, Comoglio PM 2002 Nature Rev Cancer 2:289; Chambers AF et al 2002 Nature Rev Cancer 2:563; Dudley ME et al 2002 Science 298:850; Ramaswamy S et al 2003 Nature Genet 33:49; Steeg PS 2003 Nature Rev Cancer 3:55; Christofori G 2006 Nature [Lond] 441:444; Nguyen DG, Massagué J 2007 Nature Rev Genet 8:341.

Metatarsus: The middle bones beyond the ankle but preceding the toes in a human foot. In insects the basal part of the foreleg distal to the tibia but proximal to the tarsal segments and the claw (see Fig. M57). It carries the sexcombs in the male *Drosophila*. ▶*Drosophila*, ▶sex comb, ▶metacarpus

Figure M57. Metatarsus

Metaxenia: A physiological modification of maternal tissues of the fruit in plants by the genetically different embryo, e.g., in green hybrid apples the exocarp (skin) may become reddish if the pollen carries a dominant gene for red color. ▶xenia, ▶fruit

Metazoa: All animals with differentiated tissues; thus protozoa are excluded.

Methacrylateaciduria: β -hydroxyl-isobutyryl CoA deacylase deficiency—involving the catabolism of valine—leads to urinary excretion of cysteine and cysteinamine conjugates of methacrylic acid, and to teratogenic effects. Methacrylic acid [$\text{CH}_2=\text{C}(\text{CH}_3)\text{COOH}$] is a de-gradation product of isobutyric acid [$(\text{CH}_3)_2\text{CHCOOH}$] and the amino acid valine [$(\text{CH}_3)_2\text{CH}(\text{NH}_2)\text{CHCOOH}$]. ▶isoleucine-valine biosynthetic pathway

Methanococcus jannaschii: Bacterium with a genome of 1.67×10^6 bp DNA and 1,738 ORF. *Methanococcus thermoautotrophicum*'s genome is 1.75×10^6 and has 1,855 ORF. ▶ORF, ▶missing genes; Bult CJ et al 1996 Science 273:1058.

Methylacetoaceticaciduria (11q22.3–23.1): A 3-oxothiolase deficiency in the degradation of isoleucine resulting in 2-methyl-hydroxybutyric acid, 2-methylacetoacetic acid, tiglylglycine and butanone in the urine. Tiglic acid [$\text{CH}_3\text{CH}:\text{C}(\text{CH}_3)\text{CHO}$] is trans-2-methyl-2-butenic acid. ►isoleucine-valine biosynthetic pathway

Methylase: Enzymes in bacteria protect the cell's own DNA from type II restriction endonucleases by transferring methyl groups from *S*-adenosyl methionine to specific cytosine or adenine sites within the endonuclease recognition sequence (cognate methylases). When eukaryotic DNAs are transferred to *E. coli* cells by transformation for cloning, their methylation pattern may be lost because the methylation system of the prokaryotic cell is different from that of the eukaryote. *E. coli* does not methylate the C in a 5'-CG-3' but the *dam* methyltransferase methylates A in the 5'-GATC-3' sequence and the *dcm* methyl transferase methylates the boxed C in the 5'-c[]A GG-3' group. Such methylations may change the restriction pattern of cloned DNAs depending whether the particular restriction enzyme can or cannot digest methylated DNA. ►methylation of DNA, ►methylation-specific PCR; Cheng X, Roberts RJ 2001 Nucleic Acids Res 29:3784.

M

Methylation Filtration: The procedures that separate methylated and unmethylated DNA sequenced. Since in, e.g., maize ~95% of the exons are unmethylated, active, functional genes and active transposons can be separated from the bulk DNA. In higher plants, generally 60–80% of the DNA is repetitive and methylated; only ~7% of the repetitive DNA is unmethylated. In *E. coli* strain JM107MA2 the *McrA* and *McrC* modification-restriction systems are defective and do not permit cloning of methylated DNA. Thus cloning enriches the unmethylated genic and retroposon sequences and this “filtration” can reduce the difficulties of sequencing of genes of large eukaryotic genomes (Palmer LE et al 2003 Science 302:2115; Whitelaw CA et al 2003 Science 302:2118; Rabinowicz PD et al 1999 Nature Genet 23:305). ►methylation of DNA, ►cot filtration

Methylation Interference Assay: Detects whether a binding protein can attach to the specific DNA sites and thus provides information on the binding site and on the protein. The analysis is carried out by combining DNA and binding proteins and followed by treatment with methylating enzyme. If the protein binds to a specific guanine site(s), that base will not be methylated. Piperidine breaks DNA at bases modified by methylation, and sites protected from methylation by bound protein are not cleaved by piperidine.

►methylation of DNA; Shaw PE, Stewart AF 2001 Methods Mol Biol 148:221.

Methylation of DNA (DNMT): In many eukaryotes 1–6% or more of the bases in DNA is methylcytosine. In T2, T4 and T6 bacteriophage DNA 5-hydroxymethylcytosine occurs in place of cytosine. Methylation of other bases thymine (= 5-methyluracil), adenine and guanine may also occur in prokaryotes. Adenoviral DNA is not methylated but adenoviral as well as other foreign DNA integration into the mammalian genome may be followed by methylation of cytosine (Orend G et al 1995 J Virol 69:1226). The extent of methylation of the same 5'-CG-3' nucleotides varies in different tissues. Some of the alkylations of DNA bases lead to mutations by base substitutions. Methylation protects DNA from most of the restriction endonucleases (►restriction endonuclease types). In the majority of *E. coli* strains two enzymes are responsible for DNA methylation, *dam* and *dcm* methylase; *dam* methylates adenine at the N⁶ position within the sequence 5'-GATC- 3'. This sequence occurs at the recognition sites of a number of frequently employed restriction enzymes (Pvu I, Bam HI, Bcl I, Bgl II, Xho II, Mbo I, Sau 3AI, etc). Mbo I (↓GATC) and HpaII (C↓CGG) are sensitive to methylation but Sau 3AI and MspI, respectively, are not, and their recognition sites are identical (isochizomers), therefore when the DNA is methylated, the latter ones still can be used. For several restriction enzymes to work, the DNA must be cloned in bacterial strains that do not have the *dam* methylase. Mammalian DNA is not methylated at the N⁶ position of adenine, therefore Mbo I is always supposed to work, as well as Sau 3AI. The DNAs of eukaryotes are most commonly methylated on C nucleotides, in CG sequences. The *dcm* methylase methylates the internal C positions in the sequences 5'-CCAGG-3' and 5'-CCTGG-3'; this methylation interferes with cutting by EcoRII [↓CC(A/T)GG] but not by BstNI, although at another position [CC↓(A/T)GG] of the same sequence. *E. coli* strain K also has methylation-dependent restriction systems that recognize only methylated DNA: *mrr* (6-methyladenine), *mcrA* [5-methyl-C(G)], *mcrB* [(A/G)5-methyl C]. Mammalian DNA with extensive methylation at 5-methyl C(G) is, for, e.g., restricted by *mcrA*. Once the DNA is methylated, this feature may be transmitted to the following cell generation(s) by an enzyme, *maintenance methylase* although methylation is usually lost through the meiotic cycle. In bacteria, the expression of methylated genes may be reduced by a factor of 1000 but in mammals, the reduction may be of six orders of magnitude. Methylation in the promoter region usually prevents transcription initiation but not RNA chain elongation of that gene in mammals.

In the mouse, *Dnmt3a* and *Dnmt3b* are necessary for embryonic survival (*b*) or development after birth (*a*). The double mutants (*a, b*) cannot develop beyond gastrulation (Li E et al 1992 Cell 69:915). *Dnmt1* is incapable for de novo methylation; its role is maintenance methylation of the unmethylated strand generated by replication across the methylated strand in the double helix. Dnmt 1 and PCNA (proliferating cell nuclear antigen) are attracted to damaged DNA sites and this assures the maintenance of the methylated state after replication and repair (Mortusewicz O et al 2005 Proc Natl Acad Sci USA 102:8905). Inactivation of DNMT1 does not affect the status of methylation of CpG doublets in human cancer cells that is involved in the silencing of tumor susceptibility genes in several types of cancers (see Fig. M59). In melanoma and several solid tumors about 40% of the promoter of the p16^{INK4a} gene is hypermethylated. In endometrial, colon and gastric cancer cells the microsatellite instability is accompanied by up to 70–90% methylation. By base specific cleavage of DNA and the use MALDI/TOF/MS using high-throughput technology methylation pattern can be identified (Ehrich M et al 2005 Proc Natl Acad Sci USA 102:15785). The DAP kinase gene in Burkitt's lymphoma may be completely methylated. Mutation in the human DNMT3B gene is responsible for the rare immunodeficiency, ICF. ICF (20q11.2) involves immunodeficiency, pericentromeric hypomethylation and instability in lymphocytes and facial malformations. In some fungi (*Ascobolus*, *Neurospora*) peptide chain elongation may also be inhibited. The inhibition of initiation is attributed to the reduced binding of transcription factors to methylated DNA. Also, methylation-dependent DNA-binding proteins (MDBP) may suppress transcription. Methylation by Dnmt1 may affect also histone deacetylation and chromatin remodeling.

Figure M59. Some of the major factors controlling gene silencing. Proliferating Cell Nuclear Antigen (PCNA) and Chromatin Assembly Factor (CAF) cooperate in building the nucleosomal structure. DNA Methyltransferase (DNMT) is assisted by DNA Methyltransferase Associated Protein (DMAP) and the Tumor Suppressor Gene 101 methylates primarily cytosine residues and silences gene. Histone Deacetylase (HDAC) joins the system

Proteins MeCP1 and MeCP2 mediate silencing of gene expression due to methylation of CpG. MeCP1 effect on silencing depends on the density of methylation near the promoter. MeCP2 binds only single methylated CpG pairs and can act at a distance from the transcription factor binding sites. The effect of MeCP2 is apparently not gene-specific, it is rather global. Genomic imprinting is caused by differential methylation. In mice demethylation or lack of MeCP2 may prevent the normal completion of the embryonic development. In *Arabidopsis* plants demethylation to about 1/3 of the normal level caused either by a DNA (*ddm1*) demethylation mutation or by introducing by transformation an antisense RNA of the cytosine methyltransferase (MET1) caused alterations in the morphogenesis and developmental time of the plants. Demethylation of the *XIST* leads to its expression but that inactivates both X-chromosomes in the female and the single X in the male, an obviously lethal condition. The gene silencing by methylation in *Arabidopsis* is controlled by the *MOM* gene. This protein contains a sequence with similarity to the ATPase region of SWI2/SNF2 protein family, which is involved in chromatin remodeling. Inactivating *MOM* by antisense technology releases heavily methylated genes from the silenced state. In *Arabidopsis* the *mom1* mutation releases silencing independently from DNA demethylation (Mittelsten Scheid O et al 2002 Proc Natl Acad Sci USA 99:13659). Genome-wide methylation of *Arabidopsis* DNA has been mapped at 35-bp resolution. Pericentromeric heterochromatin, repetitive sequences and small interfering RNA regions are heavily methylated. About one-third of the expressed genes contain methylated bases within transcribed areas contrary to expectations. These genes are constitutively and highly expressed. Only 5% of the promoters display methylation and frequently show tissue-specific expression. Methylation epigenetically controls hundreds of genes and intergenic noncoding RNAs (Zhang X et al 2006 Cell 126:1189). Moderately transcribed genes of *Arabidopsis* are most likely to be methylated, whereas genes at either extreme are least likely. In turn, transcription is influenced by methylation: short methylated genes are poorly expressed, and loss of methylation in the body of a gene leads to enhanced transcription (Zilberman D et al 2007 Nature Genet 39:61).

Demethylation of tumor suppressor genes (by antisense technology) restores their suppressor function whereas methylation of the same genes silences them (Robert M-F et al 2003 Nature Genet 33:61). In some organisms with small genomes (*Caenorhabditis*) methylation of the DNA is very low, thus methylation may not have a general developmental regulatory role. In *Drosophila* DNA 5-methylcytosine is detectable only at very low frequency and mainly in

the embryo but interestingly the genome encodes two proteins that resemble cytosine DNA methyltransferase and methyl-CpG-binding-domain proteins. RNAi and microRNA in several organisms are also epigenetic silencing factors.

If 5-methylcytosine is deaminated, thymine results and a C≡G pair may suffer a transition mutation to T = A. It seems that the genome of higher eukaryotes, including humans, includes 35% or more active or silent transposable elements. It had been suggested that methylation of infective (inserted) DNA is part of the eukaryotic defense system. Actually most of the methylated cytosines in mammals are in the parasitic transposable elements. This methylation suppresses their transcription and the C→T mutation leads to the formation of pseudogenes. In the small invertebrate chordate *Ciona intestinalis* non-methylated transposons and normally methylated genomic sequences were detected (Simmen et al 1999 Science 283:1164). Not uncommonly the DNA of cancer cells is undermethylated at C residues indicating the demethylation of their parasitic sequences (SINE, LINE, Alu, etc.) and leading to the destabilization of the genome. The DNA methylase (methyltransferase) enzymes therefore have been supposed to be the means to defend the genome against the deleterious effects of the infective transposable/viral elements. In repetitive DNA CpG methylation is 37% higher than in non-repetitive sequences (Meunier J et al 2005 Proc Natl Acad Sci USA 1023:5471). Although this hypothesis is in agreement with many observations, it does not seem to be of general validity, particularly for the methylation of plant transposable elements. The epigenetic state of methylation can be transferred in the ascomycete, *Ascobolus* by a mechanism resembling or related to recombination. After fertilization, the methyl moieties are generally removed from the CpGs and an unmethylated state is maintained through blastula stage. Some of the genes involved in tumorigenesis display an increased methylation on aging. Housekeeping genes stay unmethylated whereas the methylation of tissue-specific genes varies by tissues. Reduced methylation causes developmental anomalies in plants and animals. The maternal genomes in haploid and diploid gynogenetic one-cell mammalian embryos are always methylated. The polar bodies are always methylated. The paternal genomes in haploid or diploid androgenetic embryos are de-methylated. Triploid digynic embryos show two methylated maternal and one de-methylated paternal chromosome set. In the diandric triploid embryos the methylation pattern is the opposite (Barton SC et al 2001 Hum Mol Genet 10:2983). In the mammals, the active X chromosome displays more than two times as much allele-specific methylation as the inactive X. This methylation is concentrated at gene bodies, affecting

multiple neighboring CpGs. Before X inactivation, all of these active X gene body-methylated sites are biallelically methylated. A methylation-demethylation program results in active X-specific hypomethylation at gene promoters and hypermethylation at gene bodies (Hellman A, Chess A 2007 Science 315:1141). Methyltransferase enzymes comprising enhanced zinc-finger arrays coupled to methyltransferase mutants are functionally dominated by their zinc-finger component. Both in vitro plasmid methylation studies and a novel bacterial assay reveal a high degree of target-specific methylation by these enzymes (Smith AE, Ford KG 2007 Nucleic Acids Res 35:740).

Changes in methylation are apparently not required for the regulation of development of zebrafish. Methylation of the normally barely methylated *Drosophila* DNA reduces viability. In the embryonic tissues of mice CpA and CpT are also methylated to some extent not just CpG. The methylation pattern of cancer cell DNA is usually altered (the promoter of tumor suppressor genes is heavily methylated) but the overall extent of methylation is lower. Methylation of the promoter may interfere with the attachment of the transcription factors. The silencing effect of methylation may be associated with the simultaneous deacetylation of the nucleosomes. Selective methylation of specific DNA sequences may be an important goal of regulating gene expression. The DNA adduct of an oligonucleotide-quinon methide may mediate the transfer of the methide to a complementary base and thus may assure selective targeting (Zhu Q, Rokita SE 2003 Proc Natl Acad Sci USA 100:15452). Methylation may strongly suppress recombination between repeated elements and thus preventing deleterious rearrangements of the genome (Maloisel L, Rossignol JL 1998 Genes Dev 12:1381). Genomic methylation is important factor in epigenetic modification of DNA and development. The program HDFINDER can detect CpG methylation in the human genome with ~86% accuracy (Das R et al 2006 Proc Natl Acad Sci USA 103:10713). ▶transposition, ▶transposable elements, ▶LINE, ▶SINE, ▶Alu, ▶silencing, ▶cross linking, ▶chemical mutagens, ▶alkylation, ▶mDIP, ▶paramutation, ▶imprinting, ▶regulation of gene activity, ▶lyonization, ▶cancer, ▶Sp1, ▶methylation resistance, ▶demethylation, ▶hypermethylation, ▶hypomethylation of DNA, ▶ascomycete, ▶5-azacytidine, ▶HMBA, ▶methylation-specific PCR, ▶methyltransferase, ▶PCNA, ▶CpG islands, ▶MeCP, ▶histone deacetylase, ▶base flipping, ▶RIP, ▶MIP, ▶miRNA, ▶RISC, ▶integration, ▶chromatin remodeling, ▶histone deacetylase, ▶histone methyltransferases, ▶methylation of RNA, ▶housekeeping genes, ▶carcinogenesis, ▶RLSG, ▶immunodeficiency, ▶methylome, ▶PAD4, ▶epigenesis, ▶DAM, ▶digyny, ▶diandry, ▶RNAi,

Methylation of DNA in Human Disease: ►imprinting, ►Albright hereditary osteodystrophy, ►Angelman syndrome, ►Beckwith-Wiedemann syndrome, ►cancer, ►diabetes mellitus, ►muscular dystrophy, ►fragile X syndrome, ►Prader-Willi syndrome, ►Rett syndrome; Robertson KD 2005 Nature Rev Genet 6:597.

Methylation of Proteins: Reversible post-translational alteration involved in regulation most frequently at arginine and lysine sites. ►histone methyltransferases; Server for methylation prediction: <http://www.bioinfo.tsinghua.edu.cn/~tigerchen/memo.html>.

Methylation of RNA: 2'-O-methyladenosine, 2'-O-methylcytidine, 2'-O-methylguanosine, 2'-O-methyluridine, 2'-O-methylpseudouridine are minor nucleosides in RNA. The cap of mRNA is a 7-methyl guanine, and a N⁶-methyladenosine occurs near the polyadenylated tract. DNA methyltransferase homolog Dnmt2 does not methylate DNA rather it methylates tRNA^{Asp} at cytosine 38 in mouse, *Drosophila* and *Arabidopsis* (Goll MG et al 2006 Science 311:395). ►capping enzyme; Santoro R, Grummt I 2001 Mol Cell 8:719.

Methylation Resistance: ►MNNG

Methylation-Specific PCR (MSP): Methylation of DNA is usually detected by the inability of the majority of restriction endonucleases to cleave methylated sites. MSP detects methylated CpG sites in minute amounts of DNA. The DNA is treated with sodium bisulfite to convert all non-methylated cytosines to uracil. Two different primers designed to represent original CpG rich sequences then amplify the methylated and unmethylated DNAs. The amplified DNA can then be sequenced to compare the differences between the two samples. Alternatively, the DNA is digested by restriction enzyme HpaII, which does not cut at sites

of methylated DNA (CC^mGG) but its isoschizomer MspI does. The DNA is exposed also RsaI (GT^mAC) to generate smaller fragments. The fragments are amplified by PCR in the presence of α³²P-dCTP and separated by gel electrophoresis. If a fragment is present in both the RsaI and (RsaI + HpaII) digest but not in the (RsaI + MspI) samples, it is considered to be methylated. Other isoschizomer pairs with one methylation-sensitive restriction enzyme can be used similarly. ►methylation of DNA, ►polymerase chain reaction, ►bisulfite reaction; Velinov M et al 2001 Genet Test 5(2):153; Oshimo Y et al 2004 Int J Cancer 110:212.

Methylated DNA-Binding Proteins: They bind methylated DNA and recruit additional proteins and the methylome silences transcription of DNA. ►methylation of DNA; Nan X et al 1998 Nature 393:311; Ng HH et al 1999 Nature Genet 23:58.

Methylator: It simultaneously methylates several sites in different cancer suppressor genes. ►CIMP, ►tumor suppressor, ►methylation of DNA

3-Methylcrotonyl Glycinemia: It is caused by the deficiency of a mitochondrial enzyme involved in the degradation of leucine, β-methylcrotonyl-CoA-carboxylase (MCCA, 19 exons, 3q25-q27). The β subunit is encoded at 5q12-q13 (MCCB, 17 exons). As a consequence of this autosomal recessive condition, muscle defects, and in some cases urinary overexcretion of 3-methylcrotonyl glycine and 3-hydroxyisovaleric acids occurs. Some patients respond favorably to biotin because this vitamin is a cofactor of the enzyme. ►isoleucine-valine metabolic pathway, ►isovaleric acidemia, ►3-methylglutaconaciduria, ►3-hydroxy-3-methyl-glutaricaciduria, ►amino acid metabolism; Gallardo ME et al 2001 Am J Hum Genet 68:334.

5-Methylcytosine (5mC): Common in tRNA and DNA of eukaryotes. Methylcytidylic acid is frequently called the fifth nucleotide. Deamination of 5-methylcytosine at CpG sites into thymidine is one of the most common causes of disease and accounts for 20% of all human point mutations (see Fig. M60). The methyl-CpG-binding domain protein MBD4 enzymatically removes T or U from the mismatched sites and protects against tumorigenesis (Millar CB et al 2002 Science 297:403). Thymine DNA glycosylase (TDG) has similar repair function. Sodium bisulfite converts cytosine but not 5mC into uracil. On this basis the location of 5mC in the nucleotide sequence can be determined. ►5-hydroxymethyl cytosine, ►5-azacytidine, ►bisulfite reaction, ►methylation of DNA; Clark SJ et al 1994 Nucleic Acids Res 22:2990.

Figure M60. 5-Methylcytosine

Methyl-Directed Repair: ►mismatch repair

Methylene Blue: Aniline dye, for microscopic specimens, an indicator of oxidation-reduction, an antiseptic, an antidote for cyanide and nitrate poisoning.

5,10-Methylenetetrahydrofolate Dehydrogenase (MTHFD1): An enzyme in folate and purine biosynthesis is encoded in human chromosome 14q24. ►folic acid

Methylenetetrahydrofolate Reductase (MTHFR, 1p36.3): MTHFR deficiency is responsible for homocystinuria and may affect human chromosomal nondisjunction. ►homocystinuria, ►nondisjunction

Methylglutaconicaciduria: The autosomal recessive condition is caused by a deficiency of 3-methylglutaconyl-CoA hydratase, an enzyme mediating one of the steps in the degradation of leucine. The patients may develop nerve disorders such as partial paralysis, involuntary movements, eye defects, etc. In some cases there is a marked increase of methylglutaric and methylglutaconic acid (an unsaturated dicarboxylic acid) in the body fluids. Leucine administration may exaggerate the symptoms. 3-methylglutaconic aciduria (MGA) type III is encoded at 19q13.2–q13.3. ►isoleucine-valine metabolic pathway, ►isovalericacidemia, ►3-hydroxy-3-methylglutaricaciduria, ►amino acid metabolism, ►endocardial fibroelastosis; Anikster Y et al 2001 Am J Hum Genet 69:1218; Ijlst L et al 2002 Am J Hum Genet 71:1463.

Methylgreen-Pyronin: A histological stain; coloring DNA blue-green and RNA red. ►stains; Brachet J 1953 Quart J Microscop Sci 94:1.

Methylguanine-O⁶-Methyltransferase: An enzyme that reverses the alkylation of this base, and it is thus antimutagenic and anticarcinogenic. Cells defective in the enzyme (Mer⁻, Mex⁻) are extremely sensitive to DNA-alkylating agents. Mutant enzymes with increased methylguanine-O⁶-methyltransferase activity

may decrease the cells's sensitivity to alkylating mutagens. ►methylation of DNA, ►antimutator; Lips J, Kaina B 2001 Mutation Res 487:59; Zhou Z-Q et al 2001 Proc Natl Acad Sci USA 98:12566.

2-Methyl-3-Hydroxybutyryl-CoA Dehydrogenase

Deficiency (HADH2, Xp11.2): This deficiency results in motor function disorder, blindness and epilepsy due to inborn error of isoleucine metabolism. ►isoleucine-valine biosynthetic pathway; Ofman R et al 2003 Am J Med Genet 72:1300.

Methylimidazole: ►pyrrole

Methyljasmonate: The fragrance of jasmine and rosemary plants; it is a proteinase inhibitor.

Methylmalonicaciduria: There are several forms of the metabolic disorder, methylmalonic-CoA mutase deficiency (MUT), in human chromosome 6p21, and another is caused by a defect in the synthesis of adenosyl-cobalamin (cblA, vitamin B₁₂) a necessary co-factor in the biosynthesis of succinyl-CoA from L-methylmalonyl-CoA by MUT. A third type of methylmalonic aciduria is due to a defect in the enzyme epimerase (racemase) that converts D-methylmalonyl-CoA to the L form. This pathway is represented in Fig. M61. In these disorders methylmalonic acid and glycine may accumulate in the body fluids, and the affected individuals may show serious (growth and mental retardation, acidosis [keto acids in the blood]) or almost no adverse effects. High protein diet (valine, isoleucine) may aggravate the condition. Administration of vitamin B₁₂ may alleviate the problem in some cases. ►methylcrotonylglycemia, ►amino acid metabolism, ►vitamin B₁₂ defects, ►ketoaciduria

Methylmercuric Hydroxide (MMH): MMH may be added to the electrophoretic agarose running gel of RNA, and when it is stained with ethidium bromide in 0.1 M ammonium acetate the color of the RNA is enhanced. It is also used to treat mRNA for preventing the formation of secondary structure during the synthesis of the first strand of cDNA. Note that MMH is an extremely toxic volatile compound. ►cDNA, ►electrophoresis

Methylmethanesulfonate: A powerful alkylating agent and mutagen/carcinogen. ►ethylmethane sulfonate

Methylome: The methylated part of the genome, the factors involved in methylation of DNA. ►methylation of DNA, ►methylated DNA binding proteins;

Figure M61. Methylmalonyl pathway

methylome of the *Arabidopsis* genome: Silberman D et al 2007 Nature Genet 39:61.

Methylphosphonates: Oligonucleotide analogs used for antisense operations. They are readily soluble in water and resistant to nucleases. The oligonucleoside methylphosphonates form stable complexes with both RNA and single- and double-stranded DNA. They have both antiviral and anticarcinogenic effects (see Fig. M62). ▶[antisense technologies](#), ▶[mixed backbone oligonucleotide](#); Schweitzer M, Engels JW 1999 J Biomol Struct Dyn 16(6):1177.

Methyltetrahydrofolate Cyclohydrolase Deficiency: Affects folate and purine metabolism. ▶[phosphoribosylglycinamide formyltransferase](#), ▶[folic acid](#)

Methylthioadenosine Phosphorylase (MTAP): MTAP is encoded in human chromosome 9p21 area, and its defect or deletion is characteristic for many malignant tumors, and it may be associated (linked) to a tumor suppressor activity of CDK-4. Methylthioadenosine is abundant in some human tissues and it is an important donor for methylation. ▶[CDK](#), ▶[methylation of DNA](#); Hori Y et al 1998 Int J Cancer 75:51.

Methyltransferase, DNA (dnmt1, dnmt1-b, 19p13.3-p13.2): Responsible for the methylation of CpG sites. These are encoded in humans by the same gene locus but the transcript is spliced alternatively. The activity of these enzymes is increased during the initiation and progression of carcinogenesis but the methylation of DNA in tumors is altered and usually reduced. The 1,620-amino acid mammalian dnmt is essential for embryonic development of the mouse. Methyltransferases have important role in regulation of gene activity, restriction-modification in bacteria, mutagenesis, DNA repair, cancer, imprinting, chromatin organization and lyonization. DNA methylating enzymes are scarce in some insects (*Drosophila*), which do not have methylation in the genetic material. ▶[cancer](#), ▶[methylation of DNA](#), ▶[methylguanine-O⁶-methyltransferase](#), ▶[immunodeficiency](#), ▶[restriction-modification](#), ▶[set motif](#), ▶[histone tail](#), ▶[histone methyltransferases](#); Adams RLP 1995 Bioassays 17:139; Bestor TH 2000 Hum Molec Gen 9:2395; Kiss A 2001 et al 2001 Nucleic Acids Res 29:3188; Verdine GL, Norman DPG 2003 Annu Rev Biochem 72:337; Goll MG, Bestor TH 2005 Annu Rev Biochem 74:481.

Methylviolet: An aniline dye for bacterial microscopic examination.

Metree: A computer program package for inferring and testing minimum evolutionary trees; designed by the Institute of Molecular Evolution, Pennsylvania State University, Philadelphia, PA, USA. ▶[evolutionary tree](#)

METRO (message transport organizer): A mechanism and center for sorting out molecules within the developing oocyte. ▶[morphogenesis](#), ▶[RNA localization](#)

Metronidazole (2-methyl-5-nitro-1-imidazole ethanol): A radiosensitizing agent and mutagen for chloroplast DNA, and a suspected carcinogen (see Fig. M63). ▶[chloroplast genetics](#), ▶[formula](#)

MGT: The MGMT group of enzymes; they are encoded in human chromosome 10q and protect the cells against the genotoxic, recombinogenic and apoptotic effects of O⁶-methylguanine with the aid of mismatch repair. When MGMT is expressed at high level the formation of O⁶-methylguanine is substantially reduced. ▶MGMT, ▶Mer; Kaina B et al 2001 *Progr Nucleic Acid Res Mol Biol* 68:41.

MHC: Major histocompatibility complex is involved in immunological reactions; it is controlled by linked multigene families (HLA) determining cell surface antigens and thus cellular recognition. The acronym is used also to the myosin heavy chain. ▶HLA, ▶Immune system, ▶major histocompatibility complex; MHC binding peptides: <http://www-bs.informatik.uni-tuebingen.de/SVMHC/>.

MHC Restriction: ▶immune system

MIAME (minimum information about a microarray experiment): A required standard for acceptance of microarray data by the major journals since 2002. (See *Nature Genet* 32:333; *Science* 298:539; *Gene Expression Omnibus*; <http://www.mged.org>).

MIC: Minimal inhibitory concentration. ▶micRNA

M

MICA/B Proteins: Intracellular proteins, which mark (cancer) cells for destruction by natural killer cells. Association of MICA with endoplasmic reticulum protein 5 (similar to disulphide isomerase) potentiates shedding of tumor-associated killer cell ligand NKG2D and promotes the immune evasion of tumor cells (Kaiser BK et al 2007 *Nature [Lond]* 447:482). ▶killer cells, ▶disulphide bridge, ▶immune evasion

Micelle: A round body of (protein) substances surrounded by lipids.

MICER (mutagenic insertion and chromosome engineering resource): A collection of 93,960 insertional targeting vectors; 5,925 of them inactivate genes with 28% efficiency (Adams DJ et al 2004 *Nature Genet* 36:867). ▶targeting genes, ▶insertional mutation, ▶chromosome engineering

Michaelis–Menten Equation: It measures enzyme kinetics in a process:

$$(E) + (S) \xrightleftharpoons[k_2]{k_1} (E) \xrightarrow{k_3} \text{Product(s)} + (E), \text{ where } k_1, k_2, k_3 \text{ are constants of the reactions, } (E) = \text{enzyme, } (S) = \text{substrate concentration and } v = \frac{V(S)}{K_m + (S)} \text{ or } K_m = (S) \left[\frac{V}{v} - 1 \right] \text{ where } v \text{ is the velocity of the reaction when half of the substrate molecules is combined with the enzyme, } V = \text{the maximum velocity, and } K_m = \frac{[(E)-(ES)](S)}{(S)}$$
 is the Michaelis–Menten constant. also ▶Lineweaver–Burk plot).

Michel Syndrome (oculopalatoskeletal syndrome): An autosomal recessive multiple defect involving the eyelid, opacity of the cornea, cleft lip and palate, defects of the inner ear and spine column, etc. It causes complete deafness. ▶deafness, ▶eye diseases

micRNA (messenger RNA-interfering RNA): This RNA is transcribed on short sections of the complementary strand DNA; prevents gene expression. ▶antisense RNA, ▶RNAi, ▶microRNA; Mizuno T et al 1984 *Proc Natl Acad Sci USA* 81:1966.

Microarray: ▶Microarray hybridization, ▶DNA chips, ▶small molecule microarray, ▶protein array, ▶protein chips; microarray data repository: <http://www.ebi.ac.uk/arrayexpress-old/>.

Microarray Hybridization: A microtiter tray with wells containing DNA to which fluorochrome-labeled-RNA can be hybridized. After incubation and scanning the amounts of the mRNAs derived from the same tissue can then be quantitated (by fluorescence intensity). A microarray tray looks similar to the pattern shown in the Fig. M64. Its size may be as small as 18 × 18 mm. The thousands of genes expressed on a single tray may

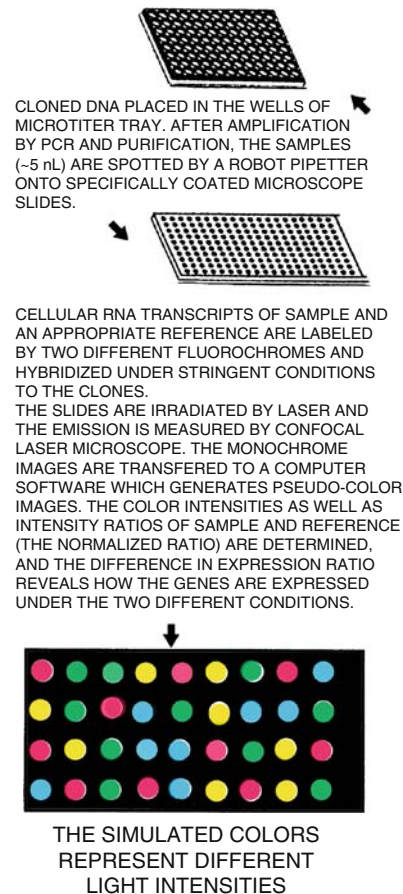

Figure M64. Microarray Hybridization

display different fluorescent colors according to the fluorochrome labeling of the probe in a spot test. Such an analysis may identify the simultaneous expression of large sets of genes at a particular developmental or disease/health stage and thus, permits a functional study at the entire genome level. Most commonly, the colors shown in the publications represent the intensity of hybridization (red the highest).

If the tissues are, for, e.g., from healthy and diseased sources, the genetic cause of the disease can be inferred on the basis of the level of expression. Depending on the type of fluorescent label used, the RNA sample may vary from 10 µg to 50 ng and the number of cells needed to extract this much material may vary from >1 to 10^9 . The analysis may begin with cDNA clones or PCR-amplified samples transferred to glass plates or nylon filters where appropriate probes are hybridized to the arrays. For the glass slides, usually fluorochrome labeling is used whereas with the nylon support phosphor imager (P^{33} , half-life ~ 25 days) is employed. The data is first evaluated by image processing after the information is fixed in JPEG or GIF formats. Then statistical and biological methods are applied (JPEG, TIFF and GIF are Adobe PhotoShop computer formats). The information reveals the function of many genes in a context in different tissues, developmental or pathological states, and may be used for simultaneous characterization of many tumor biopsies. By sophisticated computer-based analysis of the biological meaning of the information, *data mining* permits the identification of genes, which are either expressed simultaneously or in certain tissues; in a specific state of a disease or diseases; which appear epistatic or respond to a particular condition.

Microarray interrogated with short synthetic RNA oligomers permit the analysis of polymorphism at $\sim 2\%$ accuracy in up to 40,000 genes per microarray, which is more than enough for a genome the size of yeast. By the use of hierarchical clustering algorithms, parameterization or profiling methods, gene expression can be “mapped” not unlike the methods of genetic or physical mapping. However, clustered functions are independent from the physical location of the genes but may indicate the co-transcribed compartments and interaction of gene products. The pattern of expression reflects the dynamic network of timing, the physiological and developmental processes. The microarrays may be used to study the co-regulation of genes and the exploration of the global or particular effects of mutation or repression of single genes. Furthermore, the co-expression patterns of pathogens and host cells can also be revealed.

The *spotting method* outlined above uses a single clone for the analysis of each mRNA. The GeneChip Expression (Affymetrix, 3380 Central Expressway, Santa Clara, CA 95051) employs about 16 pairs

of specific oligonucleotide probes to interrogate each transcript. (The description given is based on information and images provided by Affymetrix and Gene Microarray Shared Resource, Ohio State University.) The latter procedure is better suited for reducing and identifying non-specific hybridization and background effects and therefore it is more sensitive and more accurate. Basic principles can be outlined as follows. A *target sequence* of ~ 600 nucleotides of gene is selected from a public database. About 16 to 20 *probes* are generated to match the sequences of the database. A pair of 25-base probe is of two types.

The *perfect match* (PM) is entirely identical to a tract of the DNA. The *mismatch probe* (MM) is the same as the PM except for a single mismatch in the middle. The rationale for using a MM probe is to have a control for non-specific hybridization. These probes are synthesized on a GeneChip, a small glass plate. The synthesis is a light-directed process (photolithographic fabrication) yielding large quantity of accurate probes at an economical manner (see Fig. M65).

From the biological sample, biotinylated mRNA is prepared, fragmented by heat and applied to a *probe array*, which is 1.28×1.28 cm glass surface held on a small tray. Hybridization is allowed for about 16 hours. The extent of hybridization is ascertained by the fluorescence intensity as detected by a laser scanner.

From a small segment of image, the intensity of the hybridization (i.e., the identity of the target and the probe pair) may have the alternative matches shown below. White corresponds to high hybridization intensity, black no measurable hybridization signal. Intermediate shades or colors correspond to intermediate signals. When the Perfect Match and the Mismatch signals are inconsistent, the hybridization is not detectable (see Fig. M66).

The Microarray Suite (MAS) software manages the Affymetrix GeneChip experiments. The relative expression of a transcript is determined by the difference between each probe pair (PM minus MM) and averaging the difference over the whole probe set (*Avg Diff*). The term *Abs Call* for a probe set is a qualitative measure based on three different determinations collected by MAS 4.0. The Absolute Call for a probe set can be “A” for non-detectable, “M” for marginal and “P” for present. *Diff Call*, difference call is the qualitative call for a probe set representing the outcome of one array set compared to another. There are five possibilities:

“I” increased, “MI” moderately increased, “NC” no change, “MD” moderately decreased and “D” decreased call.

Microarray hybridization is an essential tool in proteomics, for the study of genetic networks that

Figure M65. DNA chips. Different 25-mer oligonucleotide probes in an area of 1.28×1.28 cm. The array contains probe sets for more than 6,800 human genes, and the image was obtained after overnight hybridization of an amplified and labeled human mRNA sample. Image by courtesy of Affymetrix Inc. and from Fields S et al 1999 Proc Natl Acad Sci USA 96:8825; [Copyright by the National Academy of Sciences, U.S.A. 1999]

Figure M66. Hybridization signal evaluation

play an important role in development and in studies of the reaction to drugs. The impact of stress or cancer on gene expression may become amenable to interventions. The simultaneous effect of various drugs on a family of genes can be assessed. The availability of these methods is completely revolutionizing information gathering on the expression of genes, and may be exploited for the study of the simultaneous expression of many genes involved in a pathway or related pathways. A number of factors may affect the efficiency of hybridization, such as temperature, base composition (A=T versus G=C) and even at the same composition, the actual sequences of the bases, secondary structures, sequence length, distribution of mismatches, etc. Unexplained variations have also been seen with the present-day—steadily improving—technologies. An alternative approach for monitoring gene expression pattern optically measures light emission of transcriptional gene fusions of luciferase structural genes to

promoters of operons or regulons. Gene expression (mRNA), and protein levels can be analyzed under a variety of conditions and an integrated picture can be derived of metabolic networks. The same basic principle has also been applied to an array of animal cells, which are transfected with a variety of cDNAs and the expression of the transgenes that affect cellular physiology is monitored. ▶SAGE, ▶laser desorption MS, ▶electrospray MS, ▶two-hybrid method, ▶DNA chips, ▶epistasis, ▶synexpression, ▶operon, ▶regulon, ▶luciferase, ▶transcriptional gene fusion, ▶base-calling, ▶IMAGE clones, ▶genetic network, ▶global single cell reverse transcription-polymerase chain reaction, ▶macroarray analysis, ▶genomics, ▶interrogation genetic, ▶cluster analysis, ▶support vector machine, ▶activity-based protein profiling, ▶TOGA, ▶protein arrays, ▶lymphochips, ▶SOM, ▶tissue microarray, ▶light directed parallel synthesis, ▶MAGE, ▶MELANIE, ▶MIAME, ▶Atlas™ human cDNA, ▶linkage; Ermolaeva O et al 1998 Nature Genet 20:19; Nature Genet 21(1) Supplement Nature Biotechnol 17:974; Scherf U et al 2000 Nature Genet 24:236; Van Dyk TK et al 2001 Proc Natl Acad Sci USA 98:2555; Ideker T et al 2001 Science 292:929; Ziauddin J, Sabatini DM 2001 Nature [Lond] 411:107; Stoughton RB 2005 Annu Rev Biochem 74:53; computations: Quackenbush J 2001 Nature Rev Genet 2:418; Zhao LP et al 2001 Proc Natl Acad Sci USA 98:56321; Schulze A, Downward J 2001 Nature Cell Biol 3:E190; Yang YH, Speed T 2002 Nature Rev Genet 3:579; Nature Genet Suppl 2002 32:461–552; transcript concentration analysis: Held GA et al 2003 Proc Natl Acad Sci

Microarray Image Analysis: It performs gridding (location of spots on the slide), segmentation (differentiates the pixels between spots and background), information extraction (calculation of fluorescence intensity from the segmentation information). ► [microarray hybridization](http://ihome.cuhk.edu.hk/~b400559/arraysoft_image.html); http://ihome.cuhk.edu.hk/~b400559/arraysoft_image.html.

Microbe: Small organisms like the eukaryotic fungi, algae and protozoa and the prokaryotic blue-green algae, bacteria and viruses. The 2–3 billion microbial species exhibit enormous genetic diversity and are largely unknown. They are frequently associated with disease. The identification of particular microbes may be quite difficult by morphology or culture methods. Recently, broad-range polymerase chain reaction, representational difference analysis and expression library screening for specific sequences became feasible and greatly improved identification by molecular means. ► [RDA](#), ► [PCR broad-base](#), ► [microarray hybridization](#), ► [microbiome](#); <http://pbil.univ-lyon1.fr/emglib/emglib.html>; microbial genomes: <http://microbialgenome.org/>; <http://www.biocrawler.com/encyclopedic/Microorganism>; microbial orthologous groups: <http://mbgd.genome.ad.jp/>.

Microbial Safety Index: The logarithm of the reciprocal number of microbes that have survived after a procedure of sterilization. Sterilization, in principle, is the destruction of all infective agents but, in

practice, a small fraction of $\sim 10^{-6}$ may survive the treatment.

Microbiome: The collective genomes of the very large number of microbes that inhabit the human or animal body or a particular space. Their populations of 500–1000 species were estimated to exceed that of the number of somatic cells of the body. The human gut may include 10^{11} foreign cells per mL of proximal colonic content. There are 2 to 4 million genes encode metabolic capacities absent from the human proteome and thus play important roles in human nutrition (Xu J et al 2003 Science 299:2074). One study found 128 phylotypes (belonging to a taxonomic phylum) of microbes in the human stomach and the microbial community was different than that in the mouth or in the esophagus (Bik EM et al 2006 Proc Natl Acad Sci USA 103:732). The human oral cavity may harbor ~ 500 different microbial species (Paster BJ et al 2001 J Bacteriol 183:3770). The human intestinal flora of bacteria is transmitted during the birth process (vaginal delivery) from the mother and maintained in the offspring. It may be different, however, between marital partners although some changes may occur depending on toilet use, antibiotic treatment, shift in diet or infection with different parasites. Some lateral gene transfer among the various bacteria within the gut does occur yet it does not entirely homogenize the populations. The microbiome inhabiting different mammalian species is different although some similarities may be established by environmental factors and selection. The host immune system may be somewhat responsive to these microbes yet does not eliminate them. When gut microbiome was reciprocally transplanted between germ-free mouse and zebrafish the transplanted community resembled its origin but in the lineage, it resembled the abundance of the recipient host indicating a selective pressure of the host gut habitat (Rawls GF et al 2006 Cell 127:423).

According to a new estimate there appears to be 10^{16} prokaryotes in a ton of soil, much more than the estimated number of stars in the galaxy (10^{11}). These estimates may not be entirely accurate because they are based on some data and hypothesis and mathematics (Curtis TP, Sloan WT 2005 Science 309:1331). The secretion through/by the roots—that varies according to species—determines the microbe communities in the rhizosphere (Mark GL et al 2005 Proc Natl Acad Sci USA 102:17454). ► [gut](#), ► [metagenomics](#), ► [oral bacterial film](#), ► [vagina](#), ► [inclusive fitness](#), ► [Paneth cell](#); gastrointestinal microbial flora in metabolism and health: Nicholson JK et al 2005 Nature Rev Microbiol 3:431; plant pathogenic RNA viruses in human feces: Zhang T et al 2006 PLoS Biol 4(1):e3; review of human

intestinal microflora: Ley RE et al 2006 Cell 124:837; human microbiome: <http://bioinformatics.forsyth.org:7070//homd/>; human oral microbiome: http://bioinformatics.forsyth.org/old_homd/.

Microbodies: ► **peroxisomes** (see Fig. M67)

Figure M67. Microbody

Microcalorimetry: Detects the minute change in heat energy resulting from molecular interactions, associations, and dissociations. Two procedures are used: *differential scanning calorimetry* (DSC) to record the changes in temperature while proteins are unfolding and *isothermal titration calorimetry* (ITC) to record the changes in temperature while the solutions are mixed. ► **immunoprecipitation**, ► **surface plasmon resonance**

Microcell: A micronucleus, a piece of chromatin, a chromosome or a few chromosomes surrounded by a membrane. Microcells are suitable vehicles for the transfer of blocks of genetic material or entire chromosomes between organisms. ► **transchromosomal**, ► **micronucleus**

Microcell Hybrid: Contains a single (e.g., human) chromosome in a complete other (e.g., mouse) genome. The hybrid, using deletions, may permit the identification of specific functions associated with segments of the critical chromosome. ► **somatic cell genetics**, ► **transchromosomal**; Cao Q et al 2001 Cancer Genet Cytogenet 129(2):131.

Microcephaly (19.13.1, 15q15, 9q33, 1q31, 13q12.2): Abnormal smallness of the head (brain volume $\sim 400 \text{ cm}^3$); generally involves mental retardation. It is a condition due to various genetic and environmental causes (e.g., X-ray, exposure of the fetus to heat [febrile]). The incidence of the autosomal recessive form is about 2.5×10^{-5} . A deletion of chromosomal segment 1q25-q32 or mutation in 1q31-32 may be the cause of severe cases. The 8p23 locus encodes the microcephalin protein regulating brain size and it continuously undergoes adaptive positive selection for larger brain (Evans PD et al 2005 Science 309:1717). It has been suggested that the microcephalin gene was acquired by introgression into

modern human genomes 37,000 years ago and was an important factor of evolution of brain size (Evans PD et al 2006 Proc Natl Acad Sci USA 103:18178). Some of the suggestions concerning correlations among genes for microcephalin and ASPM (abnormal spindle-like, microcephaly-associated gene; human locus 1q31) and evolution of intelligence are controversial (Curat M et al 2006 Science 313:172).

Recurrence risk among sibs was estimated to be 0.19 but the risks might vary depending on the cause of the defect. It is generally accompanied by other abnormalities. Microcephaly with normal intelligence characterizes the autosomal recessive Nijmegen breakage syndrome. The latter is associated with chromosomal instability, immunodeficiency and radiation sensitivity. Microcephaly with immunodeficiency is caused by mutation in (Cernunnos) NHEJ protein factor (Buck D et al 2006 Cell 124:287). ► **mental retardation**, ► **hydrocephalus**, ► **brain**, ► **craniofacial dysostosis** (Crouzon syndrome), ► **cerebral gigantism**, ► **NHEJ**, ► **macrocephaly**; Pattison L et al 2000 Am J Hum Genet 67:1578; Bond J et al 2005 Nature Genet 37:353.

Microchaetae (pl.): Hairs of insects. ► **chaetae** for illustration

Microchannel Plate Detector: Analytical equipment for the detection of radioactive labels in proteins separated by 2-dimensional gel electrophoresis. ► **two-dimensional gel electrophoresis**; Richards P, Lees J 2002 Proteomics 2:256).

Microchimerism: The survival of donor cells in the recipient after transplantation of foreign tissues or organs. Preliminary evidence indicates the rate of survival of pig cells in humans appears to be as low as 10^{-5} . ► **xenograft**, ► **xenotransplantation**, ► **PERV**; Johnson KL et al 2001 Arthritis Rheum 44:2107.

Microchip: Integrated computer circuitry. ► **DNA chip**

Microchromosomes: Very small chromosomes of the avian genome uniform in size and rich in GC content. They replicate ahead of the larger (macro) chromosomes. Their density of genes appears very high probably because their introns are short. ► **intron**, ► **human artificial chromosome**; McQueen HA et al 1996 Nature Genet 12:321.

Microcin: An enterobacterial heptapeptide (Acetyl-Met-Arg-Thr-Gly-Asn-Ala-Asp-X) inhibiting protein synthesis where the first amino acid is acetylated and X is an acid labile group. Microcin J25 obstructs the nucleotide uptake channel of the RNA polymerase (Mukhopadhyay J et al 2004 Mol Cell 14:739; Adelman K et al 2004 Mol Cell 14:753). It is encoded by 21 bps and thus appears to be one of the smallest translated genes. ► **gene size**

Microcinematography: A time-lapse motion photorecording of living material. Successive frames delayed in real time, are projected at normal speed giving the sensation as if the events, movements of cells or chromosomes, etc., would have taken place at an accelerated time sequence. Thus, for instance the progress of mitosis that requires 1–2 hours can be seen in motion, in minutes. ▶ [phase contrast microscopy](#); Nomarski, Matter A 1979 Immunology 36(2):179.

Micrococcal Nuclease: Prepared from *Staphylococcus aureus* degrades DNA (with preference for heat-denatured molecules) and RNA and generates mono- and oligonucleotides with 3'-phosphate termini.

Microconidia: Small uninucleate conidia. ▶ [macroconidium](#), ▶ [conidia](#), ▶ [fungal life cycles](#)

Microcytotoxicity Assay: Detects allelic variants of MHC proteins. Cells are usually labeled by the green fluorescein diacetate and exposed to two different antibodies. The immunologically reacting cells are lysed and their nuclei are stained red by propidium iodide. Thus, the two alleles are distinguished in vitro. (See Wahlberg BJ et al 2001 J Immunol Methods 253:6).

Microdeletion: The loss of a segment too short to be visualized by light microscopy. Comparative genomic hybridization can detect submicroscopic alteration of 100 kb in the chromosome. Conventional karyotyping can detect changes only of 5–10 million bases. In 10% of mentally retarded individuals, 540 kb to 12 Mb de novo alterations were identified (Bert B et al 2005 Am J Hum Genet 77:606). ▶ [karyotype](#), ▶ [comparative genomic hybridization](#)

Microdose: Generally 1% of a therapeutic dose of a drug, labeled by a radioactive tracer to facilitate imaging (by positron emission tomography or accelerator mass spectrometry) without toxicity to the treated individual. The microdose permits detection of absorption, distribution, metabolism and excretion of the drug (Lappin G, Garner RC 2003 Nature Rev Drug Discovery 2:233). ▶ [tomography](#), ▶ [mass spectrum](#)

Microdot DNA: A molecular version of steganography (concealing text) used to communicate secret spy messages. The messages are represented in nucleotide sequences generated by PCR using 20-base forward and reverse primers. The encrypt code may be represented by base triplets, e.g., CGA for the letter A, CCA for B, etc. The sequences within the PCR products can be hidden within the total human DNA or a mixture of DNAs of different organisms from where it can be fished out despite the enormous complexity of the mix. This total mixture, including the secret PCR message in ~10 ng would not occupy a much larger microdot than about a full stop (.) on a

filter paper. Primers may permit amplification of the message, and it can be sub-cloned and sequenced. If the cipher is known, the message is readable in English (or any other language) by those who are familiar with the primers but for those who are not it is virtually impossible to decipher it. (See C. Taylor C et al 1999 Nature [Lond] 399:533, ▶ [PCR](#)).

Microelectrodes: Chemical sensors with micrometer or smaller dimension. The potentiometric units can detect changes across chemically selective membranes. The voltametric units are microscopic in size and detect substances on the basis of their oxidation or reduction and can detect charge changes involved in neurotransmission and in other biological systems (Wightman RM 2006 Science 311:1570). ▶ [electrode](#)

Microencapsulation: To envelop cells with a thin, generally spherical, semipermeable polymer film. The capsule protects cell viability, permits diffusion, and may release its content. Chemically and mechanically fragile structure may be used for cell therapy. Microencapsulation involves the use of a hollow cylinder of selectively permeable, thicker membrane filled with cells suspended in a matrix and sealed. Its utility is similar to microcapsules. It may damage the tissues during manipulations.

Microencephaly: Abnormal smallness of the brain caused by developmental genetic blocks or degenerative diseases. ▶ [microcephaly](#)

Microevolution: A minor variation within species that may lead to speciation. ▶ [evolution](#), ▶ [macroevolution](#); Hendry AP, Kinnison MT 2001 Genetica 112:1.

Microfilaments: Actin and myosin containing fibers in the cells serving as part of the cytoskeleton and mediate cell contraction, amoeboid movements, etc. ▶ [cytoskeleton](#)

Microfluidic Digital PCR: It can analyze single cells by multiplex PCR. ▶ [PCR multiplex](#); Ottesen EA et al 2006 Science 314:1464.

Microfluidics: These systems reduced to micrometer scale behave differently from what we usually see in the physical world. Diffusion, surface tension and viscosity affect the movement of fluids (10^{-9} to 10^{-18} liters) in a different way such as in cells and other microscopic systems. Devices that integrate diverse cellular parameters within sub-nanoliter volumes for the characterization of systems biology and such a medicine is now opening up for experimental approaches. The major merits of microfluidics are the small volumes used, small quantities of reagents are needed, high resolution and high sensitivity in analysis is possible by taking advantage of new developments in microelectronics. Microfluidics has potential for many

different applications such as separations coupled to mass spectrometry, high throughput screening and synthesis of drugs, examination of single cells or single molecules and synthesis of labeled compounds for positron emission tomography, development of new medical diagnostic tools, etc. A microfluidic genetic analysis system performs nucleic acid purification through solid-phase extraction, followed by target sequence amplification by PCR and microchip electrophoretic amplicon separation and detection is completed in <30 min. The presence of *Bacillus anthracis* (anthrax) in 750 nl of whole blood from living asymptomatic infected mice and of *Bordetella pertussis* in 1 μ l of nasal aspirate from a patient suspected of having whooping cough could be confirmed by the resultant genetic profile (Easley CJ et al 2006 Proc Natl Acad Sci USA 103:19277). ▶systems biology, ▶massive parallel signature sequencing, ▶dielectrophoresis, ▶tissue engineering, ▶protein synthesis, ▶anthrax, ▶whooping cough; Werdich AA et al 2004 Lab Chip 4:357; Shaikh KA et al 2005 Proc Natl Acad Sci USA 102:9745; Atencia J, Beebe DJ 2005 Nature [Lond] 437:648; Whitesides GM 2006 Nature [Lond] 442:368.

Microfusion: The fusion of protoplast fragments with intact protoplasts to generate cybrids (generally by electroporation). ▶cell fusion, ▶somatic hybridization, ▶cybrid

Microglia: The mesodermal cells supporting the central nervous system and constitute about 10% of the central nervous system. Microglia are a class of monocytes capable of phagocytosis. They can bind, through scavenger receptors, β -amyloid fibrils (present in Alzheimer plaques) resulting in the production of reactive oxygen species and leading to cell immobilization, and cytotoxicity toward neurons. ▶monocyte, ▶Alzheimer disease; Giulian D 1999 Am J Hum Genet 65:13; Nakajima K, Kohsaka S 2001 J Biochem 130:169; Fetler L, Amigorena S 2005 Science 309:392.

Microglobulin β_2 : The class I MHC α chain is non-covalently associated with this polypeptide, which is not encoded by the HLA complex. The α_3 domain and the microglobulin are similar to immunoglobulins and they are rather well conserved, in contrast to the α_1 and α_2 domains, which are highly variable. Its defect results in renal amyloidosis. ▶TAP, ▶HLA, ▶amyloidosis; Hamilton-Williams EE et al 2001 Proc Natl Acad Sci USA 98:11533.

Micrognathia: Abnormally small jaws.

Microgonotropens (MGT): These are inhibitors of transcription factor—DNA interactions. Transcription factors usually bind to the major groove of the

DNA, whereas MGTs associate primarily with the minor groove but to some extent also to the major groove. Efficient MGTs may regulate gene expression and may be of therapeutic value. ▶transcription factors, ▶DNA grooves; Wemmer DE, Dervan PB 1997 Curr Opin Struct Biol 7:355; White CM et al 2001 Proc Natl Acad Sci USA 98:10590.

Micrograph (photomicrograph, electronmicrograph): The photograph taken through a microscope (light- or electronmicroscope). ▶microscopy

Microinjection: A method of delivery of transforming DNA or other molecules into animal or other cells by a microsyringe. This procedure is not considered as a highly efficient method of transformation in plants. An advantage is, however, that the delivery can be targeted to cells but not into chromosomal location unless gene targeting is used. ▶transformation animals, ▶caged compounds, ▶targeting genes, ▶gene transfer by microinjection

Microinversions: Short inverted DNA sequenced in the genomes microinversions that occur across all species at a frequency of about once per megabase per 66 million years of evolution. Microinversions have low homoplasy and thus provide ample characters for phylogenetic studies. Algorithms are available for their analysis (Chaisson MJ et al 2006 Proc Natl Acad Sci USA 103:19824). ▶inversion, ▶evolution of the karyotype, ▶homoplasy

Microlesion: In genetic toxicology it denotes microscopically undetectable change in the genetic material.

Micromanipulation of the Oocyte: The penetration of some types of disadvantaged sperms can be facilitated by mechanically opening an entry point through the zona pellucida (a non-cellular envelope of the oocyte) and thus facilitating the penetration of the sperm (PZD). Alternatively, with the aid of a microneedle the sperm can directly be deposited under the zona pellucida (SZI) into the space before the vitellus (egg yolk). ▶ART, ▶preimplantation genetics, ▶in vitro fertilization, ▶oocyte donation

Micromanipulator: A mechanical device usually employing glass needles or microsyringes to carry out dissections or injections of cells, while viewed under the microscope.

Micromere (small micromeres): Small cells in the vegetal pole arising from the 8-cell blastomere and giving rise to the coelom. ▶vegetal pole, ▶blastomere, ▶coelom

Micromirror: A spatial light modulator (SLM) that provides excellent resolution, high contrast, brightness, true colors and fast response. Due to these qualities, it is used in imaging nucleic acid microarrays and for many other purposes. It is a type of

a liquid crystal display that has been used in computer monitors, high-definition TV, watches and various types of optical devices.

Microneme: The tubular organelle of apicomplexan protozoa that develop into rhoptry at the apex of the organism. ▶apicoplast, ▶*Plasmodium*, ▶malaria, ▶rhoptry

Micronucleus: The reproductive nucleus of *Infusoria*, as distinguished from their vegetative macronucleus; also a small additional nucleus containing only one or a few chromosomes in other taxonomic groups. In some organisms, broken chromosomes may be visible as micro-nuclei. ▶macronucleus, ▶*Paramecium*, ▶*Tetrahymena*, ▶microcell, ▶micronucleus formation as a bioassay, ▶protozoa

Micronucleus Formation as a Bioassay: Micronuclei are formed when broken chromosomes, chromosomal fragments fail to be incorporated into the daughter nuclei during cell division. Also, the damage to the spindle apparatus may result in the appearance of micro-nuclei. These phenomena have been exploited for testing mutagenic agents specifically causing these types of genetic damage to animal and plant cells. Such assays can be done in cultured cells but in vivo assay of meiotic plant cells or mammalian bone marrow polychromatic erythrocytes have also been used. ▶bioassays in genetic toxicology, ▶*Tradescantia*, ▶protozoa; Riccio ES et al 2001 Environ Mol Mutagen 38:69, (see Fig. M68).

Figure M68. Micronucleus

Micronutrients: They are required for nutrition in small or trace amounts. This class of approximately 40 different compounds includes vitamins, minerals, etc. The deficiency of folate, Vitamins B12, B6, niacin, C and E, etc., have been suggested to be responsible for chromosomal damage and certain types of tumors (See Ames BN 2001 Mutation Res 475:7, and ff. articles in the same issue). Some of the micronutrient deficiencies also cause mitochondrial decay with oxidant leakage and cellular aging and are associated with late onset diseases such as cancer (Ames BN 2006 Proc Natl Acad Sci USA 103:17589).

Microorganisms: *prokaryotic* → bacteria, *eukaryotic* → protozoa, fungi, algae.

Micropenis: It is much reduced in length but the testes are normal in size (see Fig. M69). This condition

occurs in several developmental anomalies as part of the syndrome.

Figure M69. Micropenis

Micropexophagy: The destruction of excess peroxisomes when the need for them is reduced. ▶peroxisome, ▶pexophagy

Microphthalmia: ▶microphthalmos

Microphthalmos (nanophthalmos): Genetically determined (dominant and recessive) forms involve (extreme) reduction of the eye(s) (see Fig. M70). In some instances, it does not involve additional defects. Its frequency in the general population is low, about 0.004%, and the incidence among Caucasian sibs is about 12–14% in the recessive form. Transformation of mice with diphtheria toxin genes attached to eye-specific (γ -crystalline, a globulin of the lens) or the pancreas-specific Elastase I, a collagen-digesting enzyme, promoted this developmental condition (ablation). The microphthalmia-associated transcription factor (MITF) mutations transform fibroblasts into melanocytes. Some of the *Mitf* mutations in mice involve partial or entire-body albinism.

Figure M70. Reduction of eye in microphthalmos

Stimulation of melanoma cells by Steel Factor (SF) activates a MAP kinase that phosphorylates the MITF resulting in the transactivation of a tyrosinase pigmentation promoter (see Fig. M71). In humans, ~5 loci control the condition. Single amino acid replacement mutations at 14q24.3 of the retinal homeobox gene CHX10 have been identified (Heilig R et al 2003 Nature [Lond] 421:601). Dominant colobomatous microphthalmia was assigned to 15q12-q15. ▶eye

diseases, ▶anophthalmos, ▶Waardenburg syndrome, ▶ablation, ▶Kit oncogene, ▶Steel factor, ▶coloboma; Planque N et al 2001 J Biol Chem 276:29330; Mitf function, regulation and signaling: Steingrímsson E et al 2004 Annu Rev Genet 38:365.

Figure M71. Dominant eyeless *Drosophila*

Micropia: ▶*copia*

Micropasmid (miniplasmid): π VX, ▶recombinational probe

Microprocessor: A multiprotein complex, also containing Drosha ribonuclease and it generates microRNAs. ▶microRNA, ▶Drosha; Gregory RI et al 2004 Nature [Lond] 432:235.

Microprojectile: ▶biolistic transformation

Micropropagation: Regeneration plants from somatic, usually apical meristem cells, by in vitro techniques. It may be useful for rapid propagation of rare plants or non-segregating hybrids or secure virus free stocks. ▶synthetic seed, ▶embryo culture; Evans DA et al (eds) 1983 Handbook of Plant Cell Culture. Macmillan, New York.

Micropyle: A pore of the plant ovule, between the ends of the integuments, through which the pollen tube (sperms) reaches the embryo sac. The diagram shows the plant micropyle at the eight-nucleate stage of the embryo sac (see Fig. M72). The pores on the ovules of arthropods (and some other invertebrates) serve for the penetration of the sperm. ▶embryosac

Figure M72. Plant ovule with micropyle

microRNA (micRNA/miRNA): About 18–25 nucleotide long regulatory molecules of diverse sequence.

miRNAs have an imperfect match to the 3' region of the mRNA. Experimental data suggest that association with any position on a target mRNA is mechanistically sufficient for a microribonucleoprotein to exert repression of translation at some step downstream of initiation (Lytle JR et al 2007 Proc Natl Acad Sci USA 104:9667). In the human genome there are > 500 miRNA genes, which target thousands of genes. Apparently, the loss of a single miRNA is not much consequence because there seems to be enough redundancy among miRNAs and in *Caenorhabditis*, three miRNAs (mir-46, mir-84 and mir-241) jointly affect a developmental stage (Abbott AL et al 2005 Dev Cell 9:403). Perfect pairing with 6- to 8-base is not a generally reliable predictor for an interaction of a miRNA. Rather, it can interact functionally with its target site only in specific 3' UTR contexts (Didiano D, Hobert O 2006 Nature Struct Mol Biol 13:849).

Exportin, a RAN-GTP dependent cargo transporter protein that carries pre-miRNAs (ca. 70 nucleotides) is transported to the cytoplasm. The first Drosha, then Dicer RNase III cut them from one arm of endogenous hairpins and they regulate translation/transcription. For the proper function of Dicer-1 there is a requirement for a double-strand RNA-binding domain protein (DGCR), Loquacious in *Drosophila* or TRBP in humans (Förstemann K et al 2005 PLoS Biol 3(7):e236). Some of the miRNAs apparently do not cause the degradation of their target(s). The let-7 microribonucleoproteins or the Argonaute protein may interfere with recognition of the cap of human mRNAs and inhibit initiation of translation (Pillai RS et al 2005 Science 309:1573). MicroRNA interference can provide viral immunity in *Drosophila* (Wang X-H et al 2006 Science 312:452). Human RISC (RNA-induced silencing complex) associates with a multiprotein complex that contains MOV10 – a translational repressor – and proteins of the 60S ribosomal subunit. This complex contains the anti-association factor eIF6 (also called ITGB4BP or p27BBP), a ribosome inhibitory protein known to prevent productive assembly of the 80S ribosome. Depletion of eIF6 in human cells specifically abrogates miRNA-mediated regulation of target protein and mRNA levels (Chendrimada TP et al 2007 Nature [Lond] 447:823).

Several methods are available for the detection of microRNAs (Jiang J et al 2005 Nucleic Acids Res 33:5394). In plants, it may not be a Drosha but one of the multiple Dicers that assumes this role after moving to the nucleus. Uridine (less frequently adenosine) is added to the 3' or 5' ends of the miRNA that enhance the decay of the RNA (Shen B, Goodman BM 2004 Science 306:997). The so-called *seed*

sequence (2–7 nucleotides) at the 3' end of the miRNA initiates the binding to the 5' end of the mRNA (Bartel DP 2004 Cell 116:181; Brennecke J et al 2005 PLoS 3: e85) although other elements may affect their effectiveness. Presence of Argonaute protein(s) is required for initiating the cleavage in the target; the Piwi domain of this protein binds the 5' end and the PAZ domain attaches to the 3' end of miRNA. The Piwi domain is a slicer structural homolog of ribonuclease H (Liu J et al 2004 Science 305:1437). miRNA affects translation by attaching to the cap-binding protein eIF-4E or it may accelerate decay of mRNA through the polyA tail (Humphries DT et al 2005 Proc Natl Acad Sci USA 102:16961). After the cut, the RNA is released to the cytoplasm where exosome and Xrn1 exonuclease destroy the fragments (Orban TL, Izaurralde E 2005 RNA 11:459). miRNA and siRNA bound to Argonaute2 may move to the cytoplasm to the site of P bodies, which can destroy them.

A mouse chromosome 12 (human chromosome 14q32) encodes two micRNAs (*mir-136*, *mir-127*) expressed in the maternally inherited chromosome and act as antisense to retroposon-like gene (*Rtl1*) expressed only from the paternal allele (imprinting, Seitz H et al 2003 Nature Genet 34:261). The Kaposi sarcoma-associated herpes virus encodes 11 distinct micRNAs; some of them are expressed in up to 2,200 copies per cell and facilitate the maintenance of the infected state by suppressing mammalian gene expression (Cai X et al 2005 Proc Natl Acad Sci USA 102:5570). Cellular miRNA provides defense against the primate retrovirus (PFV-1), a foamy virus in humans (Lecellier C-H et al 2005 Science 308:557). In *Caenorhabditis* there are about 130 miRNAs and ~800 (regulating 5,300 genes) are expected in humans; among them 53 are unique to primates (Bentwich I et al 2005 Nature Genet 37:766). The Epstein-Barr virus also encodes miRNAs to control both host and viral gene expression (Pfeffer S et al 2004 Science 304:734). Human cytomegalovirus produces miRNAs, which target the major histocompatibility complex class I-related chain B (MICB) gene. MICB is a stress-induced ligand of the natural killer (NK) cell activating receptor NKG2D and is critical for the NK cell killing of virus-infected cells and tumor cells and thus constitutes an immune evasion means (Stern-Ginossar N et al 2007 Science 317:376).

The small RNAs play an important role in the development of animals and plants by inhibiting or degrading specific mRNAs, for, e.g., the mRNAs coding for the TCP transcription factors. miRNAs can affect differentiation by acting on chromatin structure through methylation of the DNAs (Bao N et al 2004 Dev Cell 7:653). Brain morphogenesis in

zebrafish requires miRNAs (Giraldez AJ 2005 Science 308:833). Methylation is important for the biogenesis of plant micRNA through the action of the HEN1 protein, which can bind glutathione-S-transferase (Yu B et al 2005 Science 307:932). All small RNAs of plants are apparently modified by a proteinase at the 2' hydroxyl of the terminal ribose (Ebhardt HA et al 2005 Proc Natl Acad Sci USA 102:13398). Application of the advantages of mRNAs may be enhanced by the use of vectors that can provide regulatable expression of miRNAs. A lentiviral system (pSLIK) permits tetracycline-regulated expression of mRNA-like short hairpin RNAs in any organism, including mouse (Shin K-J et al 2006 Proc Natl Acad Sci USA 103:13759).

miRNAs regulate leaf polarity in dicots and monocot of plants (Juarez MT et al 2004 Nature [Lond] 428:84). Both endogenous and synthetic miRNAs can be effectively targeted to genes controlling morphogenesis of the stem of *Arabidopsis* as well as in tomato and tobacco (Alvarez JR et al 2006 Plant Cell 18:1134; Schwab R et al 2006 Plant Cell 18:1121). About 30% of the human genes appear to be conserved targets for miRNA (Lewis BP et al 2005 Cell 120:15). The various small non-coding RNAs such as the miRNA, RNAi, siRNA are basically identical. In plants, generation of siRNAs most often (but not always) requires two cleavage events (Axtell MJ et al 2006 Cell 127:565). Some miRNAs down regulate a large number of mRNAs and proteins (Lim LP et al 2005 Nature [Lond] 433:769) and coordinately regulate cell-specific target genes. The *mir-17–92* cistron (13q31) modulates the expression of several cancer genes (He L et al 2005 Nature [Lond] 435: 828). The core promoter region contains two functional E2F transcription factor-binding sites. *miR-17–92* promotes cell proliferation by shifting the E2F transcriptional balance away from the pro-apoptotic E2F1 and toward the proliferative E2F3 transcriptional network (Woods K et al 2007 J Biol Chem 282:2130). Two miRNAs negatively regulate the E2F1 transcription, and the c-Myc proto-oncogene activates the expression of six clustered miRNAs in human chromosome 13 (O'Donnell KA et al 2005 Nature [Lond] 435:839). MicroRNA arrays are generally quite different in a variety of cancer cells compared to normal cells. The level of most of the miRNAs increases in solid tumors but others display reduction and they present a signature for cancer. In ovarian cancer 37.1%, in breast cancer 72.8% and in melanoma 85.9% of the miRNA genes displayed copy number changes and presumably functional differences (Zhang L et al 2006 Proc Natl Acad Sci USA 103:9136). Several miRNAs are shared by different tumors (Volinia S et al 2006 Proc Natl Acad Sci USA 103:2257). *miRNA-372* and *miRNA-373*

down-regulate RAS and p53 tumor suppressors and contribute to the formation of germ cell tumors (Voorhoeve PM et al 2006 Cell 124:1169). Statistically significant association was found between the chromosomal location of miRNAs and those of mouse cancer susceptibility loci that influence the development of solid tumors (Cevignani C et al 2007 Proc Natl Acad Sci USA 104: 8017).

Hepatitis C virus replication is apparently aided by human miRNA-122 but it did not affect mRNA translation or stability (Jopling CL et al 2005 Science 309:1577). Several good computational methods exist for the identification and prediction of miRNA targets in different organisms (Krek A et al 2005 Nature Genet 37:495; Rajewsky N 2006 Nature Genet 38 Suppl 1: S8; Miranda KC et al 2006 Cell 126:1203). Several human miRNAs are most abundant in the cells where their mRNA targets are expressed yet several highly abundant mRNAs in the same cells do not have miRNA recognition sites (Sood P et al 2006 Proc Natl Acad Sci USA 103:2746). In human hepatocarcinoma cells, the cationic amino acid transporter 1 (CAT-1) mRNA and reporters bearing its 3'-UTR can be relieved from the miRNA miR-122-induced inhibition under stress conditions (Bhattacharyya SN et al 2006 Cell 125:1111). ▶RNAi, ▶shRNA, ▶stem cells, ▶antagomir, ▶tncRNA, ▶small RNA, ▶imprinting, ▶RNA non-coding, ▶TCP, ▶PAZ domain, ▶P body, ▶eIF-2, ▶eIF-4E, ▶imprinting, ▶Dicer, ▶Drosha, ▶exosome, ▶Xrn1, ▶Kaposi sarcoma, ▶DiGeorge syndrome, ▶microprocessor, ▶Simian Virus 40, ▶Invader, ▶longevity, ▶polyadenylation signal; Ambros V 2001 Cell 107:823; Hutvagner G, Zamore PD 2002 Science 297:2056; Carrington JC, Ambros V 2003 Science 301:336; Palatnik JF et al 2003 Nature [Lond] 425:257; Lee Y et al 2003 Nature [Lond] 425:415; MicroRNA Registry: Griffith-Jones S 2004 Nucleic Acids Res 32; Database issue D109, He L, Hannon GJ 2004 Nature Rev Genet 5:522; review: Zamore PD, Haley B 2005 Science 309:1519; genomics: Kim NV, Nam JW 2006 Trends Genet 22:165; review of applications to neurology: Kosik KS, Krichevsky AM 2005 Neuron 47:779; microRNA and disease: Chang T-C, Mendell TC 2007 Annu Rev Genomics Hum Genet 8 (Sept) doi: 101146; review of miRNA and development: Plasterk RHA 2006 Cell 124:877; MicroRNA base: <http://www.sanger.ac.uk/Software/Rfam/mirna>; MicroRNA Database: <http://microrna.sanger.ac.uk/sequences/>; <http://mimamap.mbc.nctu.edu.tw/>; miRNA target server: <http://www-ab.informatik.uni-tuebingen.de/software/welcome.html>; miRNA target prediction: <http://bibiserv.techfak.uni-bielefeld.de/mahybrid/>; miRNA target sites in QTLs: <http://compbio.utmem.edu/miR SNP/>; miRNA targets in viruses: <http://vita.mbc.nctu.edu.tw/>;

Microsatellite: The mono-, tetra- or hexanucleotide repeats distributed at random (10 – 50 copies) in the eukaryotic nuclear and mitochondrial chromosome, and can be used for constructing high-density physical maps, for the rapid screening for genetic instability, evolutionary relationships, detection of cancer in bladder cells found in the urine, etc. It was initially assumed that the alterations at the microsatellites follow a step-wise pattern and are therefore, very useful for following changes within populations or between populations. However, these expectations were not entirely realized because the variability depends on the length of the arrays such as possible size constraints to the expansion, possible increase in the flanking regions due to mutations, etc. The microsatellite region may expand (most commonly) or contract and thus, result in genetic instabilities. Microsatellite loci may mutate at a frequency of ~0.8% per gamete, more frequently than in somatic cells. Some estimates for eukaryotes are in the 10^{-4} to 10^{-5} range and make them useful for linkage analysis using PIC. The rate of mutation varies according to organisms, the microsatellite length and site, etc. In bacteria, the mutation rate in repeats appears two orders of magnitude higher. In general, longer repeats display higher mutation rates. The length of the microsatellite repeats appears longer in vertebrates than in *Drosophila*. In the majority of the cases, the expansion of the loci does not change the linkage phase of the flanking markers and therefore gene conversion is implicated. In humans they estimated one (≥ 4 bp) microsatellite per 6 kbp genomic DNA. Three quarters of the repeats are A, AC, AAAN or AG. The CA and TG repeats are distributed at random in the genome and used most commonly for linkage studies. In the human X chromosome, 3 and 4 base repeats occur in every 300–500 bp. The most common poly(A)/ poly(T) repeats are not well suited for genetic studies because of instability at PCR. Large-scale survey indicates that most of the microsatellites were generated as a 3' extension of retrotranscripts and may serve as pilots to direct integration of retrotransposons. Defective mismatch repair may be caused by mutations in the human gene MBD4/MED1 at 3q21-q22 leading to carcinomas with microsatellite instability. The *perfect microsatellite* represents one repeated motif without any insertion of a different base. The *imperfect microsatellite* has repeats with one base different from the

main type. *Interrupted microsatellite* contains several bases repeated that are different from the pattern of the rest of the repeat structure. *Compound microsatellite* includes two or more different types of repeats in adjacent microsatellites. In *Saccharomyces* the poly(AT) sequences are common. Prokaryotes display relatively few repeats and they are mainly poly(A)/poly(T). About 30% of the human microsatellites are conserved in murines. The microsatellites appear to have regulatory roles but some may be transcribed and translated as coding trinucleotides (e.g., the CAG polyglutamine tracts). Some of the untranslated upstream repeat elements are conserved among related species and may serve as enhancers by binding transcription factors. The enhancer activity may be only moderate but may increase or decrease by high copy number. Discrete repeat lengths may carry specific adaptive value in some populations. Diversity in microsatellite repeats may be generated by replicational slippage, unequal crossing over (although the reciprocal products are not always present), by gene conversion, additions and deletions. The microsatellites show a tendency of association with the non-repetitive portion of the genome. Microsatellite repeat length in the vicinity of the vasopressin 1a receptor gene of voles (*Microtus*) is correlated with behavioral traits, such as grooming the females and offspring care by males. Since vasopressin is supposed to affect social behavior, microsatellite length appears regulatory to gene expression (Hammock EAD, Young LJ 2005 Science 308:1630). ▶hereditary non-polyposis colorectal cancer, ▶mismatch repair, ▶trinucleotide repeats, ▶minisatellite, ▶VNTR, ▶PIC, ▶DNA fingerprinting, ▶PCR, ▶cryptically simple sequences, ▶unequal crossing over, ▶slippage, ▶enhancer, ▶stutter bands, ▶slip-strand mispairing, ▶IAM, ▶SMM, ▶TPM, ▶KAM, ▶behavior genetics, ▶oxytocin; Graham J et al 2000 Genetics 155:1973; Tóth G et al 2000 Genome Res 10:967; Morgante M et al 2002 Nature Genet 30:194; free software for small repeats:

Table M6. Microsatellite typing

| Father | Mother | Sib-1 | Sib-2 | Sib-3 | Paternal grandfather | Paternal grandmother | Alleles |
|--------|--------|-------|-------|-------|----------------------|----------------------|---------|
| ■■■ | ■■■ | | □□ | ■■■ | ■■■ | | Z |
| | | | | | ■■■ | | 4 |
| | ■■■ | ■■■ | | | | ■■■ | 12 |
| ■■■ | | ■■■ | | ■■■ | | ■■■ | 16 |

The ■ symbolize gel bands and the □ stand for homozygosity of the Z allele

Hadjantonakis A-K et al 2003 Nature Rev Genet 4:613; <http://micro.magnet.fsu.edu/>.

Microsomes: The membrane fragments with ribosomes and enzymes obtained after grinding eukaryotic cells and separating the cellular fractions by centrifugation. After about 9,000 x g force (10 min) the microsomes (S9) float, while other cellular particulates sediment. For the Ames genotoxicity bioassay, generally Sprague-Dawley rat livers are used. The rats are previously fed the drinking water with polychlorinated biphenyl (PCB), Araoclor 1254, a highly carcinogenic substance (requires special caution of disposal!) in order to induce the formation of the P-450 monooxygenase activating enzyme system associated with the endoplasmic reticulum.

► Ames test, ► activation of mutagens, ► carcinogen, ► centrifuge

Microspectrophotometer: A spectrophotometer, which can measure monochromatic light absorption of microscopical objects. ► spectrophotometer

Microsporangium: The sac that contains the microspore tetrad of plants and the microspores of fungi and some protozoa. ► microspore

Microspore (small spore): The immature male spore of plants that develops into a pollen grain. ► microspore mother cell, ► microspores, ► microsporocyte, ► meiosis, ► gametogenesis

Microspore Culture: The in vitro method for the production of haploid plants by direct or indirect androgenesis. (See Fig. M73).

Figure M73. Microspore culture (After Reinert J and Bajaj YPS 1977 Plant Cell, Tissue and Organ Culture. Springer, New York)

Microspore Dyad: The microspore mother cell after the end of the first meiotic division is divided into two haploid cells (the microspore dyad). ► [meiosis](#)

Microspore Mother Cell: ► [microsporocyte](#)

Microspores: Haploid products of male meiosis in plants that develop into pollen grains, and the smaller generative cells of lower organisms. ► [microsporocyte](#), ► [megaspore](#)

Microsporidia: (Archezoa): It represents an evolutionary branch of anaerobic protists, which diverged from the main line of Eukarya before the acquisition of mitochondria. ► [evolution](#)

Microsporocyte: The cell within which meiosis takes place and the microspores develop. ► [microspore](#), ► [gametogenesis](#)

Microsporogenesis: see ► [Meiosis in plants](#), Ma H 2005 Annu Rev Plant Biol 56:393.

Microsporophyll: A leaf on which microsporangia develops in lower plants.

Microsurgery: Dissection or other surgical operations carried out under the microscope, generally with the aid of a micromanipulator. ► [micromanipulator](#)

Microtechnique: The procedures used for the preparation of biological specimens for microscopic examination (involving fixation, staining, sectioning, squashing, etc.).

Microtiter Plates: It most commonly contains 96 wells but 384 or even 9600-well (etched glass or silicon wafers) are also used for storage of samples. ► [microarray hybridization](#)

Microtome: An instrument that, by means of various (sliding or rotating or rocking) motions, cuts serial thin (usually within the range of 1–20 μm) sections of the embedded or frozen specimens to be examined by light or electronmicroscopy. The cutting edge may be steel or glass. Electronmicroscopy also requires sectioning of the specimens, usually employing a diamond knife. ► [embedding](#), ► [sectioning](#), ► [stains](#), ► [smear](#)

Microtubule: Various types of long cylindrical filaments of about 25 nm in diameter within cells built by polymerization of α and β tubulin and actin proteins. Microtubules are hollow tubulin filaments of the spindle apparatus of the dividing nuclei, elements of the cytoskeleton, cilia, flagella, etc. The energy for polymerization is provided by hydrolysis of GTP to GDP. The beginning of the polymerization of the microtubules is called nucleation and in animal cells that begins at the centrosomes. Microtubule elongation is a polarized process. Microtubules move around

chromosomes and various protein complexes according to the blueprints of differentiation. Kinetochore-mediated and polar ejection forces (PEF) move chromosomes toward the spindle equator. Kid and KIF-4 proteins are behind PEF (Brouhard GJ, Hunt AJ et al 2005 Proc Natl Acad Sci USA 102:13903). The nerve axon microtubules are oriented with the plus end (their growing point) away from the cell body whereas in epithelial cells they point toward the basement membrane. In fibroblasts and macrophage cells, the microtubules originate in the center of the cell and the plus end face the outer regions. The transport function requires the cooperation of motor proteins (kinesins, dynein) that push the protein complex organelles on the microtubule trails. Microtubules are somewhat unstable molecules and antimetabolic drugs such as colchicine or colcemid may block their growth. Taxol (an anticancer extract of yew plants) stabilizes the microtubules and arrests the cell cycle in mitosis. After polymerization the microtubules undergo modification, e.g., a particular lysine of α -tubulin may be acylated and tyrosine residues removed from the carboxyl end. Microtubule-associated proteins (MAP) mediate the “maturation” of microtubules. MAPs aid the differentiation of nerve axons and dendrites that are loaded with microtubules. Microtubules move various organelles such as the chromosomes during nuclear divisions in the cells with assistance of the proteins kinesin and dynein. The cortical protein Kar9 and the Bim1/EB1 microtubule stabilizing protein control the positioning of the microtubules. The EB1 is also a suppressor of the *adenomatous polyposis coli* tumors. The cilia and flagella involved in movements are built of bundles of microtubules. The microtubule protein complexes bind ATP at their “head” and associate with organelles by their “tail”. The “plus” end of microtubules where tubulin subunits are added rapidly and the “minus” end where the addition is more slow. The microtubules usually are in a dynamic instability, i.e., they alternate between extension and shortening but they may remain also in equilibrium. There are several protein factors that move the tubulins and associated structures. In prophase, the duplicated centrosomes are separated by the bimC, KAR3 and cytoplasmic dyneins (450–550-kDa, motility 75 $\mu\text{m}/\text{minute}$). The bimC family members (120–135-kDa and with 1–2 $\mu\text{m}/\text{min}$ motility) have different names in the different species (KLP61F and KRP₁₃₀ in *Drosophila*, Cin8 in *Saccharomyces*, cut7 in *Schizosaccharomyces*). The KAR3 family (65–85-kDa, motility 1–15 $\mu\text{m}/\text{min}$) is involved also in spindle stabilization during metaphase. Cdc14 mediates the localization of the microtubule-stabilizing proteins for successful anaphase separation (Higuchi T, Uhlmann F 2005 Nature [Lond] 433:171). During prometaphase, the

microtubules are captured by the kinetochore with the assistance of the MCAK (mitotic centromere associated kinesin). The chromosomes congregating at the metaphase plane are moved by KIF4 (140-kDa) and related proteins that are also involved in chromosome alignment during metaphase. During anaphase, CENP-E and the KAR3 family of proteins propel the movement of the chromosomes toward the poles. The MKLP, bimC and cytoplasmic dynein proteins mediate the elongation of the spindle fibers. ►actin, ►tubulin, ►Cdc14, ►kinesins, ►Pac-Man model, ►dynein, ►mitosis, ►meiosis, ►centrosome, ►spindle, ►centromere, ►tau, ►katanin, ►filaments, ►dynamic instability, ►treadmilling, ►polyposis adenomatous intestinal, ►colchicine, ►taxol, ►vinblastin; Nogales E 2000 Annu Rev Biochem 69:277; Downing KH 2000 Annu Rev Cell Dev Biol 16:89; Popov AV et al 2001 EMBO J 20:397; Schuyler SC, Pellman D 2001 Cell 105:421; Lloyd C, Hussey P 2001 Nature Rev Mol Cell Biol 2:40; McIntosh JR et al 2002 Annu Rev Cell Dev Biol 18:193; Howard J, Hyman AA 2003 Nature [Lond] 422:753; Westermann S, Weber K 2003 Nature Rev Mol Cell Biol 4:938; microtubule capture by kinetochore: Kotwaliwale C, Biggins S 2006 Cell 127:1105.

M

Microtubule Associated Proteins (MAP): It controls stability and organization of microtubules. ►microtubule, ►kinesin, ►dynein

Microtubule Organizing Center: The areas in the eukaryotic cells from where the microtubules emanate and grow such as the mitotic centers (poles) that give rise to the mitotic spindle (see Fig. M74). The microtubule-binding protein TPX2 binds Aurora A kinase and targets it to the mitotic spindle and this stabilizes microtubules connecting to the spindle pole (Özlü N 2005 Dev Cell 9:237). ►spindle, ►mitosis, ►MTOC, ►centrosome, ►Aurora

Figure M74. Microtubule organizing center

Microvilli: These are small emergences on the surface of various cells and increase the surface of the cells. The microvilli of the chorion may be sampled for amniocentesis in prenatal genetic examinations. ►amniocentesis

Microwave Radiation: Electromagnetic radiation in the $\sim 10^9$ to $\sim 10^{11}$ nm range. Genetic effects are difficult to separate from the heat effects. In the 2–3 Ghz range ambiguous mutagenic effects were reported and the mutagenicity of the radiations could not be confirmed. Microwave radiation can damage cell membranes.

MIDA1: A helix-loop-helix associated protein of mammals. It is inactive in erythroleukemic cells. ►erythroleukemia, ►zuotin, ►DNA-binding protein domains, ►helix-loop-helix

Midbody (midzone): After division, microtubule fragments (midbodies) may be detected in animal cells connecting the two daughter cells by a refringent structure (see Fig. M75). PRC1 is a midzone-associated microtubule bundling protein, a substrate of Cdk. Cdk-mediated phosphorylation of PRC1 keeps it in inactive, in monomeric state. During metaphase–anaphase transition, PRC1 is dephosphorylated and that promotes polymerization of PRC1 and lead to the formation of the midbody (Zhu C et al 2006 Proc Natl Acad Sci USA 103:6196). The proteins in the midbody are essential for chromosome segregation and cytokinesis. MudPIT analysis revealed the presence of 577 different proteins. Of the 172 proteins disrupted by RNAi analysis, 58% interfered with cytokinesis (Skop AR et al 2004 Science 305:610. ►microtubules; MudPIT, Piel M et al 2001 Science 291:1499; photomicrograph is the courtesy of Drs. Kevin Sullivan and D. W. Cleveland; red color indicates the centromeres of the blue HeLa chromosomes; green tubulins.

Figure M75. Midbody

Midbrain: The middle part of the brain. Degeneration of the motor neurons in this region may be responsible for Parkinson disease. ►brain human, ►Parkinson disease

Middle Lamella: The material (pectin mainly) that fills the intercellular space in plants.

Middle Repetitive DNA: It is made up of relatively short repeats dispersed throughout the genome of (higher) eukaryotes. ▶ [SINE](#), ▶ [LINE](#), ▶ [redundancy](#)

Midgut: The middle portion of the alimentary tract of insects and other invertebrates.

Midkine: ▶ [pleiotrophin](#)

Midparent Value: ▶ [breeding value \[midpoint\]](#)

Midpoint: ▶ [breeding value](#)

Midzone: A network of antiparallel, interdigitating, nonkinetochore microtubules, which initiate and complete cytokinesis. The PRC1 cyclin-dependent protein kinase is moved to the midzone by the Kif4 motor protein and both are essential for cytokinesis (Zhu C, Jiang W 2005 Proc Natl Acad Sci USA 102:343). ▶ [cytokinesis](#), ▶ [midbody](#), ▶ [PRC1](#), ▶ [Kif](#)

MIF (macrophage inhibitory factor): A pro-inflammatory pituitary factor; it may override glucocorticoid-mediated inhibition of cytokine secretion. MIF binds to cytoplasmic protein Jab1, which induces the phosphorylation of c-Jun and through it, the activity of AP-1. Jab1 also helps the degradation p27^{Kip1}. ▶ [cytokines](#), ▶ [glucocorticoid](#), ▶ [septic shock](#), ▶ [AP1](#), ▶ [Jun](#), ▶ [p27](#); Froidevaux C et al 2001 Crit Care Med 29 Suppl 7:S13.

Mifepristone (11-[44-(dimethylamino)phenyl]-17-hydroxy-17-(1-propynyl)-(11 β ,17 β)-estra-4,9-dien-3-one): An antiprogesterin, targeted at the progesterone receptors. This receptor family includes the glucocorticoid, mineralocorticoid, androgen, estrogen and vitamin D receptors. It is used as a birth-control drug. ▶ [RU486](#) and the others mentioned, ▶ [hormone receptors](#), ▶ [breast cancer](#); Ho PC 2001 Expert Opin Pharmacother 2:1383; Zalányi S 2001 Eur J Obstet Gynecol Reprod Biol 98(2):152.

Mighty Mouse: ▶ [insulin-like growth factors](#)

Migraine: A neurological anomaly causing recurrent attacks of headaches, nausea, light and sound-avoidance. It may or may not be preceded by an aura (subjective sensation) and it appears to be controlled at chromosome 4q21 (Björnsson Á et al 2004 Am J Hum Genet 73:986). Migraine may be triggered by dietary factors (monosodium glutamate, tyramine and phenylethylamine occurring in chocolates, citrus fruits or certain cheeses) in persons with low levels of phenolsulphotransferase activity. (This enzyme catalyzes the conjugation of sulfate of catecholamines and phenolic drugs.) Its duration may be from minutes to days. The sexual migraine pops up during sexual activity, commonly at or near orgasm. It may affect females (18–24%) more frequently than males (6–12%) to a very variable degree. Migraine is

relatively rare in children (~4%) and its onset is usually begins after age 30. In males, it usually ceases after age 45 but in women it may continue well beyond menopause. It is generally attributed to multiple genes. Familial hemiplegic migraine (FHM) is however, a rare autosomal dominant condition coded in human chromosome 19p13 as is episodic ataxia type 2. CADASIL has been localized to the same chromosomal area and involves migraine. It appears that the basic defect is in a brain-specific Ca²⁺ ion channel α -1 subunit translated from 47 exons of the CACN1A4 gene. Spinocerebellar ataxia type 6 and episodic ataxia are allelic to the latter gene. Some migraines are associated with mtDNA-encoded MELAS syndrome. Another migraine susceptibility locus appears to be at Xq24. ▶ [ion channels](#), ▶ [spinocerebellar ataxia](#), ▶ [mitochondrial diseases in humans](#), ▶ [CADASIL](#), ▶ [CACN1A4](#), ▶ [serotonin](#); Guida S et al 2001 Am J Hum Genet 68:759; Wessman M et al 2002 Am J Hum Genet 70:652.

Migration: ▶ [gene flow](#)

Migration of DNA in Gels: It is affected by molecular size, configuration of the macro-molecule, concentration of the support medium (agarose, polyacrylamide), voltage, changing direction in the electric field, base composition, presence of intercalating dyes, buffer, etc.

Migration Inhibition Factor: MIF is a lymphokine. ▶ [lymphokines](#), ▶ [lymphocytes](#), ▶ [immune system](#)

Migration in Populations: ▶ [Gene flow](#)

Migration, Nuclear: Mediates polarization of cell division and provides direction for cell growth. (See Bloom K 2001 Curr Biol 11:R326)

Mik1: A mitotic kinase and an inhibitor of Cdc2. Mik1 accumulates in S phase and may mediate the transition from S phase to mitosis. ▶ [cell cycle](#), ▶ [Cdc2](#), ▶ [Wee1](#)

MIL Oncogene: The avian representative of the RAF murine oncogene, a protein serine kinase; it is also related to the murine leukemia virus (MOS). ▶ [oncogenes](#), ▶ [RAF](#), ▶ [MOS](#)

MILC (maximum identity length contrast): A statistical method for genetic analysis of multifactorial diseases. It looks for an excess of identity of parental haplotypes transmitted to the affected offspring as compared to non-transmitted haplotypes. ▶ [haplo-type](#); Bourgain C et al 2002 Ann Hum Genet 66:99.

Miliary: Minute lesions (resembling millet seeds)

Miller Units: ▶ [\$\beta\$ -galactosidase](#) (activity measurement)

Miller-Dieker Syndrome: Characterized by smooth brain (lissencephaly I, LIS1, AFAH1B1), more like in the early fetus, defects in other internal and external organs, mental retardation and death before age 20. Apparently, deletions in area 17p13.3 are responsible for the recessive phenotype. It is a cell-autonomous disease inhibiting neuronal migration. The LIS1 protein contains a C-terminal seven-blade- β -propeller domain whereas the N-terminal fragment includes the Lis homology (LisH) motif, which is widespread in more than 100 eukaryotic genes yet its function is not known (Kim MH et al 2004 Structure 12:987). The deletion always involves protein 14–3–3 ϵ and when two sites are simultaneously affected, the severity of the disease increases. (Toyo-oka K et al 2003 Nature Genet 34:274). Other genes also involving hydrocephaly and severe brain lesions may cause Lissencephaly II (DCX, Xq22.3-q23-linked doublecortin). The gene PAF (lipid platelet activating factor) encodes a subunit of brain platelet-activating acetylhydrolase. ►deletion, ►head/face/brain defects, ►malformations, ►Walker-Warburg syndrome, ►Walker-Wagner syndrome, ►lissencephaly, ►HIC; Cardoso C et al 2003 Am J Hum Genet 72:918.

Millets (*Eleusine*, *Pennisetum*): Arid climate grain crops (see Fig. M76). The cultivated *E. coracana* is $2n = 4x = 36$, tetraploid. *P. americanum* is $2n = 2x = 14$ diploid. The common millet (*Panicum miliaceum*) is an old grain crop; $2n = 4x = 36$. The foxtail millet (*Setaria italica*) is $2n = 2x = 18$ is mainly a hay crop.

Figure M76. Millet

Milroy Disease: ►lymphedema hereditary

MIM: ►mitochondrial import

MIME (Multipart Internet Mail Extensions): This was used before the Extensible Markup Language (XML) was developed ►XML

Mimicry: The process and result of protective change in the appearance of an organism that makes it resemble the immediate environment for better hiding or imitating the features of other organisms that are

distasteful or threatening to the common predators. The blister beetle *Meloe franciscanus*, which parasitize nests of the solitary bee *Habropoda pallida*, cooperate to exploit the sexual communication system of their hosts by producing a chemical cue that mimics the sex pheromone of the female bee. Male bees are lured to larval aggregations, and upon contact (pseudocopulation), the beetle larvae attach to the male bees. The larvae transfer to female bees during mating and subsequently are transported to the nests of their hosts. To mimic the chemical and visual signals of female bees effectively, the parasite larvae must cooperate, emphasizing the adaptive value of cooperation between larvae (Saul-Gershenz LS, Millar JG 2006 Proc Natl Acad Sci USA 103:14039). It has been observed that bats quickly learned to avoid the noxious tiger moths first offered to them and associated the warning sounds with bad taste. They then avoided a second sound-producing species regardless of whether it was chemically protected or not. A subset of the red bats subsequently discovered however, the palatability of the Batesian mimic (Barber JR, Conner WE 2007 Proc Natl Acad Sci USA 104:9331). ►Batesian mimicry, ►Biston betularia, ►industrial melanism, ►Müllerian mimicry, ►molecular mimics, ►pheromone; Mallet J 2001 Proc Natl Acad Sci USA 98:8928.

Mimicry, Macromolecular: Some proteins may mimic nucleic acids in shape, structure and, even to some extent, function. Such mimicry may protect a phage from the host restriction endonucleases. (See Nissen P et al 2000 EMBO J 19:489; Walkinshaw MD et al 2002 Mol Cell 9:187).

Mimicry, Structural: Pathogenic microorganisms produce virulence factors that are molecular mimics of host proteins. This way they may evade the host defense system. ►molecular mimics; Stebbins CE, Galán JE 2001 Nature [Lond] 412:701.

Mimics: Individuals that develop mimicry as a form of adaptation and evasion of predators. Also genes, which control practically the same phenotype yet they are not allelic.

Mimiotope (mimeotope): ►mimotope

Mimivirus: A very large double-stranded DNA virus (1,181,404 bp) in a 400-nanometer icosahedral particle. It contains 1,262 putative open reading frames; 10% of which encode proteins of known functions. Many of the genes are involved in protein synthesis-processing machinery. ►icosahedral, ►open reading frame, ►protein synthesis; Raoult D et al 2004 Science 306:1344; Suzan-Monti M et al 2005 Virus Res 117:145.

Mimotope: A conformational mimic of an epitope without great similarity in amino acid residues or as a response to microbial anti-DNA antibodies. ► [epitope](#); Wun HL et al 2001 *Int Immunol* 13(9):1099; Mullaney BP et al 2002 *Comp Funct Genomics* 3:254.

Mimulus sp: ($2n = 28$, $2n = 16$) are hermaphroditic/outcrossing species (~160) of plants with about two-months generation time and high (~2000) seed output (see Fig. M77). Its genome size is ~500 Mb; total map length ~2,000 cM in *M. guttatus* ($2n = 28$). (See <http://www.biology.duke.edu/mimulus/>).

Figure M77. *Mimulus luteus*

Mineral Corticoid Syndrome (ame): It causes hypertension without overproduction of aldosterone. This syndrome is activated by cortisol. 11β -hydroxysteroid dehydrogenase converts cortisol to cortisone and thus, activates the mineralcorticoid receptor. The patients are deficient in this enzyme, which is inhibited by glycyrrhetic acid (enoxolone [$C_{30}H_{46}O_4$], present in licorice). The mineral corticoid receptor and other steroid receptors regulate the activity of many genes. ► [nuclear receptor](#), ► [hypertension](#), ► [aldosteronism](#), ► [Liddle syndrome](#); Pearce D et al 2002 *J Biol Chem* 277:1451.

Mineral Requirements of Plants: The 9 macro elements (H, C, O, N, Ca, Mg, P, S) and 7 micro elements (Cl, B, Fe, Mn, Zn, Cu, Mo). Under some circumstances, other elements may also be beneficial. Using Inductively Couple Plasma (ICP) spectroscopy, 18 essential and nonessential macro- and microelements in plant tissues could be quantitatively determined. Mutations were also identified at about four dozen loci of *Arabidopsis* that control the metabolic role of these elements. It has been estimated that 2–4% of the genome of this plant involves the control of nutrient and trace element control, the “ionome” (Lahner B et al 2003 *Nature Biotechnol* 21:1215). ► [embryo culture](#)

Mini Mu: The deletion variants of phage Mu cloning vehicles that still carry the phage ends, a selectable marker and replicational origin. ► [Mu bacteriophage](#)

Miniaturization: The development of analytical tools and methods for the study of small samples, single cells, proteins or nucleotides, etc. (See Sauer S et al 2005 *Nature Rev Genet* 6:465, sequencing 25 million bases in four-hour run with 99% or better accuracy: Margulies M et al 2005 *Nature* 437:326).

Minicell: DNA-deficient bodies surrounded by cell wall (in bacteria). Since they have no DNA, they cannot incorporate labeled precursors either into RNA or protein. In case the mini-cells descended from parents with plasmids, they may contain DNA and can thus, make RNA and direct protein synthesis depending on the nature of the DNA they carry. ► [maxicells](#)

Minichromosome: In eukaryotic viruses (SV40, polyoma virus) it is the histone-containing, small nucleosome-like structure of genetic material; also in eukaryotes, an extra chromosome with extensive deletions. Such minichromosomes can be generated by the insertion of human telomeric sequences $(TTAGGG)_n$ between the centromere and the natural telomere and by eliminating the sequences distal to the insertion point. Human mini Y chromosomes have about 32.5 to 4 Mb compared with the normal Y chromosome of 50–75 Mb. Minichromosomes may also be generated by removal of non-essential distal genes from each arm. Neocentromeres may serve as well as regular centromeres for human artificial chromosomes. These minichromosomes permit the analysis of the role of different sections of the chromosomes and possibly, it may become feasible to extend the analysis of mammalian chromosomes in yeast cells. Artificial chromosomes may be exploited as large capacity cloning vectors. ► [human artificial chromosome](#), ► [neocentromere](#), ► [MCM1](#); Saffery R et al 2001 *Proc Natl Acad Sci USA* 98:5705.

Minichromosome Maintenance Factor: ► [MCM](#)

Mini-F: The basic replicon of the bacterial F plasmid. ► [F plasmid](#), ► [replicon](#)

Minigels: Minigels are used for the separation of small quantities (10 to 100 ng DNA), in small fragments (<3-kb) on about 5×7.5 cm slides (10 to 12 mL agarose), in a small gel box (ca. 6×12 cm) for 30 to 60 min at 5 to 20 V/cm. ► [electrophoresis](#)

Minigene: Some of its internal sequences are deleted in vitro before transfection. ► [transfection](#)

Minihelix of tRNA: It consists only of the T Ψ C arm and the amino acid acceptor arm and may be aminoacylated by some aminoacyl-tRNA synthetases according to the rule of the operational RNA code. The minihelix is considered to be the most ancestral part of the tRNA. ► [operational RNA code](#), ► [transfer](#)

RNA, ▶tRNA, ▶aminoacyl-tRNA synthetase; Nordin BE, Schimmel P 1999 J Biol Chem 274:6835.

Minimal Genome Size: The smallest number of genes required for survival (replication) in a specific milieu for a free-living organism. Based on transposon inactivation experiments of the genome *Mycoplasma genitalium*, the estimate was ~265–350 bp. Some viruses have only 4 genes but they are genetic parasites. Among free-living microorganisms, *Plagibacter ubique*, an abundant, heterotrophic marine proteobacterium has the smallest genome size of 1,308,799 bp (Giovannoni SJ et al 2005 Science 309:1242). ▶genome, ▶gene number, ▶*Mycoplasma*

Minimal Medium: Provides only the minimal (basal) menu of nutrients required for maintenance and growth of the wild type of the species. ▶complete medium

Minimal Promoter: It includes the most essential sequences to facilitate transcription of genes (basal promoter) without some other regulatory elements such as enhancer, transcriptional activator. ▶promoter, ▶basal promoter, ▶enhancer, ▶transcriptional activators

Minimal Residual Disease (MRD): Even after apparently successful chemotherapy of cancer, some residual cancerous cells may persist. Their detection is important to develop treatment for the prevention of relapse. Molecular techniques (PCR) are applicable for this goal. ▶PCR; Kim YJ et al 2002 Eur J Hematol 68:272.

Minimal Tiling Path: A tightly overlapping set of bacterial vector clones, suitable for sequencing eukaryotic genomes. ▶tiling

Minimization: ▶crossing over

Minimum Description Length (MDL): MDL is the principle frequently used in characterizing macromolecular sequence information. The best principle is that uses the least number of bits for the theory and the data. $L(T)$ indicates the complexity of the theory by the number of bits that encode the theory. $L(D/T)$ is the number of bits required to define the data in connection with the theory and reveals the consistency of the data with the theory. ▶bit

Minimum Evolution Methods: These methods use an estimate of a branch length of an evolutionary tree construct on the basis of pair-wise distance data calculated by various mathematical algorithms. The most plausible tree should be that which provides the smallest sum of total branch length. ▶evolutionary distance, ▶evolutionary tree, ▶least square methods, ▶four-cluster analysis, ▶neighbor joining method, ▶algorithm

Miniorgan (neo-organ) Therapy: The *ex vivo* genetically modified group of cells capable of synthesis of immunotoxins, angiogenesis inhibitors, hormones, ligands or other proteins and enzymes delivered to target cells/tissues in vivo with the purpose of correcting acquired or genetic disorders. In case the promoters can be regulated, the supply of the gene product(s) can be adjusted according to the need. ▶retroviral vectors, ▶immunotoxin, ▶angiogenesis, ▶promoter, ▶gene therapy, ▶cancer gene therapy, ▶*ex vivo*, Bohl D, Heard JM 1997 Hum Gene Ther 8:195; Rosenthal FM, Kohler G 1997 Anticancer Res 17(2A):1179.

Miniplasmid: ▶ π VX microplasmid, ▶recombinational probe

Miniprep: A small-scale quick preparation of DNA from plasmids or from other sources. (See Ferrus MA et al 1999 Int Microbiol 2(2):115).

Minireplicon: A vector consisting of a pBR322 replicon, a eukaryotic viral replicational origin (SV40, Polyoma) and a transcriptional unit. These vectors can be shuttled between *E. coli* and permissive mammalian cells. Also, deficient replicons containing only the replicational origin. ▶replicon, ▶shuttle vector; Roberts RC, Helinski DR 1992 J Bacteriol 174:8119.

Minisatellite: In eukaryotic genomes short (14–100-bp) tandem, highly polymorphic repeats occur at many locations with repeat arrays of 0.5–30 kb. In forensic work, the minisatellites are used for DNA fingerprinting. They are supposed to be products of replicational errors (slippage) and localized amplifications. Their high variability is probably due to frequent unequal crossing over and duplication-deficiency events. Gene conversion may also expand or contract minisatellites. These sequences are highly variable. The variations are associated with diabetes mellitus and various types of cancers. The minisatellite mutation rate in the human germline was estimated as ~5.2% although it may vary at different loci and may be different in the two sexes. They are used as RFLP or PCR probes in physical mapping or for characterization of populations. In contrast to humans mutations in general, minisatellite intra-allelic mutation rate is quite low at 5×10^{-6} per sperm (Bois PRJ et al 2002 Genomics 80:2). ▶microsatellite, ▶SINE, ▶VNTR, ▶DNA fingerprinting, ▶RFLP, ▶PCR, ▶small-pool PCR, ▶MVR, ▶unequal crossing over, ▶trinucleotide repeats, ▶MVR, ▶IAM, ▶SMM, ▶TPM, ▶gene conversion10:899; Vergnaud G, Denoeud F 2000 Genome Res 10:899.

Minisegregant: Bud-like extrusions of animal cells with pinched-off DNA.

MINK: MAP kinase kinase kinase; also represented as MAPKKK or Ste 11. ►Ste

MinK: A 15 K protein which in association with other proteins forms potassium ion channels.

Minocycline: A tetracycline type antibiotic capable of passing the blood-brain barrier and it is a neuroprotective by inhibition of caspases. It may delay the progression of neurodegenerative diseases (Zhu S et al 2002 Nature [Lond] 417:74).

Minor Allele Frequencies (MAF): These frequencies have a role in the susceptibility to a particular disease. Generally, the frequencies are less than 0.1 and because of their relatively small effect, the odds ratio is less than 1.3. Therefore, their identification—at an acceptable level of statistical significance—requires large populations ($>10^4$).

Minor Groove of DNA Double Helix: It is marked by an arrow in the Fig. M78.

Figure M78. Minor groove of DNA double helix

Minor Histocompatibility Antigen: It has some role in immune reactions but it is not coded in the HLA region. ►HLA, ►MHC, Dazzi F et al 2001 Nature Med 7:769.

Minos: A 1,775-basepair transposable element of *Drosophila hydei* with 255-bp inverted terminal repeats and with two non-overlapping open reading frames. ►transposable elements animals; Zagoraiou L et al 2001 Proc Natl Acad Sci USA 98:11474.

Minus END: of microtubules or actin filaments is less liable for elongation. ►plus end

Minus Position of Nucleotides: It indicates the upstream distance from first translated triplet of the transcript of a gene. ►triplet code, ►RNA polymerase

Minutes: Approximately 60 dominant mutations in *Drosophila* that slow down the development of heterozygotes and is lethal when homozygous. The phenotypes vary but generally the bristles are reduced (see Fig. M79). Some mutants increase somatic crossing over. Minutes have several chromosomal locations. They are defective in ribosomal proteins. (See Lambertson A 1998 Adv Genet 38:69; Marygold SJ et al 2005 Genetics 169:683).

Figure M79. Minute (M1)n fly

MIP (methylation induced premeiotically): The mechanism of gene silencing by causing apparently a stall of the RNA polymerase before completing the transcription of fungal genes. ►RIP

MIP-1 α (macrophage inflammatory protein; CCL3L1/CC chemokine ligand 3-like): A chemokine mediating virus and other microbial induced inflammation protein related to RANTES. It belongs to the family of FK506-binding proteins. ►RANTES, ►blood cells, ►FK506, ►peptidyl-prolyl isomerases, ►acquired immunodeficiency syndrome; Matzer SP et al 2001 J Immunol 167:4635.

MIPS (Munich Information Center for Protein Analysis): A database of functional genomes and proteomes. (See Mewes HW et al 2002 Nucleic Acids Res 30:31; <http://mips.gsf.de>).

MIR: Mammalian-wide interspersed repeat, $\sim 12\text{--}30 \times 10^4$ copies/primate genome. They may regulate the expression of genes, alternative splicing, polyadenylation sites and evolution. ►redundancy; Matassi G et al 1998 FEBS Lett 439:63.

MIR: ►ILT

Mirabilis jalapa (four-o'clock): Ornamental plant and early object of inheritance, $2n = 58$ (see Fig. M80).

Figure M80. *Mirabilis*

miRE: MicroRNA responsive element ►microRNA

miRNA: ▶ [MicroRNA](#)

miRNP: A complex of ribonuclease containing miRNA and several proteins are involved in processing of interfering RNAs. ▶ [microRNA](#), ▶ [RNAi](#), ▶ [Dicer](#), ▶ [RISC](#); Morelato Z et al 2002 Genes Dev 16:720.

Mirtron (pre-microRNA intron): Debranched introns, which mimic the structural features of pre-miRNAs to enter the miRNA-processing pathway without Drosha-mediated cleavage. ▶ [microRNA](#), ▶ [Drosha](#), ▶ [intron](#); Ruby JG et al 2007 Nature [Lond] 448:83.

MIS (Müllerian inhibitory substance): ▶ [Müllerian duct](#), ▶ [gonads](#)

Mis12/Mtw1: A protein controlling kinetochore orientation in yeast. ▶ [kinetochore](#)

Miscall: ▶ [base-calling](#)

Miscarriage: The loss of pregnancy. It occurs spontaneously in about 15–20% of the pregnancies at least once during the life of human female. Repeated miscarriage before 20 weeks of pregnancy occurs in 0.5–2% of the women and it may be caused by environmental, extrinsic factors (infections) or by uterine anomalies, hormonal problems, chromosomal aberrations, autoimmune reactions or other immune problems (Rh), metabolic dysfunction (folic acid deficiency, hyperhomocystinemia, defects in nitric oxide synthase, etc.). Although most commonly genetic (chromosomal) anomalies of the fetus is responsible for the miscarriage, recent observations point to an essential role of mutation or deletion in the HLA-G (Ober C et al 2003 Am J Hum Genet 72:1425). (See terms under separate entries, ▶ [abortion spontaneous](#); Tempfer C et al 2001 Hum Reprod 16:1644).

Miscegenation: Sexual relations between partners of different human races. In the majority of human tribes, marriage was generally limited within the tribes, however, marriage by “capture” existed in ancient societies where the conquerors in war abducted females. Miscegenation was applied particularly to marriage between whites and blacks in the United States and in some South-American societies. There is no genetic justification against interracial

marriage. Although marriage between Blacks and Orientals was not prohibited by any law, marriage between Caucasians and Blacks was unlawful in about 15 states of the U.S. until 1967 when the Federal Court ruled that the choice to marry resides with the individual. Racial and social (cast) discrimination in marriage still exists in many underdeveloped countries and in backward communities. ▶ [mulatto](#), ▶ [mestizo](#), ▶ [racism](#), ▶ [marriage](#); Hulse FS 1969 J Biosoc Sci Suppl 1:31.

Mischarged tRNA: It is linked to wrong amino acids. ▶ [aminoacyl-tRNA synthetase](#), ▶ [protein synthesis](#)

Miscoding: ▶ [ambiguity in translation](#)

Misconduct, Scientific: The fabrication, falsification or embellishing of data, the use of inadequate statistics or techniques, making unjustified conclusions, plagiarism, omitting relevant facts concerning the experimental data or the literature, misrepresenting previous or competing publications, claiming undue credit or any other unethical behavior. A survey reported in 2005 (Martinson BC et al Nature [Lond] 435:737) indicates that 33% of the (several, thousands) scientists supported by National Institutes of Health USA anonymously admitted bad behavior although only 0.3% confessed falsifying data but 27.5% felt guilty of inadequate record keeping. The corrosive behavior was substantially (15.5%) promoted by inadequate institutional policies. ▶ [ethics](#), ▶ [publication ethics](#), ▶ [scientific misconduct](#)

Misdivision of the Centromere: A vertical rather than longitudinal division; generates two telochromosomes from one bi-armed chromosome. The telochromosomes may open up to isochromosomes and may undergo misdivision again forming telochromosome (see Fig. M81). ▶ [centromere](#), ▶ [heterochromatin](#); Darlington CD 1939 J Genet 37:341; photo at telochromosome.

Misexpression of a Gene: ▶ [ectopic expression](#)

Misincorporation: During DNA replication a normal nucleotide or an analog is placed into the growing strand, at a site where correct pairing (e.g., A = T, G = C) is not available. Such an event may lead to base substitution in the following step of replication, e.g.,

Figure M81. Misdivisional cycles

$A + T \rightarrow A:C \rightarrow G \equiv C$, resulting in mutation unless mismatch repair corrects it. Misincorporation can also occur during transcription of the DNA into RNA. ▶base substitution, ▶mismatch repair, ▶DNA repair, ▶error in transcription; Freese E 1963 p 207. In: Molecular Genetics. Taylor JH (Ed.) Academic Press, New York.

Misinsertion: DNA polymerase binds to a correctly matched 3' end of a primer where right and wrong dNTP substrates compete for insertion and occasionally the wrong may succeed resulting in misinsertion. ▶DNA editing, ▶dNTP

Mis-Localization: Gene products are normally localized according to a specific pattern within the tissues, cells or at subcellular sites. Deviations from the normal pattern may lead to disease. (See Sutherland HGE et al 2001 Hum Mol Genet 10:1995).

Mismatch: One or more wrong (non-complementary) base(s) in the paired nucleic acid strands. Mismatches are generally identified (localized) by the use of fluoro-chrome labeled probes or they can be labeled by nanoparticle gold and analyzed on the basis of reduction silver (in the presence of hydroquinone at pH 3.8) by ordinary flatbed scanners with high sensitivity. Chemical cleavage of mismatch (CCM) is a hydroxylamine/osmium tetroxide-based (HOT) analysis of sequence variability in DNA. This procedure has been improved by adapting fluorescence techniques.

A bulky rhodium (a platinum type metal) complex can bind to mismatched and matched sites in the DNA of the oligonucleotide 5'-(dCGGAATTCCCG)2-3'. At the AC mismatch site, the structure reveals ligand insertion from the minor groove with ejection of both mismatched bases and destabilized mispairs in DNA may be recognized. This unique binding mode contrasts with major groove intercalation, observed at a matched site, where doubling of the base pair rise accommodates stacking of the intercalator. Mass spectral analysis reveals different photocleavage products associated with the two binding modes in the crystal, with only products characteristic of mismatch binding in solution. This structure, illustrating two clearly distinct binding modes for a molecule with DNA, provides a rationale for the interrogation and detection of mismatches (see Fig. M82). DNA polymerases generate mismatches at the rate of 10^{-4} to 10^{-5} per base pair at the nucleotide insertion step. These mistakes are typically reduced to 10^{-7} per base pair per replication by exonucleases associated with the DNA polymerase and are further reduced to 50- to 1,000-fold by the mismatch repair machinery. Deficiencies in mismatch repair increase the rate of mutation and subsequently the risk of developing cancer (Pierre VC

et al 2007 Proc Natl Acad Sci USA 104:429). ▶transition mismatch, ▶transversion mismatch, ▶mismatch repair, ▶DNA grooves; Ellis TP et al 1998 Hum Mutat 11:345.

Figure M82. Mismatch

Mismatch Extension: DNA polymerase binds to either a matched or mismatched primer end, and the mismatch is extended in replication. ▶mismatch

Mismatch of Bases: Non-complementary bases in a (hetero)duplex DNA. ▶mismatch

Mismatch Repair (MMR): An excision repair that removes unpaired or mispaired bases and replaces them through unscheduled DNA synthesis with correct base pairs. The long-patch mismatch repair may have to correct tracts of hundreds of nucleotides. Mutations in *E. coli* gene *mutL* (homodimer, subunits ~68 kDa) and *mutS* (~95 kDa subunits) increase genetic instabilities and in yeast, defects in *PMS1*, *MLH1* and *MLH2* may increase genetic instability 100 to 700-fold because of deficient mismatch repair. In yeast Msh6 (S1036P) the mutant complex, which binds the mispaired base is defective in ATP-induced sliding clamp formation and assembly of the ternary complex with Mlh1-Pms1 and prevents the access of other repair systems to access to the defect. In another mutation of Msh6 (G1142D), which binds mispaired sequences and is defective in the ATP-induced sliding clamp formation but permits the assembly of the Mlh1-Pms1 complex yet either prevents the access of other repair system or hinders Mlh1-Pms1 to activate the other repair systems (Hess MT et al 2006 Proc Natl Acad Sci USA 103:558). *mutS* may also inhibit both homologous and homeologous recombination (Pinto AV et al 2005 Mol Cell 17:113). Mismatch repair deficiency may enhance mutation rate by 1–2 orders of magnitude, depending on the background (Ji HP, King M-C 2001 Hum Mol Genet 10:2737). The consequences of deletions of RTH1, encoding a 3'→5' exonuclease are similar. The G/T binding protein (GTBP, 100K) and hMSH2 (160 K, homolog of bacterial mismatch-binding protein) are essential for mismatch recognition in human cells. In fission yeast the mismatch repair enzyme, exonuclease I, reduces mutation rate. Defects in the bacterial methyl-directed mismatch repair system may also enhance mutability (Burdett V et al 2001 Proc Natl Acad Sci USA 98:6765). The repair system is directed to DNA strands by methylation of adenine

in the d(GATC) sequences. Since newly synthesized strands are not methylated, this is the criterion for recognition by the repair system (MutH, MutL, MutS, ATP). The mismatch may be located kilobases away from the d(GATC) tract. Interaction of this complex with heteroduplexes activates the MutH-associated endonuclease that responds to an initial sequence discontinuity or nick. Excision from the 5' side of the mismatch requires the RecJ exonuclease or exonuclease VII and digestion from the 3'-end needs exonuclease I and also a helicase to unwind the strands because these proteins hydrolyze only single strands. RecJ and exo VII require that the unmethylated GATC would be downstream from the defect. Exo I usually does not have this precondition. The replacement synthesis requires DNA polymerase III. Other polymerases do not work in this system. In the eukaryotic systems, the MutL homologs are PMS1 in yeast and PMS1, PMS2 in mammals. The yeast PMS1 system corrects G-T, A-C, G-G, A-A, T-T and T-C mismatches but C-C or long insertion/deletion sequences were barely repaired if at all. The human repair system fixes 8–12 pair mismatches and C-C. An MutS homolog in mammals is called GTBP (G-T binding protein). Defects in PMS1, MLH1, MSH2 and [MSH3] enhance mutation rate in the yeast mitochondria, increases somatic mutability up to three orders of magnitude at certain loci (e.g., canavanine resistance), destabilizes (GT)_n sequences. Mutations in the yeast Rth1 5'→3' exonuclease also increases mutability, particularly of plasmid-encoded genes. MutS function is required for the normal progression of meiosis and the maintenance of the female gonads. The yeast homologs of the bacterial MutS and MutL not only correct errors in replication but block recombination between not entirely homologous (homoeologous) sequences. Heterocomplexes of the mismatch repair genes have important role in meiotic recombination (Snowden T et al 2004 Mol Cell 15:437). Defects in mismatch repair result in increased frequency of recombination, mutation and indirectly on evolution. PCNA and related proteins mediating DNA replication are essential for repair synthesis. Cadmium is a potent inhibitor of mismatch repair and greatly increases mutation (Jin YH et al 2003 Nature Genet 34:326). Double-strand DNA breaks may be repaired by gene conversion. Mismatch repair deficiency may increase the susceptibility to methylating drugs but not for others (e.g., cisplatin) or ionizing radiation. ▶[unscheduled DNA synthesis](#), ▶[DNA repair](#), ▶[glycosylase](#), ▶[PCNA](#), ▶[MRD](#), ▶[incongruence](#), ▶[gene conversion](#), ▶[double-strand break](#), ▶[Walker boxes](#), ▶[mutator genes](#), ▶[microsatellite](#), ▶[homeologous recombination](#), ▶[hereditary non-polyposis colorectal cancer](#), ▶[Lynch cancer families](#), ▶[Muir-Torre syndrome](#), ▶[gonads](#), ▶[excision](#)

Misoprostol (Misoprostol): A synthetic prostaglandin E₁ analog that inhibits secretion of gastric acid (as an antacid pill) but it also induces uterine contractions and can cause abortion. It is used also for non-surgical termination of pregnancy. ▶[prostaglandins](#), ▶[RU486](#)

Mispairing: Occurs when the homology between paired nucleotide sequences is imperfect and illicit binding takes place between nucleotides.

Misreading: A triplet is translated into an amino acid different from its standard coding role. ▶[ambiguity in translation](#)

Misrepair: ▶[DNA repair](#), ▶[SOS repair](#)

Misreplication: ▶[error in replication](#)

Missense Codon: Inserts an amino acid different from that encoded by the wild type codon at the site in the polypeptide chain. ▶[nonsense codon](#)

Missense Mutation: A change in DNA sequence that results in an amino acid substitution in contrast to mutations in synonymous codons where the change involves only the DNA but not the protein. ▶[nonsense mutation](#)

Missense Suppressor: Enables the original amino acid to be inserted at a site of the peptide in the presence of a missense mutation. ▶[suppressor tRNA](#); Benzer S, Weisblum B 1961 Proc Natl Acad Sci USA 47:1149.

Missing Genes: In the archaeobacterium, *Methanococcus janaschii*, four of the 20 aminoacyl-tRNA synthetases were not detected in the completely sequenced genome. It has been hypothesized that glutamine and asparagine are incorporated into polypeptides as transamidated derivatives of glutamate and aspartate. Furthermore, cysteine was assumed to be inserted as a trans-sulfurated serine and tRNA^{Lys} synthetase function was replaced by a protein quite dissimilar to known aminoacyl-tRNA synthetases. ▶[aminoacyl-tRNA synthetase](#); Bult CJ et al 1996 Science 273:1058.

Missing Link: The lack of transitional forms in evolution in between two species, of which one was/is supposed to have descended from the other. In 2006, a 385–359 million-year old fossil of a fish that lived in the Late Devonian period in Canada was reported to have been found. It had bony structures in the fins and other morphological features indicating a missing link to tetrapods (Daeschler EB et al 2006 Nature [Lond] 440:757). ▶tetrapod, ▶geological–evolutionary time periods

Missing Self Hypothesis: One of the functions of natural killer lymphocytes (NK) is to recognize and eliminate cells that do not express class I MHC (major histocompatibility complex) molecules. ▶killer cells, ▶MHC; Ljunggren HG, Karre K 1990 Immunology Today 11:237.

Missplicing: Incorrect splicing. ▶splicing

Mistranslation: ▶misreading, ▶ambiguity in translation

MIT.: The general designation of mitochondrial point mutations.

Mitchurin: A nineteenth-twentieth century Russian plant breeder who contributed a large number of improved varieties, mainly fruits, to the Russian and then to the Soviet agriculture. His career is often compared to that of the American Burbank. There was a very important difference, however, Burbank produced over 100 varieties to the USA agriculture without governmental pretensions that he made novel basic scientific discoveries. Mitchurin, on the other hand, published undigested and misunderstood theories and became the official forefather of lysenkoism, a state-supported charlatanism. He drew sweeping conclusions on the basis of tenuous experimental technology. ▶lysenkoism, ▶Burbank, ▶acquired characters inheritance, ▶graft hybridization

MITE (mariner insect transposon-like element, miniature inverted-repeat transposable element): A 1,457-bp DNA sequence in the vicinity of MLE containing a 24-bp tract with homology to Mos1 and supposedly responsible for the high frequency of unequal crossing over resulting in a duplication appearing as the Marie-Charcot-Tooth disease, and in the complementary deletion appearing as HNPP. Similar MITE elements occur also in rice, maize, sugarcane and other plants and control transcription. ▶Marie-Charcot-Tooth disease, ▶HNPP, ▶unequal crossing over, ▶hot spot, ▶Mos1, ▶mariner, ▶heartbreaker, ▶MLE; Casa AM et al 2000 Proc Natl Acad Sci USA 97:10083; Jiang N et al 2003 Nature (Lond) 421:163.

Mitochip: The mitochondria-specific oligonucleotide microarray that has potential to define mechanisms of

disease progression and drug toxicities involved in mitochondrial dysfunction (Desai VG, Fuscoe JC 2007 Mutation Res 616:210). ▶microarray; Zhou S et al 2006 J Mol Diagn 8:476.

Mitochondria: Cellular organelles 1–10 μm long and 0.5–1 μm wide, surrounded by double membranes. The outer membrane has a diameter of 50–75 and the inner 75–100 Å. The latter forms the structures, called cristae. Mitochondria are associated frequently with the cytoskeleton and the latter may control the distribution of this organelle within the cell and their transmission during cytokinesis.

The outer membrane is associated with monoamine oxidase and a NADH-cytochrome c reductase. Cardiolipin, phosphatidyl inositol, and cholesterol are major compounds associated with the inner membrane. Mitochondria have an important role in generation of ATP and in electron transport. ATP synthesis requires oxidative phosphorylation. The mitochondria generally encode cytochrome b, cytochrome oxidase (COX) subunits, ATPase and NADH dehydrogenase (see Fig. M83). Three protozoa (*Giardia*, *Trichomonas*, *Vairimorpha*) and *Entamoebas* are the only animals without mitochondria. All human cells, except the erythrocytes contain mitochondria. In human mitochondria 13 out of the 78 polypeptides involved in the electron transport are coded for by mitochondrial DNA.

Figure M83. Diagram of a longitudinal section of a mitochondrion showing the cristae and the DNA strings in between them. according to electronmicroscopic view the cristae are tubular rather than lamellar structures

Mitochondria are the major source of reactive oxygen (ROS) in the body. In humans, about 300 nuclear genes control mitochondrial functions. The larger mitochondrial genomes of fungi and plants have larger coding capacity. The mitochondrial DNA and the prokaryotic type ribosomes in this organelle are capable of independent protein synthesis although they may not have all their necessary tRNA genes within the mt genome. The majority of the proteins within the mitochondria are synthesized in the cytosol and imported. This import depends also on the function of cytosolic chaperones such as Hsp70 and Hsp60. In yeast and some other organisms, under

some circumstances, a single giant mitochondrion is formed that spreads all over the cell and can break up into smaller organelles (see Fig. M84). Mitochondria are usually transmitted only through the eggs. Exceptions exist, however. In a human cell, about 100–1000 mitochondria may be found but a single mouse oocyte has $\sim 1 \times 10^5$. Each may contain 2–10 or more DNA molecules and about 1000 peptides of which only 13 are coded by mtDNA. In addition, the mtDNA genome (16.5×10^3 bp in higher animals) encodes two rRNAs and 22 tRNAs. (In other organisms, the number of genes in the mitochondria may vary between 5 and 60.) Mitochondria are involved in the production of $\sim 80\%$ of the cellular ATP, carry out respiration, synthesize amino acids, nucleotides, lipids, heme, regulate inorganic ion channels and apoptosis.

Figure M84. Plant mitochondrion

During mammalian oogenesis, the number of mitochondria may be 4,000–200,000 but their number may be reduced substantially during early development of the embryo. The number of mitochondria seems to be regulated by mtTFA and mtTFA is regulated by a nuclear regulatory factor (NRF-1). The large number of mitochondria within mammalian and other higher eukaryotic cells was probably necessitated by the limited capacity of DNA repair within the mitochondria. The large number can compensate for the defective organelles. There is apparently no nucleotide excision repair (NER) in the mammalian mitochondria but base excision repair (BER), by the use of glycosylases, has been detected. Mismatch repair (MMR) also exists in mitochondria. It is not clear whether recombinational repair has a role in mitochondria. The evolutionary origin of the mitochondria has been interpreted by syntrophic hypotheses assuming the fusion of a primitive amitochondrial eukaryote with a *Clostridium*-like eubacterium or a *Sulfolobus*-like archaeobacterium. Genome signatures, the selective advantage of expanded energy metabolism, and the possibility that *Clostridium* provided an opportunity for the development of the nucleus and the cytoplasm of the eukaryotic cell support the latter hypothesis. Mitochondrial DNA analysis (Finnilä S et al 2001 Am

J Hum Genet 68:1475) is a very important tool for evolutionary and demographic studies. Some anaerobic or near-anaerobic unicellular eukaryotes do not have typical mitochondria but hydrogenosomes. An integral membrane protein, mitofusin, mediates fusion of mitochondria (Koshiba T et al 2004 Science 305:858). ▶mtDNA, ▶paternal leakage, ▶doubly uniparental inheritance, ▶Eve foremother of mitochondrial DNA, ▶CSGE, ▶compatibility of organelles with the nuclear genome, ▶respiration, ▶photorespiration, ▶promitochondria, ▶mitochondrial genetics, ▶petite colony mutations, ▶organelle sequence transfer, ▶aspartate aminotransferase [glutamate oxaloacetate transaminase, ▶GOT2], ▶mitochondrial diseases in humans, ▶cytoplasmic male sterility, ▶mitochondrial abnormalities in plants, ▶mitochondrial genetics, ▶mitochondrial plasmids, ▶mitochondrial import, ▶polar granules, ▶*Neurospora*, ▶mitochondrial plasmids, ▶mtTFA, ▶sorting out, ▶endosymbiont theory, ▶Rickettsia, ▶evolution of organelles, ▶Tid50, ▶Hsp70, ▶Hsp60, ▶Ydj, ▶rho factor, ▶hydrogenosome, ▶apoptosis, ▶aging, ▶ROS, ▶signature genomic, ▶membrane proteins, ▶amitochondriate, mitosome, evolution of mitochondria: Gray MW et al 2004 Annu Rev Genet 38:477; MAVS, Chen XJ, Butow RA 2005 Nature Rev Genet 6:815; mitochondrial fusion and fission: Okamoto K, Shaw JM 2005 Annu Rev Genet 39:503; mitochondrial origins and evolution: Embley TM, Martin W 2006 Nature [Lond] 440:623; Mt DNA in human oocyte: Shoubridge EA, Wai T 2007 Curr Top Dev Biol 77:87; human mitochondrial database: <http://www.genpat.uu.se/mtDB/>; mitochondrial proteome: <http://www.mitop2.de/>; human mitochondria: <http://www.mitomap.org/>; *Arabidopsis* mitochondrial proteins: <http://www.ampdb.bcs.uwa.edu.au/>.

Mitochondria and Cancer: Dysfunction of apoptosis may lead to abnormal cell proliferation and thus to cancer. The apoptosis blocking Bcl-2 and other proteins are localized in the mitochondrial membrane. The oxidative processes in the mitochondria may cause mutagenic lesions leading to tumor initiation and progression. ▶apoptosis, ▶cancer

Mitochondria, Cryptic: Double-strand membrane-enclosed structures in microsporidia that were supposed to lack mitochondria. Microsporidia are intracellular parasites of some animals and protists. The cryptic mitochondria are about 1/10 in size of mitochondria of animals and contain only a few proteins. The majority of the mitochondrial functions were apparently lost in these parasites as a consequence of retrograde evolution. ▶retrograde evolution, ▶hydrogenosomes; Roger AJ, Silberman JD 2002 Nature [Lond] 418:827.

Mitochondrial Abnormalities in Plants: The cytoplasmic male sterility, widespread in many species of plants and the *non-chromosomal striped* mutations of maize have proven mitochondrial defects. The latter have deletions either in the cytochrome oxidase (*cox2*) or in NADH-dehydrogenase (*ndh2*) or in ribosomal protein (*rps3*) mitochondrial genes. The mtDNA defects apparently originate by recombination between repeats (6–36-bp) at different locations within the genome. Recombinations involving larger repeats may also give rise to normal mtDNA as well as duplication-deficiency molecules. The phenotype (green and bleached stripes on the leaves, stunted growth, etc.) might suggest as if the plastids would have been involved. A similar mt-coded enzyme causes mitochondrial defects in other plants as well as in animals. ▶cytoplasmic male sterility, ▶killer plasmids, ▶senescence, ▶mitochondrial diseases in humans, ▶mitochondrial genetics, ▶mitochondrial plasmids, ▶mitochondria; Newton KJ et al 1996 Dev Genet 19:277.

Mitochondrial Complementation: When mitochondria with long deletions (4696 bp), including the site of cytochrome oxidase c (COX) is lost, mice did not show any disease when COX⁺ mitochondria were introduced. Within single cells, apparently only normal mitochondrial function could then be detected, indicating genetic complementation. The results promise the possibility of gene therapy by mtDNA. ▶mitochondrial heterosis; Nakada K et al 2001 Nature Med 7:934.

Mitochondrial Control-Regions: They encompass the areas where replication of the heavy strand (control region I, bp 16040–16400 in humans) and light strand (control region II, bp 39–380 in humans) takes place. The control regions display greater variation than the rest of the molecule and therefore, these regions are frequently studied for base variations in evolutionary and population studies. ▶DNA replication mitochondria, ▶D loop, ▶mtDNA, ▶DNA 7 S, ▶mitochondrial genetics

Mitochondrial DNA Depletion Syndromes (MDDS): MDDS involve tissue-specific decrease of mtDNA copy number and organ failure. Mitochondrial DNA synthesis depends on import of deoxyribonucleotide phosphates from the cytosol or salvage from DNA inside mitochondria. Human deoxyguanosine kinase (dGK, 2p13) and thymidine kinase-2 (TK2, 16q12) are expressed in the mitochondria. These two enzymes phosphorylate purines (guanine, adenine) and pyrimidines (thymidine, cytidine) respectively. Mutations in TK2 can reduce its activity by 14–45% and involve devastating myopathy (Saada A et al 2001 Nature Genet 29:342). Similarly, mutation in the last step of the salvage pathway (ADP forming

succinyl-CoA ligase) resulted in mtDNA depletion and encephalomyopathy (Elpeleg O et al 2005 Am J Hum Genet 76:1081). A hepatocerebral mtDNA depletion locus (MPV17, 2p21-p23) affect the inner mitochondrial membrane and causes defects in (oxidative phosphorylation) OXPHOS (Spinazzola A et al 2006 Nature Genet 38:570). ▶Alpers progressive poliodystrophy, ▶oxidative phosphorylation myopathy, ▶mitochondrial diseases in humans, ▶hepatocerebral, ▶mtDNA

Mitochondrial Diseases in Humans: Up to the 1970s no human disease was attributed to mtDNA. Approximately 0.001 fraction of the newborns have a mitochondrial disease. The role of mitochondrial DNA was definitely proven only after molecular analysis became practical. The inheritance pattern is not always clear because of heteroplasmy. *Chloramphenicol* resistance in human cells is caused by several mutations in the mitochondrial DNA-encoded 16S ribosomal RNA genes. Leber hereditary optic atrophy (LHON), a progressive disease (caused most commonly by single base pair substitution [G(A(Arg→His))] resulting in wasting away of the eyes (optic atrophy), abnormal heart beat accompanied by neurological anomalies characterizes this disease (involving 5 NADH dehydrogenases at different sites in the mtDNA) that it appears a human X-chromosomal factor has a role in determining susceptibility to the mitochondrial defect (see Fig. M85). In mice, three nuclear quantitative gene loci appear to affect mitochondrial sorting out (Battersby BJ et al 2003 Nature Genet 33:183). In LHON models of mice and dogs adeno-associated virus vector carrying the gene for the retinal pigment epithelium photoreceptor successfully restored visual function by this gene therapy (Acland GM et al 2001 Nature Genet 28:92). *Kearns-Sayre syndrome* (KSS/ PEO) a progressive external ophthalmoplegia (paralysis of the eye muscles) is characterized by pigmentary degeneration of the retina and cardiomyopathy (inflammation of the heart muscles) and other less specific symptoms are caused either by deletion or base substitution mutation in nucleotide 8,993 in the mtDNA. Deletions—in 30–50% of the afflicted—are flanked by the 5'-ACCTCCCTCACCA direct repeats and show the loss of nucleotides 8,468–13,446 and a less frequent deletion between the repeats 5'-CATCAACAACCG at positions 8,468–16,084. The larger deletions may affect simultaneously also other mitochondrial genes. The KSS involves most commonly heteroplasmy and its occurrence is frequently sporadic. The basic defect is either in a protein phage T7 gene-4-like primase/helicase of DNA (Spellbrink JN et al 2001 Nature Genet 28:223) or in DNA polymerase γ , located at 15q22-q26 (Van Goethem G et al 2001 Nature Genet 28:211). In both cases, multiple

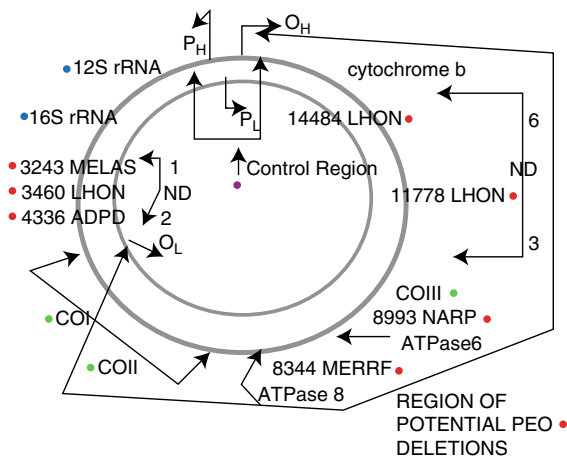

Figure M85. Incomplete Human mtDNA Map. O_H : Origin of heavy-chain replication, P_H : promoter of heavy chain replication, P_L : light strand promoter, ND: NADH-coenzyme Q oxidoreductase subunits, ADPD: Alzheimer disease late onset, CO: cytochrome oxidase subunits, NARP: neuropathy, ataxia, retinitis pigmentosa syndrome, MELAS: mitochondrial myopathy, encephalopathy, lactic acidosis, stroke-like syndrome (associated mainly with mutation in the $tRNA^{Leu}$), LHON: Leber's hereditary optic neuropathy, MERRF: myoclonic epilepsy and ragged-red fibers, PEO: progressive external ophthalmoplegia (most commonly deletions)

mutation/deletions occur in the mtDNA. One form of *myoclonic epilepsy*, MERRF (shock-like convulsions and ragged red fibers [when stained with Gömöri's modified trichrome stain]) is caused by a point mutation in the mtDNA-coded $tRNA^{Lys}$. *Mitochondrial myopathy* (muscle/eye degeneration), *encephalopathy* (brain degeneration), *encephalomyopathy* (MTTL2) mutation in $tRNA^{Leu}$, *lactic acidosis* (accumulation of lactic acid in the blood), and *stroke-like episodes* (MELAS syndrome, *mitochondrial encephalopathy with lactic acidosis and stroke-like symptoms*) are due to a mtDNA encoded $tRNA^{Leu}$ base substitution (A→G) at nucleotide 3,243 and at other sites and by mutation in $tRNA^{Cys}$ and $tRNA^{Val}$. The same $tRNA^{Leu}$ mutation occurs in about 20% of the patients with the recessive autosomal *Progressive external ophthalmoplegia* (PEO) and in some cases of diabetes mellitus ($tRNA^{Leu}$). Mutation in $tRNA^{Leu}$ A3243G leads to gradual pancreatic β -cell dysfunction upon aging and diabetes (*Mitochondrial diabetes*, Maassen JA et al 2004 Diabetes 53:S103). The *Pearson marrow-pancreas syndrome* is caused by mtDNA deletions affecting subunit 4 of NADH dehydrogenase, subunit 1 of cytochrome oxidase and subunit 1 of ATPase. This rare disease, usually heteroplasmic, is frequently fatal at infancy. *Oncocytoma*, responsible primarily for benign solid kidney

tumors, loaded densely with mitochondria, has deletions in subunit 1 of cytochrome oxidase.

In general, human males have more, or more are affected by mitochondrial mutations. About 85% of the *Leber's optic dystrophy* cases are found in males. Also, Alzheimer disease ($tRNA^{Gln}$), and Parkinson disease are associated with defective mitochondrial energy metabolism, reduced sperm motility and fertility. *Leigh syndrome* (an ATP synthase defect at nucleotide 8527–9207) is a progressive encephalopathy of children and it is accompanied by over 90% mutant mitochondria in the blood, muscle and nerve cells, although the inheritance appears autosomal. Several myopathies are associated with mutations also in various tRNAs of the mitochondria ($tRNA^{Phe}$, $tRNA^{Ile}$ [cardiomyopathy], $tRNA^{Glu}$ [cardiomyopathy], $tRNA^{Met}$, $tRNA^{Ala}$, $tRNA^{Asn}$, $tRNA^{Cys}$ [ophthalmoplegia], $tRNA^{Tyr}$, $tRNA^{Ser}$, $tRNA^{Asp}$, $tRNA^{Lys}$ [MERRF syndrome], $tRNA^{Gly}$, $tRNA^{Arg}$ [LHON], $tRNA^{Ser2}$, $tRNA^{Leu(CUN)}$ [skeletal myopathy], $tRNA^{Glu}$, $tRNA^{Thr}$ [cytochrome b subunits]). U → C transition mutation adjacent to the anticodon GAU of $tRNA^{Lys}$ may involve hypertension, dyslipidemia and atherosclerosis (Wilson FH et al 2004 Science 306:1190). In MELAS Leu^{UUR} tRNA five mutations (sites A3243G, G3244A, T3258C, T3271C and T3291C) lacked the normal taurine-containing modification (5-taurinomethyluridine) at the anticodon wobble position. Other mutations in $tRNA^{Leu^{UUR}}$ (G3242A, T3250C, C3254T and A3280G) display mitochondrial disease but not the MELAS symptoms (Kirino Y et al 2005 Proc Natl Acad Sci USA 102:7127).

Aminoglycoside-sensitivity (modest doses of streptomycin) may lead to hearing defects due to mutation in the 12S rRNA gene (Li R et al 2004 Am J Med Genet 124A:113; Li X et al 2004 Nucleic Acids Res 32:867). About 5×10^{-5} fraction of the human population is hypersensitive to chloramphenicol and may become anemic from the drug. Deletion of the COX (cytochrome oxidase) gene may result in *myoglobinuria*.

The human mitochondria harbors about 1,500 proteins and but most of them are encoded by nuclear genes. By computational technology, 1,080 gene products were allocated to mitochondria with an estimated false positive rate of 10%. The predicted number includes 8 genes implicated in disease (Calvo S et al 2006 Nature Genet 328:576). A decrease in the number of mitochondria, caused by nuclear genetic factors or drugs may lead also to disease.

The autosomal dominant progressive external ophthalmoplegia (adPEO, CPEO), a muscle weakness affecting the eyes primarily, is caused by a mutant gene in human chromosome 10q23.3-q24.3 that causes multiple deletions.

Hereditary spastic paraplegia is encoded by chromosome 16q but the 795 amino acid paraplegin protein is located in the mitochondria. Some of the late onset neurodegenerative diseases apparently have mitochondrial components. Human *colorectal tumors* frequently display purine transition mutations and appear homoplasmic. *Hereditary paraganglioma* is caused by mutation at 11q23 in the SHDS gene encoding a small subunit of cytochrome b involved in succinate-ubiquinone oxidoreductase (sybS). This disease shows vascularized benign tumors in the head and neck due to defects in the carotid body (the main artery to the head), which senses oxygen levels in the blood (Vanharanta S et al 2004 Am J Hum Genet 74:153).

The mtDNA contains 37 genes, most of them transcribed from the heavy chain, but 9 are read in opposite direction from the light chain of the DNA and they are thus somewhat overlapping. The human mitochondria encode only 13 respiratory chain proteins although it may harbor about ~1,500 proteins (see Fig. M86). Some human diseases or syndromes (hypotonia [reduced muscle tension], ptosis [dropping down eyelids], ophthalmoplegia [eye muscle paralysis], high level of lactate in the blood serum, liver defects) may be associated with a reduced level of mtDNA. Genetic counseling with mitochondrial disease is difficult because the transmission of the heteroplasmic conditions is irregular. Treatment of mitochondrial diseases so far appeared rather elusive. The mitochondrial respiratory chain involves the multisubunit complexes (I) NADH-UQ oxidoreductase, (II) succinate dehydrogenase, (III) UQ-cytochrome c oxidoreductase, (IV) cytochrome c oxidase, and (V) ATP synthase. Blocking complex I by 1-methyl-4-phenylpyridinium (MPP^+) mimicks Parkinson disease and LHON. Inhibition of complex II by 3-NPA (3-nitropropionic acid) causes the symptoms of Huntington's chorea. Cyanide and azide inhibition of complex IV resembles the expression of Alzheimer disease. The effect of oligomycin on complex V involves neuropathy, ataxia and retinitis pigmentosa-like symptoms. There are a number of diseases, which are not encoded by the mitochondrial DNA and neither are the proteins localized in the mitochondria yet they affect mitochondrial functions. Mitochondrially determined disease due to ATP

deficiency could be alleviated (Manfredi G et al 2002 Nature Genet 30:394) by introduction into the nucleus the functional mitochondrial gene. Also, the transplantation of nuclei from mitochondrial mutants into normal cytoplasm may restore normal health if the mutational defect was limited only to mitochondria (Sato A et al 2005 Proc Natl Acad Sci USA 102:16765). Dominant optic atrophy (Kjer type, 3q28-q29) causes serious vision defects in childhood and adulthood due to degeneration a mitochondrial intermembrane dynamin-like OPA1 protein (Kim JY et al 2005 Neurology 64:966). ▶mitochondria, ▶mitochondrial DNA depletion syndromes, ▶mtDNA, ▶mitochondrial genetics, ▶protoporphyrria, ▶aging, ▶senescence, ▶chondrome, ▶optic atrophy, ▶epilepsy, ▶spastic paraplegia, ▶antibiotics, ▶Leigh's encephalopathy, ▶diabetes mellitus, ▶ophthalmoplegia, ▶myoglobin, ▶Wolfram syndrome, ▶Friedreich ataxia, ▶Wilson disease, ▶Alzheimer disease, ▶Parkinson disease, ▶Charcot-Marie-Tooth disease, ▶spastic paraplegia, ▶MNGIE, ▶amyotrophic lateral sclerosis, ▶mitochondrial gene therapy, ▶homoplasmy, ▶heteroplasmy, ▶colorectal cancer, ▶apoptosis, ▶mtPTP, ▶mitochondrial abnormalities in plants, ▶atresia, ▶pleiotropy, ▶oxidative DNA damage, ▶transmitochondrial, ▶NARP syndrome, ▶myoneurogastrointestinal encephalopathy, ▶dimethylglycine dehydrogenase, ▶taurine, ▶wobble, ▶Gomori's stain; Wallace DC 1992 Annu Rev Biochem 61:1175; Smeitink J, van den Heuvel B 1999 Am J Hum Genet 64:1505; Acland GM et al 2001 Nature Genet 28:92; Thornburn DR, Dahl HH 2001 Am J Med Genet 106:102; Steinmetz LM et al 2002 Nature Genet 31:400; Taylor RW, Turnbull DM 2005 Nature Rev Genet 6:389; mtDNA – tRNA human disease: Florentz C et al 2003 Cell Mol Life Sci 60:1356; wobble site modification in tRNA leads to disease specificity: Kirino Y et al 2005 Proc Natl Acad Sci USA 102:7127; Wallace DC 2005 Annu Rev Genet 39:359; mitochondrial proteome: <http://www.mitop.de/>; human mitochondrial genome: <http://www.genpat.uu.se/mtDB/>; human mitochondrial variation database: <http://www.genomic.unimelb.edu.au/mdi/dblist/mito.html>.

Mitochondrial Gene Therapy: Several mitochondrial diseases became ascertained and studied since the 1970s. They may include (i) nuclearly encoded gene products imported to the mitochondria, (ii) strictly mitochondrially encoded defects, and (iii) gene products under dual control. Correcting the defect of proteins encoded by the nucleus and translated in the cytoplasm has about the same requisites as

Figure M86. Targeting a transit peptide to DNA (Modified after Seibel P et al. 1998 in Mitochondrial DNA in Aging, Disease and Cancer. Singh KK ed. Springer, New York)

gene therapy in general. There are more hurdles to overcome when the therapeutic DNA sequences are intended for transport into the mitochondria with the aid of cytoplasm-located vectors. The first requirement is the construction of appropriate signal peptide, which would mediate the import. There is experimental evidence for the feasibility to targeting a hairpin-shape DNA into the mitochondrial matrix with the aid of an appropriate transit/signal peptide (Fig. M86). The transforming vector must use the coding system particular for the mitochondria that may be different in different organisms. The transcript and the translation product must be suitable for processing within the mitochondria by its own protein-synthesizing machinery. The mitochondrial ribosomes are also different from the cytosolic ones. The promoter must respond to the regulatory system of the mitochondria and the expression of the gene would be optimally modulated in that environment. The maintenance replication of the introduced transgene must be secured for both somatic divisions and for the maternal germline. Problems may arise if the defective, mutant polypeptide interferes with the assembly of the functional protein complex even in the presence of a correct product of the transgene. Since the majority of the mtDNA mutations involve deletions, duplications and rearrangement of the mitochondrial genome, some diseases may not be amenable to exogenously delivered corrections. The mitochondrial genome in higher organisms is present in “polyploid” forms and the rules of the mitochondrial segregation within the cells are not entirely known. There is evidence that in the relatively very simple yeast system the mitochondrial ATPase 8 defect could be corrected by a genetic vector product in the cytoplasm. It has been reported that the β subunit of the mitochondrial ATP synthase fused to the bacterial CAT (chloramphenicol acetyltransferase) and driven by the cauliflower mosaic virus CaMV 35 S promoter and introduced into tobacco (*Nicotiana glauca*) by an agrobacterial vector, was expressed mainly in the mitochondria but not in the chloroplasts. The introduction of transgenes by the biolistic methods to both mitochondria and chloroplasts has been achieved repeatedly. There may be ways to target therapeutic agents to the mitochondria by coupling, e.g., antioxidants to alkyltriphenylphosphonium cations (Smith RAJ et al 2003 Proc Natl Acad Sci USA 100:5407).

Defects of the mtDNA frequently result in faster replication of the mutation and this type of anomaly may be corrected by antisense technologies. Antisense technology may also silence a mitochondrial gene with harmful effect. Eventually gene replacement techniques may also become practical. ▶transit peptide, ▶signal peptide, ▶genetic code, ▶biolistic transformation, ▶ATPase, ▶transformation [plants], ▶antisense technologies, ▶gene replacement,

Mitochondrial Genetics: The mitochondrial DNA is generally transmitted only by the egg cytoplasm. The failure of transmission of the mtDNA by the sperm in the majority of the species appears to be due to selective degradation. It appears that during spermatogenesis the mitochondrial nucleoid number is reduced and after fertilization the mtDNA is rapidly digested (Nishimura Y et al 2006 Proc Natl Acad Sci USA 103:1382). The wild type yeast mtDNA is inherited biparentally. The hypersuppressive petite mutants of yeast are transmitted, however, only uniparentally. In the bivalve molluscs a specific F (female) mitochondrial DNA is transmitted to both males and females whereas the M (male) mtDNA is transmitted only to the sons of males. These two types of mtDNAs recombine in the somatic tissues but the recombinant molecules are rarely transmitted (Passamonti M et al 2003 Genetics 164:603). In some species a low frequency of male transmission (paternal leakage) exists (Fig. M87).

Segregation of mitochondrial genes is followed by cell phenotype because individual mitochondria are not amenable to direct genetic analysis (see Fig. M88). (Molecular analysis can identify, however, differences among mitochondria.) Some of the genes are specific for the mitochondria and others, e.g., the cytochrome oxidase complex share subunit coding with the nucleus. This sharing may vary in different evolutionary groups, which seems to indicate interchanges between the nuclear, mitochondrial and chloroplast genomes. Despite the large number of mitochondria (>100/cell) and mtDNA molecules (4–6 per nucleoid), homoplasmic condition may be obtained at a much faster rate than expected on the basis of random sorting out. In mouse, it has been estimated that the number of segregating mitochondrial units is about 200 and the rapid sorting out was attributed to random genetic drift. (Some estimate the number of sorting mammalian mtDNAs >50,000.) The sorting out of the mitochondria—according to recent studies of yeast mutants of the MDM (mitochondrial distribution and morphology) group—is controlled by proteins of the cytoskeleton and integral proteins of the outer mitochondrial membrane, such as a dynamin-like protein. In fission yeast, mitochondrial distribution is mediated by microtubules tethered to the spindle pole bodies (Yaffe MP 11424). The ubiquitin-protein ligase suppressor, Rsp5p and the Ptc1p (serine/threonine phosphatase) seem also be involved in the regulation of mitochondrial transmission. In the mouse oocytes

mtDNA seems to be involved in neuron development and affect axonal and synaptic activity as well as cognitive functions of the brain (Roubertoux PL et al 2003 Nature Genet 35:65).

Recombinational mapping is generally useful within short distances (≈ 1 kb). Genetic maps of mtDNA are generally constructed by physical mapping procedures. Also, the relative position of the genes may be ascertained by co-deletion-co-retention analyses. These methods resemble the deletion mapping of nuclear genes. Genes simultaneously lost by deletion, or retained in case of deletion of other sequences, must be linked. Mitochondrial genes have been mapped also by polarity. It was assumed that the yeast mtDNA carried some sex-factor-like elements, ω^+ and ω^- , respectively. The omega plus (ω^+) cells appeared to be preferentially recovered in polar crosses ($[\omega^+] \times [\omega^-]$). In these so called *heterosexual crosses* the order of certain genes, single and double recombination and negative interference were observed. The exact mechanism of the recombination was not understood. The ω^+ factor turned out to be an intron within the 21S rRNA gene with a transposase-like function. Non-polar crosses have also been used to determine allelism. In the latter case all progeny was parental type and recombination was an indication of non-allelism. Linkage and recombination could also be detected in non-polar crosses but mapping was impractical. Complementation tests can be carried out in respiration deficient mutations on the basis that in "non-allelic" crosses respiration is almost completely restored within 5–8 hours whereas recombination may produce wild types only in 15–29 hours. Different loci are complementary and appear unlinked. Some loci may not complement each other. Mitochondrial fusion and complementation of mitochondrial genes in human cells has also been reported (Ono T et al 2001 Nature Genet 28:272; Westermann B 2002 EMBO Rep 3:527). Mitochondrial fusion requires the sequential interaction of the outer and inner mitochondrial membranes (Pfanner N et al 2004 Science 305:1723). The fusion of the outer membranes needs low levels of GTP (mediated by GTPase Fzo1) but the inner membrane fusion requires high GTP levels as well as inner-membrane electrical potential. Inner membrane fusion as well as the maintenance of the structure of the cristae requires the dynamin-related GTPase Mgm1 (Meeusen S et al 2006 Cell 127:383). Mutations in the genes controlling mitochondrial fusion (mitofusin, MFN2. 1p36.2) may account for the 2A type neuropathy of the Charcot-Marie-Tooth disease (Zuchner S et al 2004 Nature Genet 36:449) and optic atrophy (Zuchner S et al 2006 Ann Neurol 59:276). Primarily, dynamin-like proteins control mitochondrial fission. Mitochondrial fission

entails mitochondrial disintegration during apoptosis (Parone PA, Martinou JC 2006 Biochim Biophys Acta 1763:522). This protein is involved also in the control of cytokinesis (Chanez AL et al 2006 J Cell Science 119:2968).

Homologous recombination has been extensively studied in yeast by the Flp/FRT system. Recombination of mtDNA in vertebrate cybrids does not readily occur. In case of fusion of haploid cells, gene conversion may take place.

Transformation of mitochondria requires the biolistic method or by implantation of cell hybrids with mutant mitochondria. Unfortunately, only a fraction of the mutant mitochondria are transmitted and only through the female. Usually co-transformation by nuclear and mitochondrial DNA sequences is employed. The nuclear gene (*URA3*) is used for selection of transformant cells. The ρ^- cells cannot be selected because they are defective in respiration. They are crossed then with mt^+ cells that carry a lesion in the target gene and among the recombinants, the transformants may be recovered. It is possible that the wild type *URA3* gene is transferred from the mitochondrion into the *ura3* mutant nucleus whereas the cytochrome oxidase gene (*cox2*) is maintained in the nucleoid.

The large subunit of the mitochondrial ribosomal RNA may house a mobile element, ω^+ . This element (a Group I intron) may show polar transmission and can be used in a limited extent for recombination analysis as mentioned above. It encodes 235 amino acids and represents *SceI* endonuclease. A *Chlamydomonas smithii* intron (from the *cytb* mitochondrial gene) can move into the same but intronless gene in *C. reinhardtii*. Several other Group I introns have similar mobility and the introns usually share the peptide LAGLI-DADG, a consensus conserved also in some maturases. Other Group I introns display the GIY-10/11aa-YIG pattern. The VAR-1 yeast gene (ca. 90% A + T) encoding the small mt ribosomal subunit is also an insertion element. Other mobile elements with characteristic G + C clusters are common features of these insertion elements. Group II introns present in various fungi are also mobile. Splicing/respiration deficient mutants become revertible if the defective intron is removed. Similar mobile elements can be found in the cpDNA of *Chlamydomonas* algae. Mitochondrial plasmids may be circular or linear. Some of the circular mt plasmids display structural similarities to Group I introns and their transcripts are reminiscent of reverse transcriptases (resembling protein encoded by Group II introns).

In yeast, nuclear genes *MDM1* (involved in the formation of non-tubulin cytoplasmic filaments), *MDM2* (encodes $\Delta 9$ fatty acid desaturase) and *MDM10* (determines mitochondrial budding) control the transmission of mitochondria to progeny cells.

The subunit(s) of the mitochondrial transcriptase and the mtTFA transcription factor are coded in the yeast nucleus.

Nuclear and mitochondrial promoters share cis elements. It seems that mitochondrial signals regulate nuclear genes controlling mitochondrial functions. Partially reduced intermediates of NADH dehydrogenase and coenzyme Q (ubiquinone) are held responsible for the production of ROS. In human diseases such as cancer, ischemic heart diseases, Parkinson disease, Alzheimer disease, and diabetes ROS products have been implicated. The mitochondrial ROS activates mammalian transcription factors NF- κ B, AP and GLUT glucose transporters.

Majority of the prokaryotic mutagens are apparently effective in causing mutations in the mtDNA. The ROS molecules generated within the mitochondria may be responsible for a variety of alterations in the mtDNA.

Deletions and duplication, besides point mutations, may also occur spontaneously during the processes of aging. Mutation rates per mitochondrial D loop has been estimated to be 1/50 between mothers–offspring but other estimates used for evolutionary calculations are 1/300 per generation or 3.5×10^{-8} per site per year although the DNA polymerase γ appears to have low error rates. Some of the (recessive?) mitochondrial mutations are apparently non-detectable without molecular analysis because functionally the mitochondria are “polyploid” and their numbers in the cells are commonly very high. Due to the large number of cells, the large number of mitochondria per cell and the multiple copies of the mtDNA per mitochondria, chances for mutation are high within a multicellular organism. Also, within a single individual different mitochondrial mutations may occur and their spectrum may vary in the different tissues. By 1998, nearly 1000 mitochondrial point mutations were known and 65 were involved in human disease. Mutations in the mtDNA (5×10^{-7} /base/human generation) are much higher than in the nuclear DNA (8×10^{-8}). In the control region of human mtDNA mutation rate of 1/bp/ 10^6 years was reported (Howell N et al 2003 Am J Hum Genet 72:659). The estimates of mitochondrial mutations may be biased by genetic drift, selection, recurrent mutations, and hot spots in some hypervariable sequences.

The mutation rate/bp in both mtDNA and nuclear DNA varies substantially from region to region. About 40% of the mtDNA deletions involve 7000–9000 bp and 20% encompass 4000–5000. Their distribution is biased in as much as 95% of the deletions affect the region between bp 3300 to 12000.

Mitochondrial DNA frequently classified into macrohaplogroups including subhaplogroups on the basis of the mitochondrial protein sequence and

geographic origin. The African haplogroups (subhaplogroups) are L1, L2 and L3. The M and N haplogroups originated on L3 background in eastern Africa but migrated into Eurasia and also to the Americas from Siberia where additional variations, A, B, C, D and G accumulated (Mishmar D et al 2003 Proc Natl Acad Sci USA 100:171). Several additional haplogroups are distinguishable in Europe, Asia and the Americas facilitating the tracing of human migration (Pakendorf B, Stoneking M 2005 Annu Rev Genomics Hum Genet 6:165). High mutation rates, especially in the hypervariable sequences, may be an obstacle to definite conclusions regarding the populations’ origin. A further difficulty is that mtDNA sheds light only on maternal lineages. Another complication is the transfer of genes and gene fragments between organelles where their rate of mutation adjusts to that of the recipient organelle.

In plants, recombination repeats occur that may generate additional variation by interchanges. In somatic cell hybrids of plants, the mitochondria may recombine and non-parental sequences and duplications of genes may be generated. The pseudogenic sequences are also attributed to recombination. In maize, extensive intramolecular recombination occurs between/among the main mtDNA molecule or the subgenomic, smaller mtDNAs (Fauron C et al 1995 Trends Genet 11:228). These recombinational events may lead to variegation and other morphological alterations (Sakamoto W et al 1996 Plant Cell 8:1377). Early studies indicated an apparent lack of genetic repair systems in the mitochondria. Recent studies detected, however, several proteins (glycosylases, excinucleases, mismatch repair enzymes, Rec A like proteins, etc.) that may mediate genetic repair in the mitochondria. The *CHM* locus of *Arabidopsis* apparently encodes a mismatch repair protein, similar to the prokaryotic MutS. The protein is mitochondrially located and its mutations lead to variegation (Abdelnoor RV et al 2003 Proc Natl Acad Sci USA 100:5968). ▶physical mapping, ▶mapping function, ▶petite colony mutants, ▶deletion mapping, ▶rounds of matings, ▶interference, ▶mutations in cellular organelles, ▶homoplasmy, ▶sorting out, ▶biolistic transformation, ▶transformation of organelles, ▶chloroplast, ▶genetics, ▶mitochondria, ▶doubly uniparental inheritance, ▶transmitochondrial, ▶dynamin, ▶paternal leakage, ▶mtDNA, ▶mitochondrial import, ▶introns, ▶maturase, ▶mitochondrial plasmids, ▶mitochondrial diseases in humans, ▶killer plasmids, ▶senescence, ▶MSS, ▶mismatch repair, ▶Parkinson disease, ▶Alzheimer disease, ▶ischemic, ▶NF- κ B, ▶AP, ▶GLUT, ▶ROS, ▶mitochondrial plasmids, ▶mt, ▶bottleneck effects, ▶heteroplasmy, ▶mitochondrial recombination, ▶Romanovs, ▶sorting out, ▶RNA editing,

Mitochondrial Heterosis: It was claimed that the presence of different mitochondria might lead to complementation and increased vigor. ►hybrid vigor, ►mitochondrial complementation; Sarkissian IV, Srivastava HK 1973 Basic Life Sci 2:53.

Mitochondrial Import: Transport into the mitochondria must pass through two cooperating membrane layers. The outer membrane carries four receptors (Tom37, -70, -20, and -22). The transmembrane import channel is built of at least six proteins; the transmembrane translocation system uses at least three proteins (Tom40, -6 -7). The Tom5 forms the link (a relay) between the outer and inner channel proteins. The inner membrane import channel proteins (Tim) are Mas6p (MIM23), Sms1p (MIM17), and Mpi1p (MIM44/ISP45). The mitochondrial heatshock 70 protein (Hsp70), the MIM44 complex, and ATP play a central role in import. It appears that MIM44 first binds the incoming unfolded polypeptide chain as it is passing the entry site, and it is then transferred to Hsp70 as ATP dissociates the complex. After this the polypeptide moves further and binds again to the complex and eventually traverses also the inner membrane. Tim10p and Tim12p mediate the import of the multispanning carriers into the inner membrane. Tim12 is bound to Tim22. Tim23 passes proteins through the inner membrane. Although the mitochondria contain their own protein-synthetic machinery (ribosomes, tRNAs), the majority of the mitochondrial proteins are encoded by the nucleus and translated in, or imported from, the cytosol. Imported cytosolic tRNAs may correct mutations of mitochondrial tRNAs. The import system is also nuclearly encoded. The general import factors include the Hsp proteins, cyclophilin 20, ADP/ATP carrier (AAC), and proteases. More specialized is the

role of the imported assembly facilitator proteins. Yeast genes *SCO1*, *PET 117*, *PET191*, *PET100*, *OXA1*, *COX14*, *COX11*, and *COX10* are such facilitators. The latter two are actually involved in heme biosynthesis. The COX10 product farnesylates protoheme b. Rescue of cells with defective mitochondria by transfer of normal mitochondria from adult stem cells or somatic cells has been reported without clarification of the mechanism involved (Spees JL et al 2006 Proc Natl Acad Sci USA 103:1283). ►mitochondria, ►mitochondrial genetics, ►mtDNA, ►chloroplast import, ►cyclophilin, ►heat-shock proteins, ►Hsp70, ►Ydj, ►Hsp, ►MSF, ►farnesyl, ►heme, ►Brownian ratchet, ►mitochondrial gene therapy; Annu Rev Biochem 66:863; Bauer MF et al 2000 Trends Cell Biol 10:25; Schneider A, Maréchal-Drouard L 2000 Trends Cell Biol 10:509; Wiedemann N et al 2001 EMBO J 20:951; Rehling P et al 2001 Crit Rev Biochem Mol Biol 36(3):291; Kovermann P et al 2002 Mol Cell 9:363; Pfanner N, Wiedemann N 2002 Current Opin Cell Biol 14:400; Neupert W, Brunner M 2002 Nature Rev Mol Cell Biol 3:555; Wiedemann N et al 2003 Nature [Lond] 424:565; Chacinska A et al 2005 Cell 120:817; Wilcox AJ et al 2005 Proc Natl Acad Sci USA 102:15435; protein import review: Dolezal P et al 2006 Science 313:314; Ryan MT, Hoogenraad NJ 2007 Annu Rev Biochem 76:701; ADP/ATP carriers: Nury H et al 2006 Annu Rev Biochem 75:713.

Mitochondrial Mapping: ►mitochondrial genetics

Mitochondrial Mutations: Mitochondrial mutations occur about ten times or more frequently than in the nuclear genes (Marcelino LA, Thilly WG 1999 Mutation Res 434:177). This may be due to inadequate DNA repair. The mtDNA is “naked” (free of histones) and there is relative abundance of free oxygen radicals in this organelle. Large deletions are common in the human mitochondrial DNA encompassing the “5-kb deletion” (mtDNA⁴⁹⁷⁷) between nucleotide positions 8470–8482 and 13447–13459, respectively. Some deletions may encompass even longer segments of the mtDNA and cover the position of more than a single mitochondrial gene. These deletions are most common in muscle tissues and the brain and frequently occur by aging. The average mutation rate in the elderly appeared to be 2×10^{-4} /bp in mtDNA (Lin MT et al 2002 Hum Mol Genet 11:133). Other deletions usually occur between direct repeats of 13 to 5 nucleotides. Some of the deletions may involve only single bases. Single base mutations Thymidine 7512Cytosine and Guanine 7497Adenine in the tRNA^{Ser(UCN)} reduced the amount of this tRNA below 10% and reduced protein synthesis by 45%.

Aminoacylation was not affected so it is supposed that a posttranslational structural alteration might be involved in the pathogenic condition (Möllers M et al 2005 *Nucleic Acids Res* 33:5647). The deletion mutants and their relative extent are characterized by various PCR procedures. The data on increased frequency of point mutations during aging are somewhat ambiguous. Apparently deletions and duplications, however, accumulate by aging. Sometimes it may be difficult to ascertain whether a particular mutation occurs in the nuclear or mitochondrial DNA. In cases of ambiguity, the problem may be resolved by transferring a new nucleus (karyoplast) into an enucleated cytoplasm (cytoplast). If the expression of the mutation is limited to the donated cytoplast, the mitochondrial origin of the mutation can be proved in animal cells. In plant cells, the plastids may complicate the identification. In cancer cells, the mtDNA mutations occurred 19 to 229 times as abundantly as in the nuclear p53 gene. Interestingly, the cancer cells were largely homoplasmic for the mtDNA mutations indicating that the mutation had selective advantage. With the techniques available, the complete sequence of the mtDNA can be determined in single cells. Deficiency for uracil-DNA glycosylase in yeast results in mitochondrial mutator phenotype. Although fidelity of DNA polymerase γ , responsible for the replication of mtDNA, is not poor ($<10^{-5}$ /base substitution) and the enzyme has 3' exonuclease function to correct defects, the relative mutation rate is elevated. One possible cause of the increased mutation frequency is the disproportionally increased deoxyguanidine nucleotide pool in the mitochondria of rats (Song S et al 2005 *Proc Natl Acad Sci USA* 102:4990). The Twinkle helicase and the accessory B subunit of DNA polymerase are absolutely essential for mtDNA replication pol γ . The duplex DNA binding activity of the B subunit is needed for coordination of POL γ holoenzyme and Twinkle helicase at the mtDNA replication fork. Mutations in Twinkle and the catalytic A and accessory B subunits of the POL γ holoenzyme may result in autosomal dominant progressive external ophthalmoplegia, which is associated with deletions in mtDNA (Farge G et al 2007 *Nucleic Acids Res* 35:902). ▶oxidative DNA damage, ▶oxygen effect, ▶aging, ▶mutation rate, ▶mitochondrial diseases in humans, ▶petite colony mutants, ▶PCR, ▶somatic cell hybrids, ▶homoplasmic, ▶p53; Inoue K et al 2000 *Nature Genet* 26:176; Taylor RW et al 2001 *Nucleic Acids Res* 29 (15):e74; Jacobs HT 2001 *Trends Genet* 17:653; Chatterjee A, Singh KK 2001 *Nucleic Acids Res* 29:4935; Taylor RW, Turnbull DM 2005 *Nature Rev Genet* 6:389; <http://www.mitomap.org>.

Mitochondrial Myopathy: ▶mitochondrial disease in human

Mitochondrial Plasmids: Plasmids are circular or linear and occur in the mitochondria of some cytoplasmically male sterile lines of maize plants and relatives. Their sizes vary between 1.4 to 7.4 kb. The main types are S, R, and D. S2, R2, and D2 are the same and R1 and D1 are apparently also identical with each other. S1 appears to have emerged as a recombinant between R1 and R2. The *cms*-S plants carry the S1 and S2 plasmids. During the formation of S1, a terminal part of R1 (R*) was lost and is inserted at two sites in the mtDNA. The S elements can be either integrated or free mitochondrial episomes. The S2 element encodes (*URF1*), a protein somewhat homologous to a viral RNA polymerase, whereas another (*URF3*) appears to be homologous to a DNA polymerase. The *cms*-C and *cms*-T nucleoids are free from these plasmids, whereas in the N-nucleoids the R1 and R2 sequences (from RU) are integrated. Another 2.3-kb plasmid (or a 2.15-kb derivative) is homologous to the tRNA^{Trp} and tRNA^{Pro} in the cpDNA, and also represents the only functional tRNA^{Trp} in the mitochondrion. ▶cytoplasmic male sterility, ▶mitochondrial genetics, ▶cpDNA, ▶mitochondria, ▶tRNA, ▶killer plasmids, ▶senescence, ▶episome, ▶cytoplasmic male sterility, ▶*Neurospora* mitochondrial plasmids, ▶endosymbiont theory, ▶RU maize; Bok JW, Griffith A 2000 *Plasmid* 43:176.

Mitochondrial Proteins: Most of the mitochondrial proteins are imported from the cytosol, but the ~17 kbp mammalian mitochondrial DNA transcribes 13 polypeptides, which are then translated by the organelle. The ~337 kbp *Arabidopsis* mtDNA encodes 32 proteins. In plants, many mitochondrial genes display multiple promoters (Tracy RL, Stern DB 1995 *Current Genet* 28:205; Kühn K et al 2005 *Nucleic Acids Res* 33:337) although two nuclear genes encode the transcriptase. The total number of proteins located in mitochondria may be about 1,500. The human heart mitochondria include more than 600 distinct proteins (Taylor SW et al 2003 *Nature Biotechnol* 21:281). The proteome of the yeast mitochondria includes >750 proteins (Sickmann A et al 2003 *Proc Natl Acad Sci USA* 100:13207). ▶mitochondrial diseases, ▶mitochondrial import; Kenmochi N et al 2001 *Genomics* 77:65; Taylor SW et al 2003 *Trends Biotechnol* 21:82; mitochondrial import of proteins: Neupert W, Hermann JM 2007 *Annu Rev Biochem* 76:723; human, yeast, mouse mitochondrial proteome: <http://www.mitop.de/>.

Mitochondrial Recombination: Mitochondrial recombination is generally inferred from observations of linkage disequilibrium. However, the problem is somewhat controversial. Paternal leakage is rare and reduces the chance for recombination. Furthermore,

the paternal mitochondria may be eliminated after fertilization even if they are transmitted. In different human tissue samples from the A8344G/A16182C (MERRF syndrome) and A3243G/G16428A (MELAS syndrome) double-heteroplasmic family, all four allelic combinations of the two heteroplasmic mutations were present in the family, although, as expected, the distribution showed significant differences between individuals. Two family members carried the double-mutant (and possibly recombinant) allelic combination; and high amounts of the possibly recombinant genotype, along with all other possible allelic combinations, were present in the fibroblast sample from one individual. The data indicate that recombinant mtDNA molecules can be inherited (Zsurka G et al 2007 *Am J Hum Genet* 80:298). ▶mitochondrial genetics, ▶paternal leakage, ▶mitochondrial diseases in humans; Wiuf C 2001 *Genetics* 159:749; Innan H, Nordborg M 2002 *Mol Biol Evol* 19:1122.

Mitochondrial Suppressor: Enzyme complexes involved in oxidative phosphorylation are encoded by cooperation among nuclear (*PET*) and mitochondrial genes (*oli/ATP9*). Mutation in, e.g., in *AEP2* nuclear gene regulating *oli1* mRNA stability may prevent the formation of a functional subunit 9 of ATP synthase. Mutation in the 5'-untranslated region of *oli1* may however suppress the mutation in *aep2*. ▶mitochondrial genetics; Chiang CS, Liaw GJ 2000 *Nucleic Acids Res* 28:1542; Alfonzo JD et al 1999 *EMBO J* 18:7056; Bennoun P, Delosme M 1999 *Mol Gen Genet* 262:85; Chen W et al 1999 *Genetics* 151:1315.

Mitochondrion: The singular form of mitochondria. ▶mitochondria

Mitochondriopathies: ▶mitochondrial diseases in humans

Mitogen: Collective name of substances stimulating mitosis and thus cell proliferation (such as growth factors).

Mitogen-Activated Protein Kinases: ▶MAPK

Mitogenesis: Processes leading to cell proliferation.

Mitokinesis: A hypothetical mechanism of orderly distribution of mitochondria between two cells during cell division possibly using the cytoskeleton as a vehicle.

Mitomap: (human mitochondrial genome database): <http://www.mitomap.org>.

Mito-Mice: Mice models of mitochondrial diseases. They display deletions in their mitochondrial DNA. (See Sato A et al 2005 *Proc Natl Acad Sci USA* 102:16765).

Mitomycin C ($C_{15}H_{18}N_4O_5$): Antibiotic, antineoplastic agent that after activation causes DNA crosslinks, enhances mitotic recombination, inhibits DNA synthesis, etc.

MitoNuc: A database of nuclear-encoded mitochondrial proteins. ▶mitochondrial genetics; <http://bighost.area.ba.cnr.it/mitochondriome>

MitoPark: Conditional knockout mice with Parkinsonism caused by mitochondrial malfunction due to dopamine neuron deficiency. ▶knockout, ▶Parkinson disease, ▶dopamine

Mitosenes: DNA cross-linking compounds (such as mitomycin), frequently with antitumor activity. ▶mitomycin

Mitosis: Nuclear division leading to identical sets of chromosomes in the daughter cells. Mitosis assures the genetic continuity of the ancestral cells in the daughter cells of the body. It involves one fully equational division preceded by a DNA synthetic phase. There is normally no (synapsis) pairing of the chromosomes. The centromeres split at metaphase separate at anaphase and the chromosomes relax after moving to the poles in telophase. The centromere-spindle association is regulated by a number of kinases (Mad1, Bub1, Msp1). Msp1 is essential for meiosis II but dispensable for mitosis. Before anaphase takes place, a number of proteins (Pds1, Scc1, Ase1) regulating sister chromatid cohesion are degraded by proteasomes under the control of the cyclosome (APC). The critical features of mitosis are diagrammed and comparable photomicrographs are also shown. Mitosis is thus, different from meiosis, in which there is one reductional and one numerically equational division. During meiotic prophase, the homologous chromosomes (bivalents) are synapsed and chiasmata may be observed. At the first meiotic division the centromeres do not split, and the undivided centromeres separate at anaphase I. Meiosis reduces the chromosome number to half, in contrast to mitosis, which preserves the number of chromosomes in the daughter cells. A comparison between mitosis and meiosis is also diagrammed. Mitosis and meiosis are the genetically most important processes of the eukaryotic cells (organisms).

Mitosis maintains genetic continuity in the development of an organism from conception to the end of its life. Somatic mutation may bring about changes in the exact continuity but this usually affects only a small fraction of the genes. The subsequent mitotic divisions provide the precise mechanism for the maintenance of such mutations. The mitotic and the meiotic cell cycles show some differences in the molecular mechanisms. In mitosis before the S phase, the two key cyclins, Clb5 and Clb6, are kept inactive

by the *cyclin-dependent kinase inhibitor protein* Sic1. Two cyclins (Cln1 and 2) along with Cdc28/Cdc2 degrade Sic. In case Clb5 and Clb6 are non-functional, the initiation of the S phase is delayed until cyclins CLB1–4 are activated at a subsequent stage. In meiosis, Cdc28/Cdc2 is not required and its role is taken over by a similar protein, SPF (S phase promoting factor) encoded by the yeast gene *IME2*. Note that only a single S phase is required for meiosis I, and meiosis II does not require the synthesis of new DNA because it involves only the segregation of the sister chromatids after reduction. The pre-replication complex in yeasts includes Cdc18/CDC6 and the minichromosome maintenance proteins (MCM). For meiosis in fission yeast, these proteins are apparently not mandated. Also the vegetative replication checkpoint genes are not active when there are problems

during the S-phase events. Cdc2 kinase and Cdc10 transcription factor and Cdc22 functions were also needed for meiosis. Mutation in DNA polymerases α and ϵ and ligase (Cdc17) functions delayed meiotic S phase. Mutation in DNA polymerase- δ (Cdc6) and in GEF (Cdc24), similarly to mitosis, reduced the number of divisions completed. ▶meiosis, ▶cell cycle, ▶nucleolus, ▶nucleolar organizer, ▶nucleolar reorganization, ▶CENP, ▶cyclosome, ▶proteosome, ▶condensin, ▶sister chromatid cohesion, ▶mitotic exit, ▶lamins, ▶Cdc18, ▶CDC6, ▶MCM, ▶cdc10, ▶cdc22, ▶Cdc2, ▶APC, ▶spindle fibers, ▶centromere, ▶kinetochore, ▶centrosome, ▶sister chromatid cohesion, ▶separin, ▶interphase, ▶CDC13, see Figs. M89 and M90; Forsburg SL, Hodson JA 2000 Nature Genet 25:263; Tóth A et al 2000 Cell 103:1155; Nasmyth K 2001 Annu Rev Genet 35:673; Georgi AB

Figure M89. Mitosis. Left: The major steps of mitosis diagramed by only two chromosomes. Right: Photomicrographs of mitosis in barley $2n = 14$ (Courtesy of T. Tsuchiya). Top Right to Left: Interphase, early prophase, late prophase, middle; early metaphase, metaphase, early anaphase, Bottom: Early telophase, late telophase, two daughter nuclei in the two progeny cells

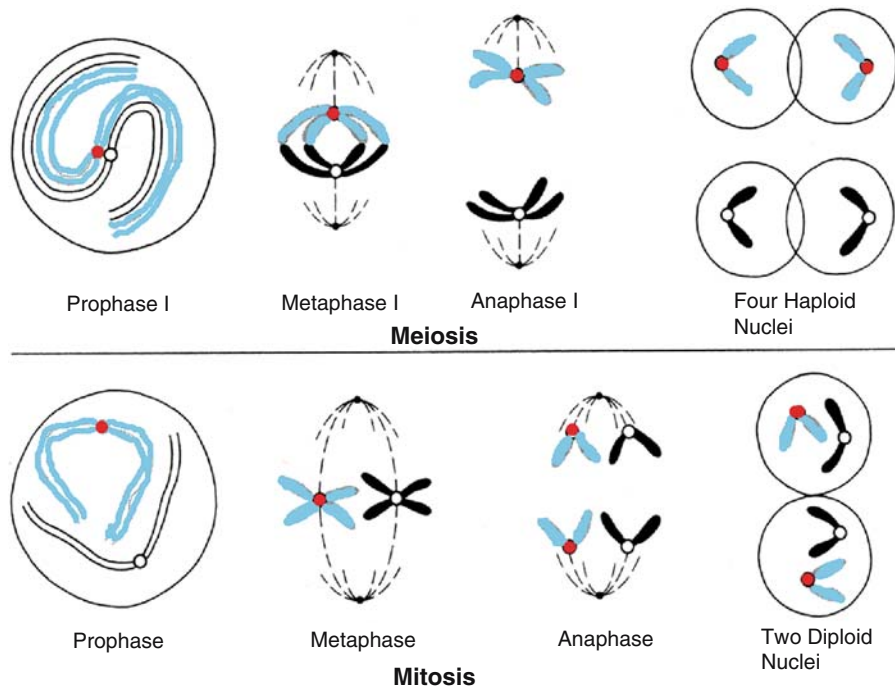

Figure M90. Meiosis and mitosis compared by cytological behavior. Meiosis: One numerical reduction & one numerically equational division synapsis & chiasma at prophase, centromeres do not split at metaphase and separate undivided at anaphase i chromosome number reduced. Mitosis: One fully equational division, no pairing & no chiasma, centromeres split in metaphase and separate at anaphase, chromosome number maintained in daughter cells

et al 2002 Curr Biol 12:105; Rieder CL, Kodjakov A 2003 Science 300:91; review of segregation of chromosomes by microtubules: Kline-Smith SL et al 2005 Current Opin Cell Biol 17:35.

Mitosome: A substantially reduced form of the mitochondrion. Mitosomes do not generate ATP but assemble iron-sulfur clusters, which are required for making ATP. Apparently, these organelles lost some of the mitochondrial functions during evolution (Tovar J et al 2003 Nature [Lond] 426:172), yet mitosomes seem to have some of the basic mitochondrial functions such as protein targeting (Dolezal P et al 2005 Proc Natl Acad Sci USA 102:10924). ▶mitochondria, ▶hydrogenosome, ▶protein targeting, ▶Giardia, ▶Trichomonas

Mitospore: Meiotic product of fungi ready for mitotic divisions.

Mitostatic: Stopping or blocking the mitotic process. Many anti-cancer agents are mito-static.

Mitotic Apparatus: Subcellular organelles involved in nuclear divisions. Mitotic apparatus include organelles such as the spindle (microtubules), centromere (kinetochore), centriole, poles, and CENP. In yeast cells, the mitotic apparatus is within the nucleus,

whereas in plants and animals the system is cytoplasmic and the nuclear membrane disappears, while the chromosomes are distributed to the poles and the membrane is reformed after completion of the process. In some organisms, the nuclear membrane does not disintegrate entirely during mitosis. ▶nuclear membrane

Mitotic Catastrophe: Mitotic catastrophe is caused by DNA damage resulting in chromosomal abnormalities, polyploidy, and formation of micronuclei. CDH1 and the slow breakdown of cyclin B1 interfere with the metaphase promoting complex. ▶CDH1, ▶cyclin B1, ▶micronucleus; Huang X et al 2005 Proc Natl Acad Sci USA 102:1065.

Mitotic Center: ▶centrosome

Mitotic Chromosomes: Chromosomes undergoing mitosis.

Mitotic Crossing Over: Recombination in somatic cells. Recombination is generally a meiotic event (▶crossing over) but in some organisms, the chromosomes may associate also during mitosis and this may be followed by genetic exchange of the linked markers. Although this may take place spontaneously, several agents capable of chromosome breakage (radiation,

Figure M91. Mitotic crossing over (at sign I) with markers in coupling and repulsion and the consequences of recombination. (On the basis of experiments of Curt Stern, 1936. *Genetics* 21:625.)

chemicals) may enhance its frequency. For the detection of somatic recombination in higher eukaryotes, the markers must be cell and tissue autonomous, i.e., they should form sectors (spots) at the locations where such an event has taken place. In the first experiments with *Drosophila*, the chromosomal construct diagrammed here, was used. If an exchange has taken place between *sn* and *y*, then only a yellow sector (homozygous for *y*) was formed. *Twin spots* were observed only when in repulsion, the exchange took place between the proximal locus and the centromere (see Fig. M91).

Somatic recombination takes place in the *Drosophila* male too, although this usually does not happen in meiosis. The characteristics of somatic recombination are that exchange is between two chromatids at the four-strand stage, but instead of reductional division, as in meiosis, the centromeres are distributed equationally. Mitotic recombination is a relatively rare event in higher eukaryotes. Somatic recombination can be studied also in plants when the chromosomes are appropriately marked, and generative progeny can be isolated from the sectors, either from the sectorial branches or by tissue culture techniques. In fungi (lower eukaryotes), in which a longer diploid phase exists (*Aspergillus*), mitotic recombination can be used even for chromosomal mapping, because some of the parental and crossover products can selectively be isolated. The meiotic and mitotic maps are collinear, but the relative recombination frequencies in the different intervals vary.

Homologous mitotic recombination in mouse can easily be detected in a transgenic construct. Similar techniques are available also for plants. Two copies,

of a differently truncated vector cassette, containing the enhanced yellow fluorescent protein (EYFP), are introduced into the animal cells. The fluorescence is expressed only when the recombination, gene conversion, or repair of collapsed replication fork takes place within the coding sequence, shown in the diagram. Spontaneous recombination in primary fibroblasts from adult ear tissue occurred at 1.3 ± 0.1 per 10^6 per cell division. In embryonic fibroblasts, or if Mitomycin C was used, the rate was found to increase by an order of magnitude.

Homology of the chromosome is required in both meiotic and mitotic recombination (Shao C et al 2001 *Nature Genet* 28:169). A single nucleotide difference may reduce recombination frequency to a detectable extent. Larger sequence differences may reduce recombination by two-three orders of magnitude or eliminate it completely.

Some researchers assume that the mechanisms of the meiotic and mitotic recombination are the same. Several facts, however, cast some doubt about this view. Many proteins are involved in both meiotic and mitotic recombination. In yeast, e.g., both Rad51 and Dmcl are required for meiotic recombination, but Dmcl is not specific for the mitotic event (Shinohara M et al 2003 *Genetics* 164:855). In general, caution must be taken in interpreting genetic phenomena in somatic cells, unless classical progeny tests or molecular information can confirm the assumptions. (See Figs. M92 and M93, ►mitotic mapping, ►parasexual mechanisms, ►mitotic recombination as a bioassay in genetic toxicology, ►twin spot, ►recombination, ►GUS; Pontecorvo G 1958 *Trends*

in Genetic Analysis. Columbia University Press, New York; McKim KS et al 2002 Annu Rev Genet 36:205.

Figure M92. The tandem arrangements of the two deletion (Δ) constructs are represented by the arrows. The coding sequences are hatched. The chicken β-actin promoter and a cytomegalovirus enhancer drive the expression. NotI, BamHI are restriction enzymes, pA is polyadenylation signal. (By permission from CA Hendricks, KA Almeida, MS Stitt, VS Jonnalagedda, RE Rugo, GF Kerrison & BP Engeward 2003 Proc Natl Acad Sci USA 100:6325. Copyright 2003 National Academy of Sciences USA)

Figure M93. Plants heterozygous for transgenic constructs of the *uidA* (β-glucuronidase, GUS) alleles, which have not-overlapping defects upon spontaneous or induced (by DNA-damaging agents) recombination within the locus produce cells with restored enzyme function. By providing the appropriate substrates, the staining of the spots reveal the recombinational event at a frequency of 10^{-6} to 10^{-7} per cell. The size and shape of the spots or sectors are determined by the pattern of differentiation of the tissue. The recombination can be further verified by polymerase chain reaction at the site as well as by the presence of molecular markers flanking the gene. Schemating drawing based on the report by Swoboda P et al 1994 EMBO J 13:484)

Mitotic Drive: Stepwise expansion of trinucleotide repeats. ▶[trinucleotide repeats](#), ▶[anticipation](#), ▶[meiotic drive](#); Khajavi M et al 2001 Hum Mol Genet 10:855.

Mitotic Exit: In a mitotic exit, after metaphase the mitotic spindle moves the chromosomes during anaphase to the poles of the cell and eventually two daughter cells are formed. PDS and Clb5 protein components of the anaphase inhibitory complex inhibit the formation of the spindle apparatus. Both PDS and Clb5 need to be degraded by the activation of Cdc20 to prepare the path for exit from mitosis. PDS degradation activates the Cdc14 phosphatase. Clb5 kinase degradation facilitates the dephosphorylation of Sic1, Cdh1, and various cyclin kinases by Cdc14, and thus permits the transition from anaphase into G1 interphase. ▶[FEAR](#), ▶[PDS](#), ▶[Clb5](#), ▶[Cdc20](#), ▶[Cdc14](#), ▶[MEN](#), ▶[Sic1](#), ▶[Cdh1](#), ▶[mitosis](#); Bardin AJ, Amon A 2001 Nature Rev Mol Cell Biol 2:815; role of CDC14: Stegmeier F, Amon A 2004 Annu Rev Genet 38:203.

Mitotic Index: The fraction of cells involved in the process of mitosis at a particular time.

Mitotic Mapping: Genetic recombination during mitosis is generally a very rare event in the majority of organisms. In some diploid fungi, its frequency may reach 1 to 10% that of meiosis. As a consequence of ionizing irradiation and certain chemicals the frequency of mitotic exchange may increase and on the basis of mitotic recombination genetic maps can be constructed (see Fig. M94). Although the order of genes is the same in mitotic and meiotic maps, the recombination frequencies may be quite different. ▶[mitotic crossing over](#), ▶[parasexual mechanisms](#), ▶[mitotic recombination as a bioassay in genetic toxicology](#)

Mitotic Non-conformity: Genetic change in fungi due to chromosome translocations.

Mitotic Recombination: ▶[mitotic crossing over](#), ▶[mitotic mapping](#)

Mitotic Recombination as a Bioassay in Genetic Toxicology: Mitotic recombination has been used in

Figure M94. Comparison of a segment of the meiotic and mitotic maps of the fungus *Aspergillus nidulans* at identical scales. (Redrawn after Pritchard, RH 1963. Methodology in Basic Genetics, Burdette, WJ, ed., p. 228. Holden-Day, San Francisco.)

Saccharomyces cerevisiae yeast. In a diploid strain (D5) heterozygous for *ade2-40* and *ade2-119* alleles, twin spots are visually detectable in case of mitotic crossing over. Homozygosity for *ade2-40* has an absolute requirement for adenine and involves formation of red color; it is often called red adenine mutation. Homozygosity for *ade2-119*, a leaky mutation, results in pink coloration. Since the two genes are complementary, the heterozygous cells do not require adenine and the colonies are white. Any environmental or chemical factor that promotes mitotic recombination is thus detectable. This procedure has not been extensively used in genetic toxicology programs. ▶mitotic crossing over, ▶bioassays in genetic toxicology

Mitotic Spindle: ▶spindle, ▶spindle fibers

Mitoxantrone ($C_{12}H_{28}N_4O_6$): Antineoplastic drug with the ability to break DNA double strands.

Mitral Cells: Mitral cells can make junctions in a beveled fashion.

Mitral Prolapse: A buckling of the heart atrial leaflets as the heart contracts, resulting in backward flow (regurgitation) of the blood. It is caused by an autosomal (11p15.4) dominant allele and it is a common congenital heart anomaly affecting 4–8% of young adults, particularly females. It may accompany various other syndromes such as ▶Marfan syndrome, ▶Klinefelter syndrome, ▶osteogenesis imperfecta, ▶Ehlers-Danlos syndrome, ▶fragile X syndrome, and ▶muscular dystrophies. ▶Non-syndromic mitral valve prolapse has been mapped to 16p11.2-p12.1 and a similar disease is caused by mutation at Xq28. In an autosomal recessive form, ophtalmoplegia (paralysis of the eye muscles) is also involved. (See ▶heart disease and the other conditions named at separate entries, Towbin JA 1999 *Amer J Hum Genet* 65:1238; Freed LA et al 2003 *Am J Hum Genet* 72:1551).

Mixed Backbone Oligonucleotide (MBO): MBO is composed of a phosphorothionate backbone and 2'-O-methyloligoribonucleotides or methylphosphonate oligodeoxyribonucleotides. Such an antisense construct is resistant to nucleases and forms stable duplexes with RNA. ▶antisense technologies

Mixed Lymphocyte Reaction (MLR): MLR is used for the detection of histoincompatibility in vitro. The principle of the test is that lymphocytes of two individuals are mixed. One (donor) serves as *responder* and the other as *stimulator*. The proliferation of the antigen-presenting cells is blocked by irradiation or by mitomycin C. The CD4 T cells proliferate as they recognize foreign MHC II molecules, and the measure of their proliferation is assessed by the incorporation of

H^3 -thymidine. The cytotoxic CD8 T cells recognize differences primarily in MHC I molecules and the extent of the killing reaction is detected by using Cr^{51} (sodium dichromate)-labeled cells. In seven days, the reaction may detect histoincompatibility between two persons. ▶MHC, ▶lymphocytes, ▶HLA, ▶microcytotoxicity test

Mixed-Function Oxidases: Generally, flavoenzymes that oxidize NADH and NADPH, and in the process, may activate promutagens and procarcinogens. ▶promutagen, ▶procarcinogen, ▶P-450, ▶microsomes, ▶monooxygenases

Mixoploid: In a mixoploid, the chromosome numbers in the different cells of the same organism vary. (Bielanska M et al 2002 *Fertility & Sterility* 78:1248).

Miyoshi Myopathy (MM, 2p13.3-p13.1): ▶dysferlin

MKDOM: A protein domain analysis program (Gouzy J et al 1999 *Comput Chem* 23:333).

MKI: MAP kinase insertion factor. ▶MAPK

MKK: A homolog of MEK. ▶MEK

MKP-1: MKP-1 dephosphorylates Thr¹⁸³ and Tyr¹⁸⁵ residues, and thus regulates mitogen-activated MAP protein kinase involved in signal transduction. ▶MAP, ▶PAC

Mle (*maleless*): *mle* is located in *Drosophila* chromosome 2–55.2, *mle3* in *Drosophila* chromosome 3.25.8, and similar genes are also present in the X-chromosomes. The common characteristics are that homozygous females are viable but the homozygous males die. The underdeveloped imaginal discs of *mle3* may develop normally, if transplanted into wild type larvae. MLE protein appears to be an RNA helicase and its amino and carboxyl termini may bind double-stranded RNA. Ribonuclease releases MLE from the chromosomes without affecting MSL-1 and -2 and RNA. MLE and MSL proteins appear to control dosage compensation. ▶Msl, ▶dosage compensation

MLE (mariner-like element): A transposable element in *Drosophila* that is present also in the human genome where it is responsible for a recombinational hot spot in chromosome 17. ▶mariner, ▶Charcot-Marie-Tooth disease, ▶HNPP, ▶MITE

MLH (muscle enhancer factor, MLH2A): A MADS box protein inducing muscle cell development in cooperation with basic helix-loop-helix proteins. ▶MyoD, ▶MADS box, ▶bHLH

MLH2: ▶hereditary non-polyposis colorectal cancer

MLH3: A mismatch repair gene that occurs with frequent variation in hereditary nonpolyposis cancer.

►mismatch repair, ►hereditary non-polyposis colorectal cancer; Wu Y et al 2001 Nature Genet 29:137.

MLINK: A computer program for linkage analysis.

MLK (mixed lineage group kinases): Members of the MAP kinase family of phosphorylases mediating signal transduction. ►MAP kinase, ►signal transduction; Gallo KA, Johnson GL 2002 Nature Rev Mol Cell Biol 3:663.

MLL (mixed lineage leukemia, All-1, Htrx): The protein encoded in human chromosome 11q23 has four homology domains, the A-T hook region, DNA methyltransferase homology, Zinc fingers, and the *Drosophila trithorax* (*trx*, 3–54.2) homology. Overexpression of the MLL5 protein, encoded at 7q22, inhibits the cell cycle. In its vicinity at 7q36, MLL3 is situated. Loss of the long arm 7 leads to myeloid malignancies. Other MLL genes were located to chromosomes 12q12 and 19q13. ►leukemia, ►cancer stem cell, ►methyltransferase, ►SET, ►COMPASS; Deng L-W et al 2004 Proc Natl Acad Sci USA 101:757.

MLP1, MLP2: Proteins associated with the nuclear pore complex that suppress the export of unspliced mRNA (Galy V et al 2004 Cell 116:63). ►nuclear pores, ►PML39

MLS (maximum likelihood lod score, multipoint lod score): A method for the analysis of linkage (in human families). The MLS increases when the proportion of relatives carrying an allele identical by descent is higher than expected on the basis of the degree of relatedness and independent segregation. ►relatedness degree, ►maximum likelihood, ►lod score, ►maximum likelihood method applied to recombination

MLV: ►Moloney mouse leukemia virus

MLVA (multi-locus variable-length repeat analysis): Basically, the same as VNTR, used for the identification of related but different bacterial strains. ►VNTR

mm: Prefix for mouse (*Mus musculus*) protein or DNA, e.g., mmDNA.

MMP (microsatellite mutator phenotype): ►microsatellite mutator

MMP: Matrix metalloproteinase. ►metalloproteinases

MMR: ►mismatch repair

MMTV: Murine mammary tumor virus.

M-MuLV: Moloney murine leukemia virus.

MMTV: ►mouse mammary tumor virus (MTV)

MN Blood Group (MN): The human chromosomal location is 4q28-q31. α -sialoglycoprotein (glycophorin A) is responsible for the M blood type, while the δ peptide (glycophorin B) is responsible for the N type (see Fig. M95). Glycophorin deficient erythrocytes are resistant to *Plasmodium falciparum* (malaria). The En(a-) blood group variants also lack glycophorin A. The M and N alleles are closely linked to the S/s alleles and the complex is often mentioned as a MNS blood group. The frequencies of the allelic combinations in England were MS (0.247172), Ms (0.283131, NS (0.08028), and Ns (0.389489). ►blood groups

Figure M95. Sialic acid

MND2: An antagonist of the anaphase-promoting complex during meiotic prophase. ►anaphase-promoting complex; Penkner AM et al 2005 Cell 120:789.

MNEMONS: L. Cuénot's historical (early 1900s) term for genes.

MNGIE (mitochondrial neurogastrointestinal encephalopathy): An autosomal recessive disease involving myopathy with ragged-red fibers, reduced activity of the respiratory chain enzymes, etc. The basic defect is attributed to the deficiency of TK2 (a thymidine kinase), which phosphorylates normally also the deoxynucleosides of other pyrimidines. The reduction of the activity of the enzyme apparently affects the maintenance of mtDNA. The TK2 gene has been located to human chromosome 16q22 (earlier to chr. 17), and more recently MNGIE was assigned to 22q13.32-qter. ►mtDNA, ►mitochondrial diseases in humans

MNNG: *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine is a monofunctional alkylating agent and a very potent mutagen and carcinogen (see Fig. M96) (rapidly decomposing in light). It methylates the O⁶-position of guanine. Cell lines exist that are highly resistant to the cytotoxic effects of MNNG, but they are even more sensitive to the mutagenic effects. ►mutagens, ►alkylating agents

Figure M96. MethylNitrosoguanidine

MNU (*N*-methyl-*N*-nitrosourea): A monofunctional mutagen and carcinogen forming O⁶-methylguanine (see Fig. M97). ▶mutagens, ▶alkylating agents, ▶mono-functional

Figure M97. Ethylnitrosourea

MØ: ▶macrophage

MO15: A CDK-activating kinase, related to CAK. Association of MO15 with cyclin H greatly increases its kinase activity toward Cdk2. ▶cell cycle, ▶cyclin, ▶CDK, ▶CAK, ▶Cdk2

MoAb: ▶monoclonal antibody

mob: The *mob* bacterial gene facilitates the transfer of bacterial chromosome or plasmids into the recipient cell. In order to transfer the plasmids, there is a need for the cis-acting *nick* site and a *bom* site. At the former the plasmid is opened up (nicked) and the *bacterial origin of mobilization* (*bom*) makes possible the conjugative transfer. ▶Hfr, ▶conjugation

Mobile Genetic Elements: Mobile genetic elements occur in practically all organisms, represent different types of mechanisms, and serve diverse purposes. They share some common features. They are capable of integration and excision from the genome (like the temperate bacteriophages), or movement within the genome (like the insertion and transposable elements). These elements may fulfill general regulatory functions in normal cells (such as the switching of the mating type elements in yeast). Phase variation in *Salmonella*, antigenic variation as a defense system in bacteria (*Borrelia*) and protozoa (*Trypanosomas*), parasitizing plant genomes by agrobacteria, etc., may depend on such elements. They have a role in the generation of antibody diversity in vertebrates by transposition of immunoglobulin genes. They have played an important role in the evolution of the genomes (Kazazian HH Jr 2004 Science 303:1626). There is an apparent paucity of DNA transposon mobilization in mammals, and in amniotes in general in comparison with other organisms. (e.g., plants) This paucity may result from the relative difficulty in

horizontal transfer into animals' germ lines (Han K et al 2007 Science 316:238), although about 50% of the genome of simians consists of transposable elements. (See items under separate entries, ▶transposable elements, ▶SDR, ▶SINE, ▶LINE, ▶Alu, ▶organelle sequence transfers, ▶transposons, ▶retroposons, ▶retrotransposons, ▶pathogenicity islands; classification: <http://aclame.ulb.ac.be/>).

Mobility Shift Assay: When two molecules (DNA-protein, protein-protein) bind, upon electrophoretic separation the mobility is retarded. ▶gel retardation assay; Filee P et al 2001 Biotechniques 30:1944.

Mobilization: In mobilization, the binding of the ribosome to a mRNA initiates polysome formation. Mobilization also refers to the process of conjugative transfer; and to the release of a compound in the body for circulation.

Mobilization of Plasmids: The transfer of conjugative plasmids to another cell. ▶conjugation

Mobilome: Potentially mobile part of the genome, such as episomes, transposons, integrons, and genomic islands.

Möbius Syndrome: In this condition, congenital partial or full paralysis and dysfunction of a cranial nerve, face and limb malformations, and mental retardation also may occur. A dominant locus was found at 3q21-q22 and another dominant on the long arm of chromosome 10. Recessive and X-linked inheritance was also suspected.

Mod Score: A maximized lod score over recombination fractions (θ) and genetic models (φ). ▶lod score, ▶model genetic

Modal: Adjective of mode. ▶mode

Mode: The value of the variates (class of measurements) of a population that occurs at the highest frequency. ▶mean, ▶median

Model: A model represents the essential features of a concept with minimum detail. It assists in making predictions about an operation under different conditions and sheds light on the contribution of the components of the system. In the *procedural system* of modeling, the focus is on the steps from the data to the conclusion. An example: looking for binding sites of transcription factors in the promoter regions of genes to shed light on expression by searching for over-represented elements in the promoters of each gene cluster. Or we can test the genes with similar binding sites to determine whether they are co-expressed. In the *declarative approach*, the modeling extends to both binding sites in the promoter and to expression levels. In the next step, the validity of the

model is tested by the maximum likelihood estimation regarding its fit to the data available. The testing of the sequences may be evaluated by the hidden Markov chain procedure. ► [maximum likelihood](#), ► [hidden Markov chain model](#), ► [probabilistic graphical models of cellular networks](#), ► [small-world networks](#), ► [modeling](#); Friedman N 2004 *Science* 303:799.

Model, Genetic: In human genetic analysis, the genetic model is specified by the type of inheritance, e.g., dominant/recessive, autosomal/sex-linked, penetrance/expressivity, frequency of phenocopies, mutations, allelic frequencies, pattern of onset, etc.

Model, Molecular: Three-dimensional physical representation of molecules. (See molecular modeling for beginners: <http://www.usm.maine.edu/~rhodes/index.html>; <http://www.natsci.org/Science/Compchem/feature14b.html>).

Model Organisms: All organisms share basic molecular mechanisms. Relatively simple biological systems of common evolutionary descent facilitate rigorous experimental studies because of ease of manipulation, short lifecycle, small genomes, etc. “Model organisms” are frequently of no economic interest beyond making research efficient, fast and less demanding in labor and funds yet they make possible the understanding basic genetic and molecular mechanisms common in other biological systems. About 75% of the human disease genes have some counterparts in *Drosophila* and even particular genes of the plant *Arabidopsis* display about 40% similarity to a human disease gene, e.g., responsible for breast cancer. Such models are *E. coli* for prokaryotes, *Saccharomyces cerevisiae* for fungi and other eukaryotes, *Caenorhabditis elegans*, *Drosophila melanogaster*, zebrafish for lower animals and humans, mouse and rat for higher animals and humans, *Arabidopsis thaliana* for higher plants and can provide useful information for more complex systems. No single “model organism” is suitable for the study of all biological problems. Obviously dogs can be exploited better for the study of behavior than yeast. For the study of chromosomal mechanisms broad bean (*Vicia faba*) is better than *Arabidopsis*. The use of several types of research methods is immoral or otherwise objectionable in humans (e.g., controlled mating, testing of new drugs and mutagens, genetic engineering) and mouse models are indispensable and invaluable. Since DNA sequence and proteome information is becoming available generalizations on functions, development and evolution is much facilitated. Model organisms have provided useful means to study human disease, regulatory networks, development, behavior, comparative analysis of gene function and other basic and applied biological problems. The animal disease models

usually do not fully represent the human conditions. (See Reinke V, White KP 2002 *Annu Rev Genomics Hum Genet* 3:153, survey of recent genetic technologies: Nagy A et al 2003 *Nature Genet* 33 (Suppl): 276; Davis RH 2004 *Nature Rev Genet* 5:69; Neff MW, Rine J 2006 *Cell* 124:229; ► [Homophila](#); human disease *Drosophila* gene database: <http://superfly.ucsd.edu/homophila>; <http://www.nih.gov/science/models/>).

Model-Free Analysis: A term from human genetics indicating no need for a genetic model because the persons and ancestors have already been genotyped. ► [genotyping](#), ► [model genetic](#)

Modeling: Physical, mathematical, and/or hypothetical construction for the exploration of the reality or mechanism of theoretical concepts. In modeling a protein structure, it is assumed that the amino acid sequence specifies the three-dimensional structure. The normal structure represents most probably the global free-energy maxima. ► [simulation](#), ► [Monte Carlo method](#), ► [model](#); protein structure prediction: <http://predictioncenter.org>; protein modeling principles and tools: Schueler-Furman O et al 2005 *Science* 310:638; annotated mathematical models of biological systems: <http://www.ebi.ac.uk/biomodels/>.

Modem (modulator/demodulator): The modem either links the computer to another computer through a telephone line, e.g., fax modem (sends printed and graphic information), or a modem sends and retrieves information from a mainframe computer to other computer operators through information networks such as BITNET, INTERNET, and various online services.

Modification: Most commonly in molecular biology, methylation. ► [methylation of DNA](#), ► [methylase](#)

Modified Bases: Modified bases occur primarily in tRNA and are formed mainly by post-transcriptional alterations. More than 35 different modified nucleosides were known by the 1970s (Hall RH 1971 *The Modified Nucleosides in Nucleic Acids*. Columbia Univ. Press, New York), and over 100 became known later (<http://medlib.med.utah.edu/RNAmods/>). The most common modified nucleosides are ribothymidine, thiouridine, pseudouridine, isopentenyl adenosine, threonyl-carbamoyl adenosine, dihydrouridine, 7-methylguanidine, 3-methylcytidine, 5-methylcytidine, 6-methyladenosine, inosine, etc. These modified bases have important roles in the function of tRNA, e.g., 1-methyladenosine in the T ψ C loop at position 58 facilitates the translation from the tRNA_{1^{Met}} initiation codon of yeast. ► [transfer RNA](#), ► [ribosome](#), ► [initiation codon](#), ► [thiouracyl](#); Anderson J et al 2000 *Proc Natl Acad Sci USA* 97:5173; <http://genesilico.pl/modomics/index2.pt>; rRNA small subunit: <http://medlib.med.utah.edu/SSUmods/>.

Modifier Gene: A modifier gene affects the expression of another gene. ►epistasis; Nadeau J 2001 Nature Rev Genet 2:165; Burghes AHM et al 2001 Science 293:2213.

Modified Mendelian Ratios: These ratios are observed when the product(s) of genes interact. Such situations in case of two loci can be best represented by modified checkerboards using the zygotic rather than the gametic constitutions at the top and at the left side of the checkerboards.

At the top, a standard constitution is shown where for each locus the genotypes are $1AA, 2Aa, 1aa$, and $1BB, 2Bb, 1bb$, respectively, etc. Although in the boxes only the relative numbers of the phenotypes (genotypes) are shown (as a modification of the 9:3:3:1 Mendelian digenic ratio), their genetic constitution can be readily determined from the top left checkerboard. These schemes assume complete dominance. Additional variation in the phenotypic classes occurs in case of semidominance or codominance and the involvement of more than two allelic pairs. In common usage these modifications are mentioned as gene interactions but actually the products of the genes do interact.

Sometimes it is not quite easy to distinguish between two segregation ratios within small populations and statistical analysis may be required. Example: let us assume that we wish to ascertain whether the segregation is 3:1 or 9:7. With 3:1 the standard error of the recessives is $\sqrt{\frac{3n}{16}}$ and with 9:7 it is $\sqrt{\frac{63n}{256}}$. Since deviations from the expectation can be either + or -, the statistically acceptable misclassification of 0.025 can rely on the deviate of 0.05. From a table of the normal deviates (►normal deviate), the expected number of recessives must be or exceed 1.9599 times the standard error. Thus, for 9:7 ($7/16n$ - recessives) = $1.9599\sqrt{\frac{63n}{256}}$ and for the 3:1 segregation the expected is $r - 1/4(n) = 1.9599\sqrt{\frac{3n}{16}}$. By adding up, we get:

$$n([7/16] - [1/4]) = 1.9599\sqrt{n}\left(\sqrt{\frac{63}{256}} + \sqrt{\frac{3}{16}}\right)$$

$$\text{and } \sqrt{n} = \frac{16}{3} \left\{ 1.9599 \left[\left(\frac{7.9373}{16}\right) + \left(\frac{1.7321}{4}\right) \right] \right\}$$

$$= 937121.$$

Since $n = 9.7121^2 = 94.32$, about 95 individuals permit a distinction between the two hypothetical segregations at a level of 0.025 probability. In a similar way, other segregation ratios can also be tested. ►Mendelian segregation, ►Punnett square, ►semidominance, ►codominance, ►phenotype, ►genotype, ►normal deviate, see Fig. M98.

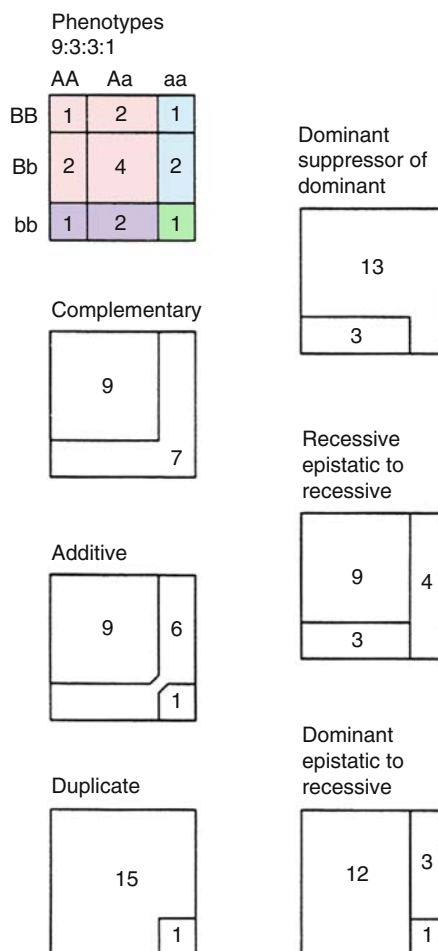

Figure M98. Modified Mendelian ratios

Modularity: Separability of a pattern into independently functionable units of a complex system. Developmental domains may be formed by specific transcription factors. These modules may subsequently affect other sets of transcription factors in a series of cascades of gene expression until the final differentiated structures arise. (See evolution of modularity: Kashtan N, Alon U 2005 Proc Natl Acad Sci USA 102:13773).

Modulation: Reversible alteration of a cellular function in response to intra- or extracellular factors.

Module: Single or multiple motif containing structural and functional units of macromolecules (proteins, DNA, RNA) and possibly small molecules. Their function is not a simple sum of that of the isolated components. Modules may be combined in alternative patterns and increase the functionality of the cell. Modules may be spatially isolated in the cell, e.g., as a ribosome, the complex site of polypeptide synthesis, or may only functionally be separated as, e.g., a particular signal transduction pathway. Modules

have the ability, however, for hierarchical interaction. One evolutionary advantage of the modular organization is that a mutation in a modular component may alter the function of that module without an upset in the whole system of the organism. Module components involved in a central role of the biology of the cell, e.g., histones, must be well conserved across phylogenetic ranges. Gene modules are coexpressed groups of genes within a genetic network. ►motif, ►genetic network, ►regulated gene, ►Williams syndrome; Bar-Joseph Z et al 2003 Nature Biotechnol 21:1337.

Modulon: ►origin

Modulins: Protein factors modulating bacterial infection. (See Neff L et al 2003 J Biol Chem 278:27721).

MODY (maturity-onset diabetes of the young): Apparently dominant, monogenic forms of familial diabetes with an onset at or after puberty but generally before age 25. Human chromosomal location is 20q11.2 (MODY1), 7p13 (MODY2), or 12q24 (MODY3), and it is a heterogeneous disease. MODYs are responsible for about 2–5% of non-insulin-dependent cases of diabetes. MODY1 is responsible for the coding of HNF-4 α , a hepatocyte nuclear transcription factor, a member of the steroid/thyroid hormone receptor family and an upstream regulator of HNF-1 α . MODY2 encodes the glycolytic glyco kinase, which generates the signal for insulin secretion. MODY3 displays defects in the hepatocyte nuclear factor HNF-1 α , a transcription factor that normally transactivates an insulin gene. SHP/NRPB2 (1p36.1) modulates the expression of HNF-4 α and contributes to obesity. ►diabetes mellitus, ►diabetes insipidus, ►GLUT; Barrio R et al 2002 J Clin Endocrinol Metab 87:P2532.

Moebius Syndrome: The major characteristics of the moebius syndrome are the facial paralysis of the sixth and seventh cranial nerves and often limb deformities and mental retardation. The dominant disorder was located to human chromosome 13q12.2-q13. The recurrence rate is below 1/50. ►neuro-muscular diseases, ►mental retardation, ►periodic paralysis, ►limb defects

Mohr Syndrome: ►orofacial digital syndrome II

Mohr-Tranebjaerg Syndrome (ddp): A recessive deafness encoded in xq21.3-qx22, involving poor muscle coordination, mental deterioration, but not blindness. In the same chromosomal region there is a transcribed region, DFN-1, which shows symptoms similar to DDP, but also blindness. ►deafness

MOI: ►multiplicity of infection

Molar Solution: 1 gram molecular weight compound dissolved in a final volume of 1 L.

Mole: *Talpa europaea*, 2n = 34, an insect-eating small underground mammal (see Fig. M99).

Figure M99. Mole

Mole: ►gram molecular weight; ►fleshy (placental) neoplasia

Mole: An abnormal mass of tissue in the uterus, developed from a degenerated oocyte. Alternatively, it may be of neoplastic nature. Hydatidiform moles may occur when one or two spermatozoa fertilize an enucleated egg. Moles frequently occur in the melanocytes of the skin and are generally benign and limited in growth. Mutations in the protein kinase BRAF, a downstream effector of the RAS oncogene, occasionally progress toward melanoma. Generally, the mutation induces cell cycle arrest and the induction of p16^{INK4a}, a tumor suppressor. In addition, the cells express a senescence-associated acidic β -galactosidase (SA- β -gal). The p16^{INK4a} and other factors apparently prevent proliferation and the cells and the mole remains senescent. This is an evidence of RAS oncogene induced senescence (Michaloglou C et al 2005 Nature [Lond] 436:720). ►nevus, ►tumor suppressor, ►galactosidase, ►senescence, ►RAS, ►melanoma, ►hydatidiform mole, ►p16^{INK4a}

Molecular Ancestry Network: <http://www.manet.uiuc.edu/>.

Molecular Beacon: A molecular tool for allele discrimination; it is a short hairpin oligonucleotide probe that binds to a specific oligonucleotide sequence and produces fluorescence signal. ►beacon molecular; Tyagi S et al 1998 Nature Biotechnol 16: 19; Rizzo J et al 2002 Mol Cell Probes 16(4):277.

Molecular Biology: The study of biological problems with physical and chemical techniques and interpretation of the functional phenomena on macromolecular bases. (See database: <http://nar.oupjournals.org>).

Molecular Breeding: The goal of molecular breeding is to develop highly efficient new vectors for genetic engineering. The procedure includes the reshuffling the coding regions of viral glycoprotein genes, which determine tropism of the proteins. This is followed by selection of vectors with exquisite specificity, improved gene transfer, etc. Molecular breeding may also mean application of molecular biology methods for the development of new crops or animal stocks. ►molecular pharming, ►plantibody, ►plant vaccine; Stöger E et al 2002 Mol Breeding 9(3):149, <http://www.phytome.org>.

Molecular Chaperone Heterocomplex (MCH): MCH includes heatshock proteins Hsp90 and Hsp70, chaperone interacting proteins Hop, Hip and p23, and peptidyl-prolyl isomerases, FKBP51, 52, and Cyp-40. ▶chaperones, ▶chaperonins, ▶heat-shock proteins, ▶cyclophilins, ▶FK506, ▶FKB; Bharadwaj S et al 1999 Mol Cell Biol 19:8033.

Molecular Clock: ▶evolutionary clock

Molecular Cloning: Reproduction of multiple copies of DNA with the aid of a vector(s). (See Sambrook J, MacCallum P 2006 Molecular Cloning. Cold Spring Harbor Lab, Press).

Molecular Combing: Spreading and aligning purified and extended DNA molecules on a glass plate and appropriate probes and optical tools reveal quantitatively at high resolution the amplification or losses of the genome. (See Allemand JF et al 1997 Biophys J 73:2064; Gueroui Z et al 2002 Proc Natl Acad Sci USA 99:6005).

Molecular Computation: Molecular computation could be called “reversed mathematics” because it uses DNA or protein sequence information in an attempt to solve complex mathematical problems. ▶DNA computer

Molecular Disease: The term “molecular disease” implies that the molecules involved in a disease have been identified, e.g., in sickle cell anemia, a valine replaces a glutamic acid residue in the hemoglobin β -chain. Since this first example, numerous diseases have been explained in molecular terms.

Molecular Drive: Copies of redundant DNA sequences are rather well conserved in the genomes although one would have expected divergence by repeated mutations. The force behind this tendency for uniformity within species has been named molecular drive or concerted evolution. The current literature uses mainly the latter term, which has priority. ▶concerted evolution

Molecular Evolution: Studies the relationship of the structure and function of macromolecules (DNA, RNA, protein) among taxonomic groups. ▶evolutionary distance, ▶evolutionary tree, ▶evolutionary clock, ▶evolution of the genetic code, ▶polymerase chain reaction. ▶ K_A/K_S , ▶RNA world, ▶origin of life, ▶phylogenomics; Nei M 1996 Annu Rev Genet 30:371; MANET, Wrenn SJ, Harbury PB 2007 Annu Rev Biochem 76:331; Phylemon: <http://phylemon.bioinfo.cipf.es/>.

Molecular Farming: The use of transgenic animals or plants for the production of substances needed for the pharmaceutical industry or for other economic activities. ▶transgenic, ▶pharming

Molecular Genetics: The application of molecular biology to genetics. It is a somewhat unwarranted distinction because genetics as a basic science must always use all the best integrated approaches.

Molecular Hybridization: Annealing two different but complementary macromolecules (DNA with DNA, DNA with RNA, etc.). ▶ C_{0t} curve, ▶probe

Molecular Imaging: A non-invasive imaging of targeted molecules in living organisms. The purpose is to identify a specific [altered] biological process with the aid of a molecular probe that is subject to alteration by the process and the alteration is detectable by light or near-infrared emission or by radioisotopes. An example is shown by the Fig. M100.

Figure M100. Using an appropriate vector firefly luciferase driven by a tissue-specific promoter is injected at the original tumor site. When metastasis takes place a new tumor site is detectable

Another example is that the dopamine receptor gene (D2R) in an adenovirus vector is injected into the tail of a mouse, and two days later the positron-labeled D2R ligand, (^{18}F) FESP (the dopamine analog 3-(2-(^{18}F) fluoroethyl)piperone, is injected into the mouse's bloodstream. MicroPET tomography then reveals the concentration of the molecular target by direct labeling. There are a wide variety of techniques for imaging other molecules. Direct-binding probes reveal the quantity of the target whereas indirect probes shed information on the activity status of the target. For the detection, one of the tomography or magnetic resonance imaging techniques or optical devices for luciferase activity are used. ▶tomography, ▶nuclear magnetic resonance spectroscopy, ▶luciferase, ▶GUS; Herschman H R 2003 Science 302:605.

Molecular Markers: ▶RFLP, ▶RAPD, ▶VNTR, ▶molecular weight, ▶ladder

Molecular Medicine: The integration of molecular, clinical and genomic information for developing improved therapy. (See Bellazzi R, Zupan B 2007 Int J Med Inform 40:787).

Molecular Mimics: Molecular mimics may trigger an autoimmune reaction because they have sequence homology to bacterial or viral pathogens. It is assumed that viral infection may lead to the synthesis of antigens structurally or functionally resembling self-proteins. Naïve T cells may be then activated by this antigen and may also mount an immune response to self-proteins. Some proteins appear to mimic the structure of nucleotides, e.g., domain 4 of EF2 peptide elongation factor mimicks the anticodon stem and loop of tRNA. Similarly, the eukaryotic release factors mimic tRNA. ▶autoimmune diseases, ▶bystander activation, ▶immune response, ▶immune tolerance, ▶tRNA, ▶structural mimics; Putnam WC et al 2001 Nucleic Acids Res 29:2199; Quin W et al 2007 Mol Immunol 44:2355.

Molecular Modeling: Aims to determine the three-dimensional atomic structure of macromolecules. Database and software information is available at <http://www.ncbi.nlm.nih.gov/Structure/>; <http://www.rcsb.org/pdb/home/home.do>.

Molecular Motor: ▶motor protein

Molecular Pharming: ▶pharming

Molecular Plant Breeding: This technique uses DNA markers to map agronomically desirable quantitative traits by employing the techniques of RFLP, RAPD, DAF, SCAR, SSCP, etc. The purpose is to incorporate advantageous traits into crops. (See separate entries, ▶QTL)

Molecular Plumbing: The generation of blood vessels by tissue culture techniques for the purpose of replacing defective organs.

Molecular Structure Database Tool: <http://bip.weizmann.ac.il/oca-bin/ocamain>.

Molecular Weight: The relative masses of the atoms of the elements are the atomic weights. The sum of the atomic weights of all atoms in a molecule determines the molecular weight of that molecule (MW). In the determination of the relative mass the mass of C^{12} is used, which is approximately 12.01 (earlier the mass of the hydrogen was used, 1.08 but the calculations with it were more difficult). The relative molecular weight is abbreviated usually as M_r . The molecular weight of macromolecules is generally expressed in daltons, $1 \text{ Da} = 1.661 \times 10^{-24}$ gram. Molecular weights are determined by a variety of physico-chemical techniques. In gel electrophoresis of DNA fragments are compared with sequenced (known base number) restriction fragments. For λ phage the fragments can be generated by *HinD* III [125 to 23,130 bp], by *HinD* III - *Eco* RI double digests [12 to 21,226 bp], or *Eco* RI [3,530 to 21,226 bp] or pUC18

plasmid cleaved by *Sau* 3AI [36 to 955 bp] or Φ X174 digested by *Hae* III [72 to 1,353 bp]. Alternatively, commercially available synthetic ladders containing 100-bp incremental increases from 100 to 1,600 bp or several other sizes are most frequently used. For the large chromosome-size DNAs studied by pulsed-field gel electrophoresis, T7 (40-kb), T2 (166-kb), phage G (758-kb), or even larger constructs obtained by ligation are used. For protein electrophoresis, bovine serum albumin (67,000 M_r), gamma globulin (53,000 and 25,000 M_r), ovalbumin (45,000 M_r), cytochrome C (12,400 M_r), and others can be employed. ▶ladder

Molecule: Atoms covalently bound into a unit.

Moloney Mouse Leukemia Oncogene (MLV): MLV integrates at several locations into the mouse genome; an integration site has been mapped to human chromosome 5p14. The Moloney leukemia virus-34 (Mov34) integration causes recessive lethal mutations in the mouse. Homolog to this locus is found in human chromosome 16q23-q24. The Mos oncogene encodes a protein serine/threonine kinase. It is a component of the cytotostatic factor CSF and regulates MAPK. ▶oncogenes, ▶CSF, ▶MAPK

Moloney Mouse Sarcoma Virus (MSV, MOS): The c-oncogene maps to the vicinity of the centromere of mouse chromosome 4. The human homolog MOS was assigned to chromosome 8q11-q12 in the vicinity of oncogene MYC (8–24). Break-point at human 8;21 trans-locations have been found to be associated with myeloblastic leukemia. It has been suspected that band 21q22, critical for the development of the Down syndrome, is responsible for the leukemia that frequently affects trisomic individuals for chromosome 21. The cellular mos protein (serine/threonine kinase) is also required for the meiotic maturation of frog oocytes. If the c-mos transcript is not polyadenylated maturation is prevented. Overexpression of c-mos causes precocious maturation, and after fertilization, cleavage is prevented but disruption of the gene may lead to parthenogenetic development of mouse eggs. This protein is active primarily in the germline, may cause ovarian cysts and teratomas, and oncogenic transformation also in somatic cells. ▶cell cycle, ▶teratoma, ▶polyadenylation, ▶leukemia, ▶Down syndrome, ▶c-oncogene

Moloney Murine Leukemia Virus: ▶MoMuLV

Molscrip: A computer program for plotting protein crystal structure. ▶protein structure; Kraulis PJ 1991 J Appl Crystallogr 24:946; Spock program manual: <http://quorum.tamu.edu/Manual/Manual/Manual.html>.

Molting: Shedding the exoskeleton (shell) by insects during metamorphosis (developmental transition stages). ▶Drosophila

Molybdenum: A cofactor of several enzymes in prokaryotes and eukaryotes. In mammals, it is required by xanthine dehydrogenase, aldehyde, and sulphite oxidase. An autosomal recessive molybdenum cofactor (molybdopterin) deficiency/sulphite oxidase deficiency involves neonatal seizures, neuronal damage, and is a rare lethal condition that manifests between ages two to six. Two open reading frames in human chromosome 6p encode the protein. ▶nitrate reductase, ▶gephyrin

Moments: The expectations of different powers of a variable or its deviations from the mean, e.g., the first moment is $E(X)$ = the mean, the second moment is $E(X^2)$, the third $E(X^3)$. The first *moment about the mean*: $E(X - E[X])^2$, the second $E(X - E[X])^3$. The third moment about the mean (if it is not 0) indicates skewness, the fourth moment reveals kurtosis. The moment of the joint distribution of X and Y is the covariance. ▶skewness, ▶kurtosis, ▶covariance, ▶correlation

MoMuLV (Moloney murine leukemia virus): A retrovirus with two copies of the genomic RNA in the capsid. The surface of the virus is decorated with trimeric transmembrane glycoprotein (Env). During infection, Env spikes mediate binding of the virus to the cell surface receptor, and structural rearrangements of Env enable the fusion with the cell membrane and entry of the virus into the cell. Cryo-electron tomography was found to reveal the structural basis of this process. The viral membrane is represented by purple and the green structure represents Env (see Fig. M101). The ~30 kDa receptor-binding domain fits into the Env.

Figure M101. Envelope structure complex of MoMuLV *in situ* as mentioned in the text. For details see Förster F, Medalia O, Zauberman N, Baumeister W & Fass D 2005 Proc. Natl. Acad. Sci. USA 102:4729. (Courtesy of Dr. Friedrich Förster)

MoMuLV is frequently used for vector construction. It is potentially useful for transformation of both rodent and human cells. Integration is very efficient because the viral genome is retained in the reverse-transcribed DNA form of the virus. It can be targeted to rapidly dividing and not to post-mitotic cells. The *gag*, *pol*, and *env* protein genes are dispensable and also ensure that the virus is incapable of autonomous replication, but the ψ packaging signal is required. If the target cells do not have the ψ , the virus does not spread to other tissues. This is a particular advantage when tumor cells are targeted but normal cells are spared. For example, herpes simplex virus thymidine kinase (*HSV-tk*)-containing viral vectors thus convey ganciclovir-sensitivity only to tumor cells (which divide), and 10–70% may then be selectively killed by this cytotoxic drug. Similar vector designs can be applied to some degenerative diseases. (Parkinson disease, Huntington's chorea, Alzheimer disease and other neurodegenerative diseases). The protective gene can be transfected into cultured cells and then can be grafted back onto the target tissue of the same patient. ▶ganciclovir, ▶retroviral vectors, ▶gene therapy; D'Souza V, Summers MF 2004 Nature [Lond] 431:586; Förster F et al 2005 Proc Natl Acad Sci USA 102:4729.

MONA (Al Aqueel-Sewairi syndrome, 16q12-q21): Multicentric osteolysis with nodulosis and arthritis due to deficiency of matrix metalloproteinases.

Monarch Butterfly: ▶navigation, ▶*Bacillus thuringiensis*

Monastrol: A protein causing monopolar (rather than the normal bipolar) spindle in dividing cells. It blocks kinesin-related proteins (such as those in the bimC family, e.g., Eg5). ▶kinesin, ▶bimC; Kapoor TM et al 2000 J Cell Biol 150:975.

Mondrian: A type of representation of microarray of RNA transcripts resembling the “Broadway boogie-woogie” by the Dutch painter Piet Mondrian (1872–1944). It identifies open reading frames within the sequenced genomic DNA. (See Penn SG et al 2000 Nature Genet 26:315; art in science).

Mongolian Spot: A transient or long-lasting bluish birthmarks most commonly found upon the buttocks of infants. Its prevalence among Asians and East Africans 95–100%, Native Americans 85–90%, Hispanics 5–70%, and Caucasians 1–10%. It is caused by the entrapment of melanocytes during their migration from the neural crest into the epidermis during fetal development. (After Dr. Numabe, H., Tokyo University).

Mongolism (mongoloid idiocy): Now rejected name of Down's syndrome, human trisomy 21. Besides the epicanthal eyefold other—non-mongoloid—features

are more characteristics for the condition (see Fig. M102). ►Down syndrome, ►trisomy

Figure M102. Mongoloid eyefold

Monilethrix: Autosomal dominant (human chromosome 14q) and possibly autosomal recessive baldness (alopecia) due to defects of the keratin filaments of the hair. ►filaments, ►baldness, ►hair; Schweizer J 2006 J Invest Dermatol 126:1216.

Monitor: A video monitor receives and displays information directly received by a computer, while a television monitor accepts broadcast signals. Monitoring: keeping track of something.

Monoallelic Expression: In a diploid (or polysomic) cell or individual only one of the alleles is expressed such as the genes situated in one of the mammalian X chromosomes or as is the case of maternal or paternal imprinting. Besides X-chromosomal genes, imprinted autosomal genes display monoallelic expression. In addition several other autosomal genes (odorant receptors, pheromone receptors, immunoglobulins, T cell receptors, interleukins) are transcribed in random monoallelic manner. These alleles also show asynchronous replication, which may be responsible for their differences in expression. The asynchrony within a particular chromosome appears coordinated (Singh N et al 2003 Nature Genet 33:339). Monoallelically expressed autosomal genes of mammals display a substantially higher frequency of LINE1 sequences (Allen E et al 2003 Proc Natl Acad Sci USA 100:9940). Actually some lower organisms (*Plasmodium*, *Trypanosoma*) also express only one allele of some genes of the diploid. ►lyonization, ►imprinting, ►allelic exclusion, ►*Plasmodium*, ►*Trypanosoma*

Monoamine Oxidase: ►MAO, ►Norrie disease

Monobrachial Chromosome: A monobrachial chromosome has only one arm (see Fig. M103). ►telocentric, ►chromosome morphology

Figure M103. Monobrachial chromosome

Monocentric Chromosome: A monocentric chromosome has a single centromere, as is most common.

Monochromatic Light: Literally, light of a single color, practically light emission with a single peak within a very narrow wavelength band.

Monocistronic mRNA: A monocistronic mRNA codes for a single type of polypeptide. It is transcribed from a single separate cistron (not from an operon). Eukaryotic genes are usually monocistronic. The class I genes, 18, 5.8 and 28 S rRNAs, including spacers, are transcribed as a single unit containing one of each gene's pre-rRNAs and are cleaved subsequently into mature rRNA. The 5 S RNA genes are transcribed from separate promoters by pol III. ►ribosome, ►cistron

Monoclonal Antibody (MAB): The MAB is of a single type, produced by the descendants of one cell and specific for a single type of antigen. In case the epitome domains are highly conserved, the specificity of the monoclonal antibody is reduced. MABs are generated by injecting into mice, purified antigens (immunization), than by isolating spleen cells (splenocytes, B lymphocytes) from the immunized animals and fusing these cells, in the presence of polyethylene glycol (a fusing facilitator), with bone marrow cancer cells (myelomas) that are deficient in thymidine kinase (TK), or HGPRT. This process assures that the non-fused splenocytes rapidly senesce in culture and die. The unfused myeloma cells are also eliminated on a HAT medium because they cannot synthesize nucleic acids, either by the de novo or by the salvage pathway. The selected myelomas do not secrete their own immunoglobulins and thus, hybrid immunoglobulins are not produced. Single hybridoma cells are then cultured in multi-well culture vessels and screened for the production of specific MABs by the use of radioimmunoassays (RIA) or by enzyme-linked immunosorbent assay (ELISA). Most of the hybridomas will produce many types of cells and are of limited use; a few, however, may be more specific and these are re-screened for the specific type needed. E.g., animals immunized with melanoma cells produce HLA-DR (Human Leukocyte Antigen D-related) antibodies or melanotransferrin (a 95-kDa glycoprotein) or melanoma-associated chondroitin proteoglycan (heteropolysaccharides, glucosaminoglycans attached to extracellular proteins of the cartilage). Monoclonal antibodies have been used effectively for identification of tumor types in sera and histological assays. A human trial using humanized mouse monoclonal antibody in the hope to find an effective treatment for autoimmune conditions had a tragic outcome. Six healthy individuals in a London hospital were injected with anti-CD28 mAB that rather than suppressing regulatory T cells—as expected on the basis of experiment with mice and monkeys—turned ‘superagonist’ and activated all types of T cells,

and not just the regulatory T cells. The individuals in the trial developed serious organ failures and one fell into a coma for three weeks. Apparently, the mAb of TGN1312 caused an unexpected 'cytokine storm' indicating that there is still a lot to be learned before antibodies can be generally used for therapeutic purposes (Vitetta ESD, Ghetie VF 2006 Science 2006 313:308).

Some MABs have been successfully applied for direct tumoricidal effect. Radioactively labeled monoclonal antibodies of Melanoma Associated Antigens (MAA) have been used for imaging (immunoscintigraphy) and detecting melanoma cells in the body when other clinical and laboratory methods failed. The "magic bullet" approach of combining specific monoclonal antibodies (prepared from individual cancer patients) against a specific cancer tissue with Yttrium⁹⁰ isotope (emitting β rays of 2.24 MeV energy and 65 h half-life), or ricin (LD50 for mice by intravenous administration 3 ng/kg) or the deadly diphtheria toxin, or tumor necrosis protein (TNF) is expected to home in on cancer cells and destroy them. This attractive scheme has not been proven successful in clinical trials so far. (►abzymes). More recently, several monoclonal antibody drugs targeting tyrosine kinase (Gleevec, Trastuzumab) and antiangiogenesis Avastin have been approved for therapeutic use alone or in combination with other treatments. A newer approach is to clone separately cDNAs of a variety of light and heavy chains of the antibody and allowing them to combine in all possible ways, thus producing a combinatorial library of antibodies against all present and possible, and emerging and future epitopes. These antibodies can then be transformed into bacteria by using λ phage or filamentous phage such as M13. The phage plaques can then be screened with radioactive epitopes. The advantage of using filamentous phages is that they display the antibodies on their surface and permit screening in a liquid medium that enhances the efficiency by orders of magnitude. Although monoclonal antibodies did not completely fulfill all the (naïve) therapeutic expectations, they still remain a power-tool of biology and currently they represent more than 20% of the biopharmaceuticals being evaluated in clinical trials. Monoclonal antibodies cannot be produced against self-antigens or against less than about 1-kDa antigens. In the latter case, high molecular weight carrier proteins such as bovine serum albumin or limpet hemocyanin are used. Typical yield of MAb from hybridoma cells is 10–100 $\mu\text{g}/10^6$ cells/day. Currently, mammalian cells are used mainly to produce IgG and obtain post-translational modifications (e. g., glycosylation), which are essential for the maintenance of the conformation of the immunoglobulin effector function. For transient expression of antibody genes, most commonly COS cells are

employed. For stable-expression myeloma cell lines, SP2/0, NS0, and Chinese hamster ovary (CHO) cells are used. Antibodies can be produced in transgenic mammals, insects, and plants. Mouse adenocarcinoma-associated antigen (EpCAM [GA73302]) is a highly expressed target of mouse monoclonal antibody (mAb CO17–1 A) and it can be produced in transgenic *Nicotiana tabacum* plants after transformation by *Agrobacterium* vectors. Although the glycosylation pattern of the plant monoclonal antibody differs from that of the animals, it inhibited colon cancer cells in nude mice similarly to its mammalian counterpart (Ko K et al 2005 Proc Natl Acad Sci USA 102:7026). ►antibody, ►immunoglobulins, ►immune system, ►T cells, ►B cells, ►lymphocytes, ►somatic cell hybrids, ►hybridoma, ►MAB, ►TK, ►HGPRT, ►HAT medium, ►senescence, ►RIA, ►ELISA, ►hybridoma, ►heterohybridoma, ►melanoma, ►ricin, ►LD50, ►diphtheria toxin, ►epitope, ►combinatorial library, ►phage display, ►quasi-monoclonal, ►bispecific monoclonal antibody, ►keyhole limpet hemocyanin, ►humanized antibody, ►CD28, ►immunization genetic, ►phage display, ►HAMA, ►COS, ►transformation transient, ►CHO, ►plantibody, ►genetic engineering, ►antibody polyclonal, ►receptin, ►aptamer, ►genetic medicine; Ritter MA, Ladyman HM (Eds.) 1995 Monoclonal Antibodies. Production, Engineering and Clinical Application, Cambridge University Press, New York; Alkan SS 2004 Nature Rev Immunol 4:153; <http://www.antibodyresource.com/>; <http://bioresearch.ac.uk/browse/mesh/D000911.html>.

Monoclonal Antibody Therapies: Monoclonal antibody therapies open a variety of applications in medicine. Although at the moment they do not offer perfect solutions, they do have a lot of potential. Reocclusion of blood vessels after angioplasty—caused by unwanted aggregation of the platelets—may be alleviated by the 7E3 antibody fragments of the chimeric mouse-human Fab. Single- or two-chain fragments of the antibody variable region and the urokinase fusion protein (scFv-uPA) or tissue plasminogen activator (tPA) conjugated to anti-fibrin antibody have been designed for thrombolysis. Monoclonal antibodies may be generated against interleukins (IL-1), TNF, and cell adhesion molecules (selectins, integrins) to block inflammatory responses after wounding or autoimmune diseases (rheumatoid arthritis, septic shock), T cells, T cell receptors, etc. Monoclonal antibody-mediated cytotoxicity responses are activated or inhibited through the Fc γ receptors of the antibody. By computational design and engineering, the affinity of these receptors can be increased by two orders of magnitude and can broaden the therapeutic applicability to cancer (Lazar GA et al 2006

Proc Natl Acad Sci USA 103:4005). ▶magic bullet, ▶ADEPT, ▶vascular targeting, ▶immunotoxins, ▶antiviral antibodies, ▶tissue plasminogen activator, ▶thrombin, ▶platelet, ▶fibrin, ▶selectins, ▶integrin, ▶rheumatic fever, ▶septic shock, ▶auto-immune diseases, ▶T cell, ▶T cell receptor, ▶plantibody, ▶antibody, ▶antibodies intracellular, ▶abzymes, ▶gene therapy, ▶cancer gene therapy, ▶genetic medicine, ▶biomarkers; Baselga J 2001 Eur J Cancer 37 Suppl 4:16.

Monocotyledones: Plants that form only one cotyledon such as the grasses (cereals).

Monocytes: Mononuclear leukocytes that become macrophages when transported by the blood stream to the lung and the liver. ▶microglia, ▶atherosclerosis, ▶MCP-1, ▶leukocyte, ▶macrophage

Monoecious: Plants with separate male and female flowers on the same individual (see Fig. M104). ▶autogamous, ▶outcrossing, ▶protandry, ▶protogyny

Figure M104. Monoecious plant

Monofactorial Inheritance: A single (dominant or recessive) gene (factor) determines the inheritance of a particular trait. Although this term has some value for classification of inheritance, in most of the case the phenotype is the function of a number of genes with different alleles that respond to a variety of internal and external factors at the same time. Thus, strictly monogenic inheritance may not exist. The so-called monogenic human diseases generally are expressed as syndromes. As of February 2006, 1,822 “monogenic” human allelic variants were identified by OMIM. Sequencing of the human disease genes and encoded proteins often reveals more than a single alteration even within the single gene. Also, environmental factors and the genetic background may modify the phenotypes substantially. ▶Mendelian laws, ▶reaction norm, ▶syndrome, ▶pleiotropy, ▶SNIPs, ▶epistasis, ▶digenic diseases, ▶QTL; Nadeau JH 2001 Nature Rev Genet 3:165.

Monofunctional Alkylating Agent: A monofunctional alkylating agent has only a single reactive group.

Monogenic Heterosis: Same as overdominance, superdominance.

Monogenic Inheritance: Same as monofactorial inheritance.

Monogerm Seed: A monogerm seed contains only a single embryo. The fruit of some plants (e.g., sugar beet) is frequently used for propagation and usually it contains multiple seeds. This fruit may, however, be genetically modified to contain a single seed or mechanically fragmented to become monogerm. The agronomic advantage of the monogerm seed is that the emerging seedlings are not crowded and the labor-consuming thinning may be avoided or is at least facilitated.

Monogyne: Social insects with single functional female (queen) in the colony. ▶polygyne

Monohybrid: A monohybrid is heterozygous for only one pair of alleles. ▶monofactorial inheritance

Monoisodisomic: In wheat, $20'' + i1''$, $2n = 42$, [“=disomic, i=isosomic].

Monoisosomic: In wheat, $20'' + i'$, $2n = 41$, [“=disomic, ‘=monosomic, i=isochromosome].

Monoisotrisomic: In wheat, $20'' + i2''$, $2n = 43$, [“=disomic, i=isosomic, “=trisomic].

Monokine: Lymphokine produced by monocytes and macrophages. ▶lymphokine

Monolayer: Non-cancerous animal cell cultures grow in a single layer in contact with a solid surface, i.e. in a monolayer. It also designates a single layer of lipid molecules. ▶tissue culture, ▶cell culture

Monolithic Substrate: Polymer or silicon substrate with microchannels or other functional elements.

Monomer: One unit of a molecule (which frequently has several in a complex); a subunit of a polymer ▶protein

Monomorphic Locus: In the population, a monomorphic locus is represented by one type of allele.

Monomorphic Trait: A monomorphic trait is represented by one phenotype in the population.

Mononucleosis: Caused by cytomegalovirus; infectious mononucleosis is the result of activation of the Epstein-Barr virus. ▶cytomegalovirus, ▶Epstein-Barr virus

Monooxygenases: Monooxygenases introduce one atom of oxygen into a hydrogen donor, e.g., P450 cytochromes, and have varied functions in cells in normal development, as detoxifiants, and in converting promutagens and procarcinogens into active compounds. ▶mixed-function oxidases, ▶P450

Monoparous: Species, which generally produce a single offspring at a time. ▶[multiparous](#)

Monophyletic: Monophyletic organisms have evolved from a single line of ancestry. ▶[polyphyletic](#)

Monoploid: A monoploid has only a single basic set of chromosomes. ▶[haploid](#)

Monopolar Spindle: A monopolar spindle pulls all chromosomes to one pole (see Fig. [M105](#)).

Figure M105. Monopolar spindle

Monoplin (Mam1): A kinetochore associated protein that assures that during meiosis I the homologous chromatids (held together by cohesin) are pulled to the same pole. The Csm1/Lrs4 proteins reside in the nucleolus and shortly before meiosis I they leave that location to associate with Mam1. ▶[meiosis](#), ▶[cohesin](#), ▶[co-orientation](#); Toth A et al 2000 Cell 103:1155; Rabitsch KP et al 2003 Dev Cell 4:535.

Monoprotic Acid: A monoprotic acid has only a single dissociable proton.

Monosaccharide: A carbohydrate that is only one sugar of basic units $C_nH_{2n}O_n$ and thus can be diose, triose, pentose, hexose, etc., depending on the number of C atoms; the sugars can also be aldose (e.g., glucose, ribose) or ketose sugars (e.g., fructose, deoxyribose).

Monosaccharide Malabsorption (22q13.1): Monosaccharide malabsorption is controlled by a sodium/glucose transporter at the intestinal brush border.

Glucose/galactose malabsorption may be remedied by fructose.

Monosodium Glutamate ($HOOCCH(NH_2)CH_2CH_2COONa \cdot H_2O$): Monosodium glutamate is used as a flavor enhancer (0.2–0.9%) in salted food or feed, for repressing the bitter taste of certain drugs, or as a medication for hepatic coma. ▶[Chinese restaurant syndrome](#)

Monosomic: In a monosomic, the homologous chromosome(s) is represented only once in a cell or all cells of an individual. The gametes of diploids are monosomic for all chromosomes. A monosomic individual of an allopolyploid has $2n - 1$ chromosomes. About 80% of the human $45 + X$ monosomics involve the loss of a paternal sex chromosome. Medical cytogeneticists frequently refer to deletions as “partial monosomy”, but this is a misnomer and should be avoided because such a condition is hemizygosity for a particular locus or chromosomal region. Monosomics can produce both monosomic and nullisomic gametes. ▶[nullisomics](#), ▶[chromosome substitution](#), ▶[monosomic analysis](#)

Monosomic Analysis: Monosomic analysis is very efficient in Mendelian analysis of allopolyploids, such as hexaploid wheats. Monosomic individuals can produce monosomic and nullisomic gametes and their proportions are different in males and in females (see Fig. [M106](#)). The proportion also depends on the individuality of the particular chromosomes. On the average, the gametic output and the zygotic proportion of selfed monosomics of wheat is as shown in the body of the table. Very few nullisomic sperms are functional, whereas the majority of the eggs are nullisomic because most of the monosomes (in the absence of a partner) remain and get lost in the meta-phase plane and the eggs receive only one representative from each chromosome that has paired during prophase I. The monosomics can be used to assign genes to chromosomes and if the proper genetic constitution is used cytological test may not be required. On the basis of the Fig. [M106](#) and the Table [M7](#) it is obvious that 75% of the F_1 will be of recessive phenotype if the genes are in the chromosome of the monosomic female. In case the recessive

Figure M106. Gene localization to chromosome with monosomics

Table M7. Monosomic analysis

| | | |
|-----------------|--|----------------------------------|
| Eggs ↓ | <div>Monosomic (0.96) ← Sperms → Nullisomic (0.04)</div> | |
| Monosomic 0.25 | Disomic ≈ 24% (0.25 x 0.96) | Monosomic ≈ 1% (0.25 x 0.04) |
| Nullisomic 0.75 | Monosomic ≈ 72% (0.75 x 0.96) | Nullisomic ≈ 3% (0.75 x 0.04) |

is in the monosomic female, only 3% will be recessive in the F₂ offspring. ▶nullisomy; Morris R, Sears ER 1967 In Wheat and wheat improvement; Quisenberry KS, Reitz LP (Eds.) Am Soc Agron Madison WI Sears E R 1966 Hereditas Suppl 2:370; Tsujimoto H 2001 J Hered 92:254.

Monospermy: Fertilization by a single sperm.

Monotelodisomic: In wheat, 20” + t2”, 2n = 43, [“=disomic, t = telosomic, “=trisomic].

Monotelomonoisomic: In wheat, 20”+ t’+ i’, 2n= 42, [“=disomic, ‘=monosomic, t = telosomic, i = isosomic].

Monotelo-Monoisotrisomic: In wheat, 20”+ (t+ i)1”, 2n = 43, [“=disomic, “=trisomic, t = telosomic, i = isosomic].

Monotelosomic: In wheat, 20” + t’, 2n = 41, [“=disomic, ‘=monosomic, t = telosomic].

Monotocous Species: A monocotous species produces a single offspring by each gestation.

Monotrene: An animal belonging to the taxonomic order Monotremata, a primitive small mammalian group, including the spiny anteater and the duck-billed platypus (see Fig. M107). They lay eggs and nurse their offspring within a small pouch through a nipple-less mammary gland. They show other organizational similarities to marsupials. ▶marsupials, ▶sex determination

Figure M107. Platypus

Monotypic: A taxonomic category represented by one subgroup, e.g., a monotypic genus includes a single species.

Monoubiquitin: In a monoubiquitin, the surface of the ubiquitin may be ordained for separate multiple functions, e.g., for degradation or endocytosis. The various monoubiquitins are specialized to one function only although the function itself may vary, e.g., it may involve regulation of histones H2A and H2B, endocytosis, or budding of the retroviral Gag polyprotein. Monoubiquitins can be attached to separate sites, or *polyubiquitin* chains are attached at a single lysine⁴⁸. Polyubiquitin attachments at Lys⁶³ activates several proteins but this complex is not targeted to the proteasome. ▶ubiquitin, ▶sumo, ▶histones, ▶endocytosis, ▶retrovirus, ▶proteasome, ▶deubiquitinating enzymes; Hicke L 2001 Nature Rev Mol Cell Biol 2:195.

Monozygotic Twins: Monozygotic twins develop from a single egg fertilized by a single sperm, therefore they should be genetically identical, except mutations that occur subsequent to the separation of the zygote into two blastocytes after implantation into the wall of the uterus. Monozygous female twins may be phenotypically discordant in case of heterozygosity of X-linked genes. The difference may be caused by the inactivation of one or the other X chromosome. Although MZ twins are generally identical genetically, their birthweight may be different because of differences in intrauterine nutrition due the path of blood circulation. Developmental malformations may affect only one of the MZ twins. The concordance in susceptibility to infectious diseases has been investigated but the information is not entirely unequivocal. Multifactorial diseases are more concordant in MZ twins than among dizygotic twins. ▶twinning, ▶dizygotic twins, ▶heritability estimation in humans, ▶zygosis, ▶concordance, ▶discordance, ▶co-twin, ▶lyonization

Monte Carlo Method: A computer-assisted randomization of large sets of tabulated numbers that can be used for testing against experimentally obtained data to determine whether their distribution is random or not. It is used for simulation when the analysis is

intractable or too complex. ► [modeling](#), ► [simulation](#), ► [Markov chain](#); Roederer M et al 2001 Cytometry 45:47; Roederer M et al *ibid* 37.

Moolgavkar-Venzon Model: A revised version of Knudson's two-mutation model of carcinogenesis. It considers the possibility that after the first mutation not all the cells survive, and allows for differential growth of the cells before the occurrence of malignant transformation. ► [Knudson's two-mutation hypothesis](#); Armitage-Doll model, Holt PD 1997 Int J Radiat Res 71(2): 203.

Moore-Federman Syndrome: A dwarfism with stiff joints and eye anomaly. ► [dwarfism](#)

Mooring Sequence: An 11 nucleotide element anchored downstream to the base C to be RNA edited (CAAUUUGAUCAGUAUA). ► [RNA editing](#)

Moose, North American: (*Alces alces*), $2n = 70$.

Morality: Socially accepted principles and guidelines for the distinction of right from wrong in human behavior, usually based on customs and generally required to be abided by, by society. Moral standards are categorically binding principles independent of one's wishes or desires and therefore transcend all other kinds of potentially conflicting norms. Some moral rules are present in all human societies; these rules may have, however, distinct variations. ► [behavior genetics](#), ► [ethics](#), ► [ethology](#), ► [informed consent](#)

Morbidity: The diseased condition or the fraction of diseased individuals in a population. A wide range of biomarkers, reflecting activity in a number of biological systems (e.g., neuroendocrine, immune, cardiovascular, and metabolic), has been found to prospectively predict disability, morbidity, and mortality outcomes in older adult populations. Levels of these biomarkers, singly or in combination, may serve as an early warning system of risk for future adverse health outcomes. Markers for neuroendocrine functioning (epinephrine, norepinephrine, cortisol, and dehydroepiandrosterone), for immune activity (C-reactive protein [one of the acute phase proteins that increase during systemic inflammation], fibrinogen, IL-6, and albumin) is appropriate. For cardiovascular functioning (systolic and diastolic blood pressure), and for metabolic activity [high-density lipoprotein (HDL) cholesterol, total to HDL cholesterol ratio are being used. Glycosylated hemoglobin] over a 12-year period in a sample of men and women ($n = 1,189$) 70–79 years of age was informative cardiovascular problems. Almost all these markers entered into one or more high-risk pathways, although combinations of neuroendocrine and immune markers appeared frequently in high-risk

male pathways, and systolic blood pressure was present in combination with other biomarkers in all high-risk female pathways (Gruenewald TL et al 2006 Proc Natl Acad Sci USA 103:14158). ► [mortality](#); Petronis A 2001 Trends Genet 17:142.

Morgan: 100 units of recombination, 100 map units, usually the centiMorgan, 0.01 map unit is used. ► [map unit](#)

Morphactins: Various plant growth regulators.

Morphallaxis: ► [regeneration in animals](#), ► [epimorphosis](#)

Morpheins: Proteins in which one functional homooligomer can dissociate, change conformation, and reassociate into a different oligomer. ► [conformation](#)

Morphine: An opium-like analgesic and addictive alkaloid; methylation converts it to the lower potency codein. Noradrenergic signaling mediates opiate reward (Olson VG et al 2006 Science 311:1017). ► [alkaloids](#), ► [opiate](#), ► [animal hormones](#)

Morphoallele: Gene involved in morphogenesis. ► [morphogenesis](#)

Morphogen: A compound that can affect differentiation and/or development, and can correct the morphogenetic pattern of a mutant that cannot produce it if it is supplied by an extract from the wild type. In some sea algae (*Ulva*, *Enteromorpha*), marine bacteria (Cytophaga-Flavobacterium-Bacteroides), on the surface of the algae, control leaf-like morphology. The bacteria-produced thallusin (see Fig. M108) determines foliaceous morphology and spore germination (Matsuo Y et al 2005 Science 307:1598). In the higher plant *Cardamine hirsuta* (see Fig. M109), the KNOX (KNOTTED1-like homeobox) regulated by the asymmetric leaf 1 protein makes the leaves dissected, whereas in another crucifer, *Arabidopsis* leaves, KNOX is excluded making the leaves simple (Hay A, Tsiantis M 2006 Nature Genet 38:942). In tomato, the wildtype plant has compound leaves composed of several leaflets. The semidominant *lanceolate* (*LA*) mutation in chromosome 7 alters the leaf shape and structure. *LA* encodes the TCP transcription factor

Figure M108. Thallusin

with miR319 (microRNA) binding site. Base substitution mutations in the binding site reduce or eliminate TCP inhibition required for the development of the wild type compound leaf (see Fig. M110).

Figure M109. *C. hirsuta* *A. thaliana*

M

The exact chemical nature of many morphogens is unknown, however, some hormones and proteins have these properties. There is some evidence that some morphogens (produced by Wingless and Hedgehog) are moved in the cell by association with glycosphosphatidylinositol (Panáková D et al 2005 Nature [Lond] 435:58). The morphogen is either a transcription factor or a type of transcriptional regulator. The slope of the *Decapentaplegic* gene expression acts as a morphogen on wing development and the expression gradient regulates growth (Rogulja D, Irvine KD 2005 Cell 123:449). Control by morphogens involves concentration gradients over a threshold level. Generally, the initial morphogen signal recruits other similar signals and signal receptors (encoded by genes) which act positive or negative manners and determine cell fates and bring about a differentiatonal event(s). Generally the production rate, the effective diffusion coefficient, the degradation rate, and the immobile fraction of the morphogen contribute to the pattern of the morphogenic differentiation (see Fig. M111) (Kicheva A et al 2007 Science 315:521). The activin signal (a member of the transforming growth factor- β family) spreads in a passive gradient about 300 μ m or 10 cells diameter within a few hours in the vegetal cells of animals. ►morphogenesis, ►vegetal pole, ►activin, ►cross-talk, ►signal transduction, ►selector genes, ►cue, ►wingless, ►hedgehog, ►TCP, ►microRNA; Pagès F, Kerridge S 2000 Trends Genet 16:40; Tabata T 2001

Morphogenics: Morphogenics employs a dominant negative mismatch repair gene to create genetic diversity within defined cellular systems and results in a wide range of phenotypes. It has been used in immunology and drug development (Nicolaidis NC et al 2005 Ann NY Acad Sci 1059:86). ►mismatch, ►mismatch repair

Morphogenesis: The process of development of form and structure of cells or tissues and eventually the entire body of an organism beginning from the zygote to embryonic and adult shape. Morphogenesis is mediated through morphogens in response to inner and outer factors. Morphogenesis takes place in three phases: determination, differentiation, and development. Determination is a molecular change preparing the cell (or virus) to competence for differentiation. Differentiation is the realization of molecular and morphological structures that determines the differences among cells that are endowed with identical genetic potentials. The events of differentiation are coordinated in sequences of development. These steps generally occur in this order, yet may run in overlapping courses for different aspects of morphogenesis. The morphogenetic events vary in different organisms because this is the basis of their identity, yet some basic principles are common to all. The start point of morphogenesis is difficult to pinpoint because these events run in cycles of generations (what comes first: the egg or the hen?). The life of an individual begins with fertilization of the egg by the sperm and the formation of the zygote. The zygote has all the genes that it will ever have (*totipotency*) yet many of these genes are not expressed at this stage. (New genes may be acquired during life cycle by mutational conversion of existing ones or by transformation and transduction). Also, there are *maternal effect* genes that control oogenesis and affect the zygote from outside without being expressed at this stage within the embryo's own gene repertory. Morphogenesis cannot be explained by one general set of theory, e.g., *gradients of morphogens* or the *signal relay* system. Apparently, evidence for

either can be found in different morphogenetic pathways. Many structures in higher eukaryotes are under the control of partially redundant gene families. In different tissues different sets of transcription factors or transcriptional activators and enhancers may orchestrate in a combinatorial manner the expression of different cell types, adapted to a particular organ. The cytoskeleton and cell adhesion may determine cell shape. Signals originating outside or inside the cell may act as morphogens and by their concentration gradients along their distribution path may trigger morphogenetic changes. Alternatively, it has been suggested that signals induce a change in one type of cell that then through a relay of series of cells influences other cells to various types of changes. For example, signals transmitted to metalloproteinases, collagenase-1, and stromelysin-1 mediated by the RAS family (Rac) GTP-binding proteins are also involved in cell morphogenesis. ▶*Drosophila*, ▶homeotic genes, ▶morphogens, ▶signal transduction, ▶clonal analysis, ▶developmental genetics, ▶signal transduction, ▶RNA localization, ▶RAS, ▶Rac, ▶metalloproteinases, ▶cytoskeleton, ▶CAM, ▶imaginal disks, ▶oncogenes, ▶morphogenesis in *Drosophila*, ▶pattern formation, ▶RNA localization, ▶founder cells, ▶segregation asymmetric, ▶organizer, ▶anchor cell, ▶Hensen's node, ▶morphogenetic furrow, ▶development, ▶mRNA targeting, ▶compartmentalization, ▶primitive streak, ▶cue, ▶Notch, ▶left-right asymmetry, ▶selector genes; Madden K, Snider M 1998 Annu Rev Microbiol 52:687; Chase A 2001 Bioessays 23:972; high resolution X-ray computed tomography of animal morphology: <http://www.digimorph.org/>.

Morphogenesis in *Drosophila*: Morphogenesis in *Drosophila* has been the most extensively studied with

genetic techniques (see Fig. M112). Oogenesis requires four cell divisions within the oocyst (see illustration of maternal effect genes) resulting in the formation of 16 cells, one oocyte, and 15 nurse cells. The latter become polyploid and are surrounded by a single layer of somatic (diploid) follicle cells. The nurse cells are in communication with the egg through cytoplasmic channels. Both the nurse cell genes (somatic maternal genes) and the egg (germ-line maternal genes) influence the fate of the zygote through morphogens. The oocyte itself is transcriptionally not active. These maternal effect genes determine the polarity of the zygote (see Fig. M113). The anterior-posterior gradients of the morphogens account for the future position of the head and tail, respectively. Genes *gurken* (*grk*, 2–30) and *torpedo* (2–10) play an important role in anterior-posterior polarity and later during development also of dorso-ventral determination. The dorso-ventral determination is responsible for the sites of the back and belly, respectively. The medio-lateral polarities are involved in the determination of the left and right sides of the body. The larvae and the adults develop from 12 compartments, one for the head, three for the thorax, and nine for the abdomen, formed already during the blastoderm stage of the embryo.

Mutation of the maternal genes mentioned in the box below usually cause recessive embryo lethality although the homozygous mothers are generally normal. The males are usually normal and fertile. The molecular basis of their actions is known in a few cases. E.g., the amino terminal of the DL protein is homologous to the C-REL (avian reticuloendothelial viral oncogene homolog) protooncogene, which is present in human chromosome 2p13–2cen, and in mouse chromosome 11. The N terminus of *dorsal* is homologous to the product of gene *en* (*engrailed*,

Figure M112. Embryogenesis in *Drosophila*

Figure M113. Head and wing landmarks of *Drosophila*

2–62) that is also expressed during gastrulation in stripe formation of the embryo. The carboxyl terminus of the *sna* gene product appears to contain five Zinc-finger motifs indicating a DNA binding mechanisms of transcription factors.

Somatic maternal effect lethal genes: in *Drosophila* {1} *tsl* (*torsolike*, chromosome 3–71) controls the anterior-posteriormost body structures (labrum, telson). Genes {2} *pip* (*pipe*, 3–47), {3} *dl* (*dorsal*, 2–52.9) eliminate ventral and lateral body elements, and their product is homologous to the *c-rel* proto-oncogene, a transcription factor homolog, NF-κB. {4} *ndl* (*nudel*, 3–17) exaggerates dorsal elements of the embryos, {5} *wbl* (*windbeutel*, 2–86) controls dorsal epidermis, and the {6} *sna* (*snail*, 2–51) strong alleles eliminate most mesodermal tissues. {7} The *gs* (*grandchildless*, 1–21), *gs(2)M* (chromosome 2) cause blockage of the embryos of normal-looking homozygous females before the blastoderm stage at temperature above 28.5 C°.

Maternal and germline genes (A very incomplete list. Numbers in parenthesis indicate map locations):

{8} *ANTC* (*Antennapedia Complex*, 3–47.5): This contains elements *lab* (*labial*), *pb* (*proboscipedia*) *Dfd* (*Deformed*), *Scr* (*Sex combs reduced*), and *Ant* affecting head structures in anterior-posterior relations. The *lab* and *pb* elements share cuticle protein genes. Elements (*ftz*) *fushi tarazu*, (*zen*) *zerknüllt*, and *z* (*zen-2* [*zpr*]) affect segment numbers and (*bcd*) *bicoid* functions as a maternal effect gene eliminating anterior structures (head) and duplicating posterior elements (telsons). The product of *bcd* also binds

RNA and acts as a translational suppressor of the *caudal* (*cad*) protein product. The *bcd* and *zen* genes are included in a 50-kb transcription unit called *Ama* (*Amalgam*). The latter four do not have homeotic functions. *Scr* regulates the segmental identity of the anterior thorax and the posterior part of the head is under the control of (*Scr*, *Dfd*, *pb* and *lab*). The entire complex encompasses 355-kb genomic DNA with multiple exons. Eight of the gene products are transcription factors and *Ant*, *Scr*, *Dfd*, *pb*, and *lab* have homeotic functions. The *Antp* (*Antennapedia*) gene has both lethal and viable loss-of-function and gain-of-function recessive and dominant alleles controlling structures anterior to the thorax and the thoracic segments. The first mutations observed converted the antennae of the adult into mesothoracic legs. The gene has two promoters and four transcripts that control differently the spatial expression, relying also on alternate splicing. The *bcd* gene is situated within *zen*, and *Ama* is a maternal lethal that affects head and thorax development. The strong alleles in the females replace the head and thorax of the embryos with duplicated telsons.

Injection of *bcd*⁺ cytoplasm into the embryo (partially) remedies the topical alterations brought about by mutant alleles. The RNA transcript sticks to the anterior pole of the embryo and forms a steeply decreasing gradient in the posterior direction. This *bcd* gradient is regulated by genes *exu*, *swa*, and *stau*, (see them below) and the gradient may be eliminated by mutations in these genes. In *bcd*[−] embryos, the anterior activity of *hb* is eliminated and replaced by

mirror image posterior *hb* stripes. The four exons are transcribed in either a long, complete RNA (2.6-kb) or a short one (1.6-kb) with exons 2 and 3 spliced out. The protein contains homologous tracts to the non-maternal effect genes *prd* (*paired*, 2–45, involved in the control of segmentation) and *opa* (*odd paired*, 3–48, that deletes alternate metasegments). Exon 3 contains the homeodomain with only 40% homology to other homeoboxes. The C-termini of the *bic* protein appears to be involved in transcription activation by binding to five high-affinity upstream sites of *hb* (TCTAATCCC). *Dfd* (*Deformed*) is a weak homeotic gene with recessive and dominant lethal alleles affecting the anterior ventral structures of the head; occasionally thoracic bristles may also appear on the dorsal part of the head. It is composed of five exons coding for a 586-residue protein. Gene *ftz* (*fushi tarazu* [segment deficient in Japanese]) has both recessive late embryo lethal and dominant and viable regulatory alleles affecting genes in the *BXC* (*Bithorax complex*), *Ubx* (*Ultrabithorax*, 3–58.8), involved in the control of the posterior thorax and abdominal segments. The general characteristics of *ftz* are the pair-rule feature, i.e., in the mutants the even numbered abdominal and nerve cord segments are deleted (or fused). The striped pattern of the abdomen is controlled within a 1-kb tract upstream of the beginning of transcription, whereas a more distal upstream element regulates the central nervous system and an even more distal tract is required for the maintenance of the striped pattern. The homeobox is within the second of the two exons of this gene. The *ftz Rpl* mutations may transform the posterior halteres into posterior wing, while the *ftz Ual* mutations convert patches of the first adult abdominal segment into a third abdominal segment-like structure. (The latter two types are not embryonic lethal as the others). The *lab* (*labial*) mutations are embryonic lethal because of the failure of head structures. The protein product of the gene contains *opa* (*odd paired*, 3–48; deletes alternate metasegments) as well as a homeodomain although it does not display homeotic transformations. Gene *pb* (*proboscipedia*) may convert labial (“lip”) portions into prothoracic leg structures or antennae. From the nine exons, #4 and #5 contain the homeobox and in exon 8 there are again *opa* sequences. The gene products (RNA and protein) are localized to the general area affected by the mutations. Null mutations in gene *Scr* (*Sex combs reduced*) are embryonic lethals. Homeotic transformations involve the labial and thoracic areas. Dominant mutation reduces the number of sex comb teeth. Gene *z2* (*zen-2*) has no detectable effects upon development. Gene *zen* (*zerknüllt*) mutations may involve embryo lethality and the products may be required for post-embryonic development.

{9} *arm* (*armadillo*, 1–1.2): Cell lethal at the imaginal disc stage because an anterior denticle belt replaces the posterior part of each segment. Transcripts have been found in all parts of the larva.

{10} *bcd* (*bicoid*): See *AntC*

{11} *bic* and *Bic* (*bicaudal*, 2–67, 2–52, 2–52.91): Genes affect the anterior poles of the embryo by replacing these segments with posterior ones in opposite orientation. *Bic* apparently encodes a protein homologous to actin, a part of the cytoskeletal system.

{12} *btd* (*buttonhead*, 1–31): Mutations fail to differentiate the head.

{13} *BXC* (*Bithorax complex*, 3–58): *BXC* is a cluster of genes that determine the morphogenetic fate of many of the thoracic and abdominal segments of the body. The second thoracic segment, which develops the second pair of legs and a pair of wings, is the most basic part of the complex. The genetic map appears as follows:

abx bx Cbx **Ubx** bxd pbx iab2 **abd-A** Hab iab3 iab4
Mcp iab5 iab6 iab7 **Abd-B** iab8 iab9

The entire complex is organized into three main integrated regions: *Ubx* (*Ultrabithorax*) is responsible for parasegments PS 5–6, *abd-A* (*abdominal-A*) defines the identity of PS7–13, and *Abd-B* (*Abdominal-B*) is expressed in PS10–14. In the *Ubx* domain, *anterobithorax-bithorax* (*abx-bx*) region specifies PS5 and *bithorax-postbithorax* (*bxd-pbx*) defines PS6. In the *abd-A* region are *iab2*, *iab3*, and *iab4*, and in *Abd-B* are *iab5* to *iab9* elements. Mutations in *iab* (*infra-abdominal*) tracts cause the homeotic transformation of an anterior segment to a more anterior abdominal (A) segment (e.g., A2→A1 or A3 [or more posterior ones]→A2, etc.) Mutation *abx* (*anterobithorax*) causes changes in thoracic (T) and abdominal (A) segments: T3 → T2, *bx* (*bithorax*): T3 → T2, *Cbx* (*Contrabithorax*): T2 → T3, *Ubx* (*Ultrabithorax*): A1+ T3 → T2 and T2+ T3→T1, *bxd* (*bithoraxoid*): A1 → T3, *pbx* (*postbithorax*): T3 → T2, *abd-A* (*abdominal-A*): A2 to A8 → A1, *Hab* (*Hyperabdominal*): A1+ T3 →A2, *Mcp* (*Miscadstral pigmentation*): A4 & A5 to an intermediate between A4 & A5, *Abd-B* (*Abdominal-B*): A5, A6, A7, which may be weakly transformed into anterior forms. Most of these changes involve only some structures in the segments but additional alterations may also occur.

{14} *cact* (*cactus*, 2–52) mutations reduce the dorsal elements and enhances ventral structures. This gene encodes a homolog of the I κ -B protein, which forms a complex with product of *dl*, a NF- κ B homolog transcription factor, which is released from the complex upon phosphorylation of the *cact* product. After entering the cell nucleus, it may participate in the activation of its cognate genes.

{15} *capu* (*cappucino*, 2–8) mutations may be lethal. It causes somewhat similar alterations as *stau* in addition to making pointed appendages on the head.

{16} *ci^P* (*cubitus interruptus^P*, Dominant, 4.0): The wing vein 4 is twice interrupted proximal and distal to anterior crossvein. In homozygotes, the anterior portions of the denticle belts are duplicated in a mirror image manner in place of the posterior parts, and they are lethal.

{17} *dpp* (*decapentaplegic*, 2–4.0, [old name was *ho*]) is a complex locus with multiple developmental functions (it is homologous to BMP, TGF- β). The haploid-insufficiency *Hin*/+ condition is dominant embryonic lethal because of defects in gastrulation. The *Hin-Df* (deficiency) and *hin-r* (recessive) are also lethal. The *hin-emb* is an embryonic lethal mutation. It is complementary to the *shv* (*shortvein*) and *disk* (*imaginal disk*) region genes in the same complex. The *shv-lc* recessive larva-lethal mutants complement all *disk* alleles but mutant *Hin* and *hin-r*. Mutants *shv-lnc* do not complement *disk*, *Hin* or *hin-r*, and *shv-p* alleles are viable and complement the disk mutants but not *Hin* or *hin-r*. Another mutation in the *shv* region, *Tg* (*Tegula*) causes the roof-like appearance of the wings. This mutation is complementary to all *dpp* genes. The *disk* group of mutations is either viable or lethal and may affect the eyes, wings, haltere, genitalia, head, imaginal disks, etc. The *dpp* gene apparently acts as regulator of mesodermal genes and it encodes a secreted protein of the TGF- β family transforming growth factor, involved in mammalian cancerous growth.

{18} *ea* (*easter*, 3–57) involves maternal effect lethal with loss- or gain-of-function effects on the dorsal, mesodermal, or lateral structures, depending on the alleles. The mutants may be rescued by injection of normal cytoplasm.

{19} *ems* (*empty spiracles*, 3–53): The interior of the breathing orifices are partially missing and it is embryo lethal.

{20} *en* (*engrailed*, 2–62): some point mutations and chromosome breaks are viable. Others display “pair rule” defects, adjacent thoracic and abdominal segments fuse.

{21} *eo* (*extra organs*, 1–[66]) in the homozygous lethal embryos causes head defects and ventral hole.

{22} *eve* (*even skipped*, 2–58), lethal segmentation and head defects, “pair rule” effects. Its expression is reduced in *h* mutants and *en* segments do not appear. The expression of *Ubx* protein is high in the odd-numbered parasegments 7 to 13 rather than in every segment from 6 to 12; the *ftz* segments are disrupted.

{23} *exu* (*exuperantia*, 2–93) replaces the anterior part of the head with an inverted posterior mid-gut and anal pit (proctodeum).

{24} *fs(1)K10* (*female sterile*, 1–0.5) and a whole series of other *fs* genes in chromosome 1 may have both specific and overlapping effects. Expression may depend on cues from the oocyte. Eggs of homozygous females are rarely fertilized but if they are, the gastrulation is abnormal, the anterior ends are dorsalized.

{25} *fu* (*fused*, 1–59.5): Veins L3 and L4 are fused beyond the anterior crossvein with the elimination of the latter. Heterozygous daughters of homozygous mothers have a temperature-sensitive segmentation problem that is not observed in reciprocal crosses.

{26} *ftz* (*fushi tarazu*): See *AntC* above (also in a separate entry).

{27} *gd* (*gastrulation defective*, 1–36.78) causes dorsal and ventral furrowing of the gastrula stage embryos.

{28} *gsb* (*goosberry*, 2–107.6) is homozygous lethal because the posterior part of segments are deleted and the anterior parts duplicated in mirror image fashion.

{29} *gt* (*giant*, 1–0.9): increased size larvae, pupae and imago based on increased cell size. DNA metabolism is abnormal and both viable and lethal alleles are known affecting many ways the entire embryo. The protein product appears similar to that of *opa*.

{30} *h* (*hairy*, 3–26.5) displays extra microchaetae along the wing veins, membranes, scutellum, and head. It is also a “pair rule” gene and affects the expression of *ftz*. It also regulates the expression of genes in the ASC (*achaete-scute* complex, 1–0.0) involved in the control of hairs and bristles. The major gene products are located in the posterior and adjacent anterior parts of segment primordia.

{31} *hb* (*hunchback*, 3–48) alleles have different effects; the class I alleles among other effects lack thoracic and labial segments, class II mutants retain the prothoracic segment, class III alleles retain also the labial parts, class IV mutations prevent the formation of the mesothoracic segments, class V alleles also cause various gaps as well as segment transformations. These alleles are transcribed from two different promoters and produce up to five different transcripts. The products of this locus interact with those of *kr* and *ftz*. The product of *nos* activates some of the *hb* alleles. The dMi-2 proteins in cooperation with *hb* repress *Polycomb* (see ► *Polycomb* under separate entry at P).

{32} *hh* (*hedgehog*, 3–81): in homozygous embryos a posterior-ventral portion of each segment is removed and the anterior denticle belt is substituted for in a mirror image. The embryos may not have demarcated segments. The gene has two activity peaks: during the first 3–6 hr and at 4–7 days of development (see more under separate entry).

{33} *kni* (*knirps*) [3–46]: these are lethal zygotic gap mutants. Its shorter transcript is expressed only

until the blastoderm stage but the longer one is expressed even after gastrulation. The NH₂ end of the protein is homologous to one of the vertebrate nuclear hormone receptors. The *kni* box, a Zn-finger domain, is homologous to parts of the products of genes *knrl* (*knirps-related*, 3–[46]) and *egon* (*embryonic gonad*, 3–[47]).

{34} *Kr* (*Krüppel*, 2–107.6) mutants show gaps in thoracic and abdominal segments and other anomalies, and are lethal when homozygous. The protein product has similarity to the Zn-finger domain of transcription factor TFIIB. It interacts with transcription factors TFIIB and TFIIE β . In monomeric form it is an activator, in the dimeric form at high concentration it represses transcription. This protein binds to the AAGGGGTAA motif upstream of *hb*. It also affects other maternal effect genes. The GLI oncogene is a homologue.

{35} *nkd* (*naked cuticle*, 3–47.3): Denticle bands are partially missing; germ bands are shortened and thus lethal.

{36} *nos* (*nanos*, 3–66.2) is active in the pole cells, and transport of its product in anterior direction is required for the normal abdominal pattern, and it is essential for the normal development of the germline. It is a maternal lethal gene. Its product represses that of *hb* in the posterior part of the embryo. Deficiency of both *hb* and *nos* is conducive, however, to normal development.

{37} *oc* (*ocelliless*, 1–23.1): Some alleles are viable although the ocelli are eliminated; others (*otd*) involve lethality because of neuronal defects.

{38} *odd* (*odd skipped*, 2–8): Embryonic lethal because posterior part of the denticle bands are replaced by the anterior parts in mirror image fashion in T2, A1, A1, A3, A5, and A7.

{39} *opa* (*odd paired*, 3–48): Alternate metasegments are genetically ablated. Denticle bands of T2, A1, A3, A5, A7, and naked cuticle of T3, A2, A4, and A6 are absent. The product of *en* is lost but that of *Ubx* increases in even-numbered parasegments.

{40} *osk* (*oskar*, 3–48): Homozygous females and males are fertile but the embryos produced by homozygous females are defective in the pole cells and consequently also in abdominal segments; IT affects also *BicD* and *hb* expression.

{41} *phl* (*pole hole*, 1–0.5) blocks the formation of anterior–posterior end structures as well as the entire 8th abdominal segment. The phenotype is similar to that caused by *tso*. It is the *raf* oncogene in *Drosophila*.

{42} *pll* (*pelle*, 3–92) gene causes maternal embryo lethality by preventing the formation of ventral and lateral structural elements.

{43} *prd* (*paired*, 2–45): In strong mutants the anterior parts of T1, T3, A2, A4, A6, and A8 and

posterior parts of T2, AS1, A3, A5, and A7 are absent.

{44} *run* (*runt*, 1–[65.8]; syn. *legless* [*leg*]): A “pair rule” embryo lethal; eliminates the central mesothoracic and the uneven numbered abdominal denticle belts. The deletions are accompanied by duplication of the more anterior structures. The wild type allele appears to regulate the expression of *eve* and *ftz*.

{45} *slp* (*sloppy paired*, 2.8): Parts of the naked cuticle are missing from T2, A1, A3, A5, and A7 in an irregular way and it causes lethality.

{46} *sna* (*snail*, 2–51): Embryonic lethals causes the dorsalization and reducing or eliminating of most of the mesodermal tissues. The C-terminus of the polypeptide encoded has five Zn-finger motifs.

{47} *snk* (*snake*, 3–52.1) is a maternal lethal gene with dorsalizing effects. The encoded polypeptide contains elements homologous to serine proteases.

{48} *spi* (*spitz*, [*spire*], 2–54) is embryonic lethal blocking the development of anterior mesodermal tissues.

{49} *spz* (*spätzle*, 3–92): Maternal lethal alleles accentuate dorsal structures.

{50} *stau* (*staußen*, 2–83.5) ablates pole cells and other anterior structures and some abdominal segments; causes the *grandchildless-knirps* syndrome. The Staufen protein binds RNA, and along with the Prospero RNA, is asymmetrically partitioned into the ganglion mother cells (GMC) and thus, they determine neuroblast cell fate. It functions also nonsense-mediated decay.

{51} *swa* (*swallow*, 1–15.9) is expressed in the nurse cells and the product is transported to the oocyte and into the blastoderm until gastrulation, leading to problems with nuclear divisions, head, and abdominal defects. In *swa* homozygotes the *bcd*⁺ products are disrupted.

{52} *tl* (*Toll*, 3–91): Females heterozygous for the dominant or homozygous for the recessive *tl* mutant alleles produce lethal embryos that are defective in gastrulation and dorsal or ventral structures. The gene product is an integral membrane protein. Toll-like proteins are receptors of interleukin signals in the innate immunity system of mammals.

{53} *tll* (*tailless*, 3–102) deletes several posterior structures (Malpighian tubules, hindgut, telson), but brain and other anterior structures are also missing. Its expression is required for the manifestation of “pair rule” genes, *h* and *ftz*, in the 7th abdominal segment and for site-specificities of *cad* (*caudal*, 2–[55]) involved with head, thorax, and abdominal structures and regulation of *ftz*, *hb* (see above), and *fkh* (*fork head*, 3–95, involved with homeosis in both anterior and posterior structures of this non-maternal embryonic lethal). Gene *tll* has negative effects on genes *kni*, *Kr*, *ftz* and *tor*.

{54} *tor* (*torso*, 2-[57]) locus has both loss-of-function and gain-of-function alleles. The former type of alleles eliminate anterior-most head structures and segments posterior to the 7th abdominal segment. The latter type alleles are responsible for defects in the middle segments and enlargement of the most posterior parts of the body. The gene is expressed in the nurse cells, oocytes, and early embryos. The expression of *ftz* is reduced in the gain-of-function *tor* mutants, whereas *phl* mutations are epistatic to *tor*. With the exception of the NH₂ terminus, the protein is homologous to the growth factor receptor kinases of other organisms. It is concentrated in both pole cells and at the surface cells. Apparently, the product of this gene receives and transmits maternal information into the interior of the embryo.

{55} *trk* (*trunk*, 2-36) mutants lack anterior head structures as well as segments posterior to the 7th abdominal band.

{56} *Tub* (*tubulin* multigene families, scattered in chromosome 2 and 3). The α *Tub* genes are responsible for the production of α -tubulin and are apparently active in the nurse cells; the transcripts accumulate in the early embryo and the ovaries and control mitotic and meiotic spindle and cytoskeleton. The β -tubulin genes are expressed in the nurse cell, early embryos, and various different structures and organs.

{57} *tud* (*tudor*, 2-[97]): The germline autonomous mutants display the “grandchildless-knirps” phenotype and lack pole cells, yet about 30% of the embryos survive into sterile adults.

{58} *tuf* (*tufted*, 2-59): Segment boundaries are duplicated in a mirror image and other parts deleted and neuronal pattern altered.

{59} *twi* (*twist*, 2-100): Mutants are embryo lethal with defects in mesodermal differentiation. The embryos are twisted in the egg case. Mutations at the *dl*, *ea*, *pll*, and *Tl* loci prevent the expression of *twi*. The *twi* polypeptides are homologous to DNA-binding myc proteins.

{60} *Ubx* (*Ultrabithorax*, 3-58.8): See *BXC*

{61} *vas* (*vasa*, 1-[64]) affects the pole region and segmentation (*grandchildless-knirp* syndrome). The protein product is homologous to murine peptide chain translation factor eIF-4A.

{62} *vls* (*valois*, 2-53): The phenotype is very similar to that caused by *vas*.

{63} *wg* (*wingless*, 2-30): Visible, viable, and lethal alleles control segmentation pattern and imaginal disk pattern (wings and halteres). Its protein product is homologous to the mouse mammary oncogene *int-1* (INT1/Wnt). It appears that *frizzled* (*fz*) is the receptor of *wg*. The signal then may be transmitted to *Dsh* and *Arm* (β -catenin) and transcription of *En* is turned on with the assistance of

other factors. (See more under ►*wingless* and ►*wnt* entries).

{64} *zen* (*zerknüllt*) is a segment of *ANTC* {8} affecting segmentation and dorsal structures of the early embryo.

The maternal germline mutations are genetically identical in the unfertilized egg and their gene products generally cause lethality in the egg or in the homozygous embryos. The heterozygous mothers are semi-sterile and the males are usually fairly normal in appearance and in function. The molecular bases of a few such lethal genes are known. E.g., the *phl* gene appears to be homologous to the *v-raf* protooncogene and *phl* gene is the *Drosophila raf* gene that encodes a serine-threonine kinase protein also in humans and mice. The *snk* locus encodes a protein that appears to have a calcium-binding site at the NH₂-end and with homology to several serine proteases at its C terminus. The product of the *ea* gene has some homology to an extracellular trypsin-like serine proteases. Specific cytoplasm extracted from some (e.g., *osk*, *tor*, *ea*, *bcd*) unfertilized normal eggs or from normal embryos when injected into the mutant cytoplasm end may rescue the embryos that develop into sterile adults. The 923-amino acid protein encoded by *tor* has no homology to other known proteins in the NH₂-end but the rest of it is similar to a growth factor receptor tyrosine kinases and a hydrophobic segment appears to be associated with the cell surface membrane. The product of the *Tl* locus is an integral membrane protein with both cytoplasmic and extracytoplasmic domains containing 15 repeats of leucine-rich residues resembling yeast and human membrane proteins. The cytoplasmic domain is homologous to the interleukin-1 receptor (IL1R), the heterodimeric platelet glycoprotein 1b, and coded in human chromosome 2q12 and mouse chromosome 1 near the centromere.

Although all of the mutants assigned to different chromosomal locations have different molecular functions, the phenotypic manifestation may not necessarily distinguish that. The majority of the morphogenetic-developmental mutations is pleiotropic (e.g., affects the pole cells and causes the *grandchildless-fushi tarazu* syndrome). Many display epistasis and indicate the complex interactions of the regulatory processes involved (e.g., the expression of *twi* may be prevented by mutations at *dl*, *ea*, *pll*, and *Tl*). The genes may be expressed at a particular position but their products form a diminishing gradient (e.g., *bcd*, *nos*). The DNA-binding protein encoded by *bcd*, depending on its quantitative level, then regulates qualitatively the transcription of, e.g., *hb*. Some of the genes display the so-called “gap” effect. They eliminate particular body segments, e.g., *kni*, *Kr*; and *hb*. The so-called “pair rule”

genes may eliminate certain body segments and replace them with others (e.g., *ftz*, *eve*) or eliminate half of the segments and fuse them together in pairs (e.g., *en*). Several of the genes, particularly those in the huge *BTC* and *ATC* clusters, may display homeotic effects. Although a great deal of information has been gathered on these genes primarily during the last decade, more specific knowledge is required for understanding the precise functions (especially the interacting circuits) of the morphogenetic processes. With the aid of microarray hybridization, information on the interacting systems will greatly expand. It appears that these genes are frequently preferentially expressed at a particular position. Their mRNA or protein product is then spread in a gradient to the sites of the required action. In some instances, only the RNA is spread and the protein is made locally. The position of morphogenetic function is controlled by a hierarchy of signals. These genes are expressed differently in different time frames and in coordinated sequences. The coordination is provided by the interaction of gene products. The same protein may turn on a set of genes and turn off others, depending also on the local concentration of the products.

According to their **main** effects, some of these genes may be classified into groups, others are more difficult to place in any of the groups because they all affect several stages and different structures. (The horizontal line stands for the embryo axis and the arrows or gaps illustrate the typical sites of action; the best representative genes are bracketed):

 HOMEOTIC GENES: genes within the *Antennapedia Complex* (8), and the *Bithorax Complex* (13)

The development of wing veins is controlled by several genes. Locus *vn* (*vein*, 3–16.2, *Vein*, 3–19.6) disrupts longitudinal vein L4, posterior crossvein and sometimes L3, *ri* (*radius-incompletus* 3–46.8) interrupts L2, and mutations in *px* (*plexus*, 2–100.5) produce extra veins. *N* (*Notch*, 1–3.0) complex (*Ax*, *Co*, *fa*, *l(1)N*, *N*, *nd*, *spl*), with a very large number of (dominant and recessive) alleles, are homo- and hemizygous lethal and remove small portions of the ends of the wings and affect also hair and embryo morphogenesis, thickening of veins L3 and L5, and hypertrophied nervous system. *Notch* gene homologs are also present in vertebrates. The *N* complex codes for a protein with EGF-like repeats.

The *Ax* (*Abruptex*) homozygotes reduce the length of longitudinal vein L5 and commonly L4, L2, and sometimes L3. The various *Ax* alleles are either positive or negative regulators of *Notch*. The *Notch* signals are modulated by *fringe* and this gene determines the dorsal ventral boundaries. *Co* (*Confluens*) causes thickening of the veins. The *fa* alleles affect the eye facets and are non-complementary to the *spl* gene that also causes rough eyes and bristle anomalies. Gene *nd* (*notchoid facet*) is homozygous viable and displays some of the characteristics of the other genes within the complex. *E(spl)* (*Enhancer of split*, 3–89) mutation became known for exaggerating the expression of *spl* (enhancer in this context does not correspond to the term enhancer as used in molecular biology). This gene produces 11 similar transcripts. They share homologies with *c-myc* oncogene (a helix-loop-helix) protein and also with the β -transducin G protein subunit, known to involve signal transduction. *Dl* (*Delta*, 3–66.2) causes thickening of the veins (and a number of other developmental defects) and is responsible for a protein that has an extracellular element with nine repeats resembling the EGF, an apparent transmembrane and an intracellular domain with apparently five glycosylation residues. *Egfr* (*Epidermal growth factor receptor* [synonyms *top* {*Torpedo*}, *Elp* {*Ellipse*}, *fbl* {*faint little ball*}, 2–100) genes cause embryonic lethality and a number of other developmental effects including extra wing veins, eyes, etc.

The genes *wg* (see above {63} and *dpp* (see {17}) are involved in anteriorposterior specifications of the

embryo and thus, also in wing formation. Several other genes also affect wing and vein differentiation. Molecular evidence permits the assumptions that *Dsh* (dishevelled), a cytoplasmic protein is one of the receptors of the *Wg* protein signal. *Dsh* binds to *N* (*Notch*, a transmembrane protein) and inhibits its activity. When *N* binds to *Delta* it activates *Su(H)*, the suppressor of *hairless* (*H*). *Su(H)* then moves to the cell nucleus and operates as a transcription factor. The *Wg* signal can also activate the *Shaggy-Zeste white* (*Sgg-Za3*) serine- threonine kinase and the phosphorylation of *Armadillo* may lead the *Wg*-dependent gene expression. The level of *Armadillo* may be elevated also by binding *Wg* to a member of

Figure M114. Epidermogenic and neurogenic pathways in *Drosophila*

the frizzled family (Dfz2). This *frizzled* (*fz*, 3–41.7) appears to be another receptor of Wg. Diffusible protein product of *optomotor-blind* (*omb*, 1–{7.5}), which was initially identified on the basis locomotor activity, is also required for the development of the distal parts of the wing within the *wg-dpp* system.

A general picture of neurogenesis is also emerging (see Fig. M114). (Modified after Campos-Ortega, Knust 1992 p. 347. In: Development. Russo VEA et al (Eds.) Springer Vlg., New York):

amx (*almondex*, 1–27.7) is a locus with multiple functions including eyes [some alleles complement the *lozenge* mutants]. Most relevantly, in the mutants there is hyperplasia of the central - peripheral nervous system and a concomitant reduction in epidermogenesis.

mam (*master mind*, 2–70.3) also affects the eyes but mutations lead to neural hyperplasia and epidermal hypoplasia.

neu (*neural*, 3–50) mutations also cause neural hyperplasia and epidermal hypoplasia.

N and *DI* have been briefly described above. Both have protein products with epidermal growth factors (EGF)-like repeats. EGF has growth promoting signals and has ability to bind appropriate ligands.

E(spl): The wildtype alleles encode a protein with helix-loop-helix motifs, characteristic for transcription factors and displays similarities also to one subunit of the trimeric G proteins, which have key roles in several signal transduction pathways.

ASC (*achaete-scute complex*, 1–0.0) controls sensilla and micro- and macrochaetae that are sensory organs of the flies and correspond to the peripheral nervous system. The ca. 100-kb region contains four major distinguishable areas *ac* (*achaete*), *sc* (*scute*), *l(1)* *s* (*lethal scute*) and *ase* (*asense*). All four reduce and alter the pattern of the sensory organs. The dominant components, the *Hw* (*Hairy wing*) mutations, increase hairiness. Another regulatory mutation has been named *sis-b* (*sisterless b*). The complex includes nine transcription units. Four of them appear to be transcription factors because of the helix-loop-helix motifs.

svr (*silver*), *elav* (*embryonic lethal abnormal vision*), and *vnd* (*ventral nervous system defective*) all are affected in the nervous system and located at 0 position of the X chromosome just like *ASC*. A large number of other genes at various locations are

also involved in the nervous system. One must remember that in even a relatively simple organism, such as *Drosophila* ~ 14,000 genes exist and their functions are too complex to be represented by simple models. ▶ *Drosophila*, ▶ *homeotic genes*, ▶ *morphogens*, ▶ *gap genes*, ▶ *clonal analysis*, ▶ *developmental genetics*, ▶ *signal transduction*, ▶ *imaginal disks*, ▶ *oncogenes*, ▶ *pattern formation*, ▶ *selector genes*, ▶ *RNA localization*, some genes are described with more details under separate entries, ▶ *selector genes*; Morisato D, Anderson KV 1995 Annu Rev Genet 29:371; Mann RS, Morata G 2000 Annu Rev Cell Dev Biol 16:243.

Mortality: The condition of being mortal, i.e., subject to death. The rate of mortality is computed as the average number of deaths per a particular (mid-year) population. An important factor of (particularly) infant death rate is the coefficient of inbreeding. First cousin marriages (inbreeding coefficient 1/16) approximately double infant mortality. The rate of human mortality calculated as the number of deaths per 1000 population may vary substantially in different parts of the world. In the years 1955–59, in the USA it was 9.4, in England 11.6, in Japan 7.8. In some other parts of the world it was double or higher. *Extrinsic mortality* is an age and condition-independent concept. Infant mortality rate is highly correlated with the level of income in the world's 231 countries. In the 48 high-income countries, it is 0.8%, whereas in the lowest-income 67 countries, it was 79.2% by latest reports in 1999 (United Nations Demographic Yearbook, New York). In the same group of countries, birth was 7.9 and 55.8%, respectively. These figures indicate high birth rates and high infant and child mortality in the low-income countries. In the high-income countries the female literacy rate was 96, whereas in the low-income countries it was 68 and the health expenditure in dollars of purchasing power parity (PPP) was 2435 and 59 per capita, respectively. In the AIDS pandemic South Africa and Botswana, in the age group 15–49, mortality was 20.1 and 38.8%, respectively between 1997–1999. The median age in years in England, a high-economy country, was 40 and in the lower-resource-but-transitional country of Iran it was 20. More than 50/1000 births in developed countries are affected by genetically determined anomalies and almost 30% of them involve early mortality. Congenital heart disease involves more than 40% mortality and congenital malformation of the central nervous system is the second greatest cause of mortality at about 26%. In Western Europe, about 50% of the pregnancies with severe genetic/developmental defects are medically terminated. ▶inbreeding coefficient, ▶age-specific birth and death rates, ▶longevity, ▶aging, ▶juvenile mortality, ▶morbidity, ▶alcoholism substance abuse, ▶addiction, ▶smoking, ▶counseling genetic, ▶family planning, ▶prenatal diagnosis; Christianson A, Modell B 2004 Annu Rev Genomics Hum Genet 5:219; www.mortality.org.

Morula: A mass of blastomeres, containing 8–16 cells in the mouse (see Fig. M116) (the number of cells in humans is about twice or more) before implantation of the zygote onto the uterus by transfer the morula from the oviduct. ▶blastomeres, ▶blastocyst

Figure M116. Morula

Mos: ▶mariner

MOS (*mos*): ▶Moloney mouse sarcoma virus oncogene, ▶MITE

Mosaic: Mixture of genetically different cells or tissues. Mosaicism is generally the result of somatic mutation, change in chromosome number, deletion or duplication of chromosomal segments, mitotic recombination, nondisjunction, sister chromatid exchange, sorting out of mitochondrial or plastid genetic elements, infectious heredity, intragenomic reorganization by the movement of transposons or insertion elements, lyonization, gene conversion, lyonization etc.

A mosaic hybrid may be the result of co-dominance of the parental alleles (see Fig. M117). Some breeds, however, display homozygosity for mosaicism. Introduction of foreign DNA into the cells by transformation or gene therapy may also be the cause of mosaic tissues. Somatic mutation may be of medical importance and may lead to oncogenic transformation and the expression of cancer. Somatic reversion of recessive genes causing disease, e.g., reversion of adenosine deaminase (ADA) or the tyrosinemia (FAH) genes, followed by selective proliferation of the normalized sector, may alleviate the disease. Loss of the extra chromosome in trisomics or nondisjunction in monosomics may restore the normal chromosome number. When a mutation is induced only in a single strand of the DNA, its expression may be delayed, but in mice fur patches may occur in the heterozygotes

and these animals are called *masked mosaics*. ▶[sex-chromosomal anomalies in humans](#), ▶[variegation](#), ▶[lyonization](#), ▶[allophenic](#), ▶[mosaic variegated aneuploidy](#); Extavour C, Garcia-Bellido A 2001 Proc Natl Acad Sci USA 98:11341; Yousouffian H, Pyeritz RE 2002 Nature Rev Genet 3:748.

Mosaic Analysis with Double Marker (MADM): Two reciprocally chimeric genes, each containing the N terminus of one marker and the C terminus of the other marker interrupted by a loxP-containing intron, are knocked in at identical locations on homologous chromosomes (see Fig. M118). Functional expression of markers requires Cre-mediated interchromosomal recombination. Such a system can generate loss of heterozygosity in tumor suppressor genes and their fate in cancer development can be followed (Zong H et al 2005 Cell 121:479; Mazumdar MD et al 2007 Proc Natl Acad Sci USA 104:4495). ▶[Cre/loxP](#), ▶[LOS](#), ▶[tumor suppressor gene](#)

Mosaic Variegated Aneuploidy (MVA, BUB1B/BUBR1, 15q15): MVA is characterized by somatic aneuploidy (trisomy, monosomy) of different chromosomes and in different tissues, apparently due to defects in the spindle checkpoints and nondisjunction. The premature termination of the transcript leads to the formation of a truncated protein. The recessive disorder causes reduced intrauterine growth, microcephaly, eye anomalies, and other morphological

defects (Hanks S et al 2004 Nature Genet 36:1159). The mutation leads to carcinogenesis, and the condition is frequently associated with rhabdomyosarcoma, Wilms tumors, leukemia, colorectal cancer, etc. The same defect occurs in yeast and various vertebrates. ▶[cancer](#), ▶[aneuploidy](#), ▶[Wilms tumor](#), ▶[leukemia](#), ▶[colorectal cancer](#)

Mosolov model: In the Mosolov model, an extremely long DNA fiber is tightly packed into a very compact eukaryotic chromosome (see Fig. M119). One of the many existing models is shown here. Each line represents an elementary chromosome fiber, including the nucleosomal structure at various stages of folding. E conceptualizes the chromomeres. The elementary fiber is about 25 Å in diameter and forms a tubular coil (solenoid). D signifies the tightly coiled coils of the metaphase chromosomes. ▶[packing ratio](#), ▶[nucleosome](#), ▶[chromosome structure](#), ▶[chromosome coiling](#), ▶[SMC](#), ▶[condensin](#)

Most Recent Common Ancestor: ►MRCA, ►coalescent

Motheaten: Mutation in the SH2 domain of a tyrosine phosphatase of mice leading to autoimmune anomalies. ►tyrosine phosphatase, ►autoimmune disease, ►SH2; White ED et al 2001 J Leukoc Biol 69:825; Hsu HC et al 2001 J Immunol 166:772.

Mother-Fetus Compatibility: ►immune tolerance, ►Rh blood groups, ►incompatibility, ►mylotarg

Motif: A small, non-random assembly of structural domain or sequence of amino acids or nucleotides present in different macromolecules. Motifs are generally preserved during evolution and usually convey some functionality. The probability of a motif is matrix of probabilities. The column number in the matrix is the length (N) of the motif. The number of rows is four in DNA (the four kinds of nucleotides) and it is 20 in protein (the 20 common amino acids). Row number *i* and column number *j* specify the probability for finding a special appearance (instance) of a motif. ►protein domains, ►module, ►MP-score, ►matrix algebra, ►MOST; <http://www.bioinf.man.ac.uk/dbbrowser/PRINTS/>; motifs in different sets of genomic data: <http://fraenkel.mit.edu/webmotifs/>; new motif discovery: <http://genie.dartmouth.edu/scope/>.

Motif Ten EL6:47 PM (MTF): MTF promotes transcription by DNA-dependent RNA polymerase II when it is located in the core promoter at +18 to +22 from the initiator element (A+1). ►core promoter; Lim CY et al 2004 Genes Dev 18:1606.

Motif-Trap Technology: In motif-trap technology, random fragments of DNA fused to fluorescent protein are screened and their location in the cells is monitored. The procedure may facilitate the identification of the function of the unknown sequences. ►aequorin; Cutler SR et al 2000 Proc Natl Acad Sci USA 97:3718.

Motilin: A 22-amino acid, well-conserved, peptide hormone regulating motility of the intestinal tract. (See Coulie B et al 2001 J Biol Chem 276:35518).

Motor Proteins: Motor proteins can move along microtubules and actin filaments or macromolecules by deriving energy from the hydrolysis of energy-rich

phosphates such as ATP. They transport various molecules and vesicles within the cell. Motor proteins mediate some of the processes involved in establishing body plans, such as left-right, dorso-ventral, and anterior-posterior differentiation. Representatives include myosin, kinesin, dynein, helicases, bimC, etc. The MyoVa motor is involved in melanosome transport and organization of the endoplasmic reticulum in Purkinje cells. Motor protein defects are involved in several human diseases. ►microtubule, ►anaphase, ►duty ratio/duty cycle, ►myosins, ►actin, ►kinesin, ►dynein, ►Purkinje cells, ►albinism, ►cytoskeleton, ►caveolae; Karcher RL et al 2001 Science 293:1317; Schliwa M, Woehlke G 2003 Nature [Lond] 422:759; review: Mallik R, Gross SP 2004 Current Biol 14:R971; motor proteins in nanotechnology: van den Heuvel MGL, Dekker C 2007 Science 317:333.

Mountjack (*Muntiacus muntjack*): The male is $2n = 7$ and the female is $2n = 6$ but the *Muntiacus reevesi* is $2n = 46$ (see Fig. M121).

Figure M121. Mountjack chromosomes after Wurster & Bernischke

Mouse: The mouse of a computer is a pointer device.

Mouse (*Mus musculus*, $2n = 40$): Rodent belonging to the subfamily *Murinae*, including about 300 species of mice and rats (see Fig. M122). They are extensively used in genetics and physiological studies because of their small size (25–40 g), short lifecycle (10 weeks), life span of about two years, gestation ~19 days, having 5–10 pups/litter, and their practically continuous breeding. The genome is $\sim 1.8 \times 10^6$ kDa in $2n = 40$ chromosomes. The mouse genome is ~14% smaller than the human genome, yet about 40% of their genomes can be aligned. In one m² laboratory space up to 3,000 individuals can be studied annually. From embryonic stem cells, viable, fertile adults can be differentiated (Eggan K, Jaenisch R 2003 Methods Enzymol 365:25). Very detailed linkage information is available. According to the 1996 map the genetic length, based on 7,377 genetic markers including RFLP and other markers, is 1,360.9 units. The average spacing between markers then was 400 kb. A nucleotide sequence draft became available in 2002 and the final annotated sequence was expected by 2006. Transformation, gene targeting and other modern techniques of molecular genetic manipulations are well worked out. It is also very important

Figure M122. Mouse has a very large number of spontaneous and induced variations involving morphological, physiological, biochemical, and behavioral traits. that the mouse be used as a human genetic model for immunological, cancer, and other human diseases. About >85% of the autosomal gene repertory of the mouse displays conserved synteny with that in the human genome. The X chromosomal genetic structure is practically identical in man and mouse. *Mus spretus*, “a non-laboratory” relative, is similar in appearance to the laboratory mouse but it harbors many genetic differences and can form fertile female hybrids with the laboratory strains, which are inbred. Both of these species differ from the house mouse, *Mus domesticus*. In mice, Robertsonian translocations are common, and therefore the chromosome number may vary in different populations and in different individuals: <http://www.immunologylink.com/transgen.htm>. ►databases, ►animal models, ►ENU, ►MICER, ►IGTC, ►Encyclopedia of the Mouse Genome, ►Mouse Genome Database, ►Mouse Genome Informatics Group, ►Portable Dictionary of the Mouse Genome; Mapping information in *Nature* (Lond.) 380:149, knockout, radiation hybrid map: *Nature Genet* 1999 22:383; YAC-based physical map: *Nature Genet* 1999 22:388; Festing MFW 1979 *Inbred Strains in Biomedical Research*. Mouse Mammary Tumor Virus (MMTV): MMTV causes mammary adenocarcinomas (see Fig. M123). The virus is transmitted to the offspring by breastfeeding. If the virus is transposed within 10-kb distance to the *Wnt-1* oncogene (homolog of the *Drosophila* locus *wingless* [*wg*]), the insertion may activate the oncogene because of the very strong enhancer in the viral terminal repeat. APOBEC3 proteins are packaged into virions and inhibit retroviral replication in newly infected cells, at least in part by deaminating cytidines on the negative strand DNA intermediates. A3 provides partial protection to mice against infection with MMTV (Okeoma CM et al 2007 Nature [Lond] 445:927). Retroviral insertion mutagenesis revealed 33 insertion sites as potential sources of tumor (Theodorou V et al 2007 Nature Genet 39:759). ▶ [DNA-PK](#), ▶ [pattern formation](#), ▶ [retroviruses](#), ▶ [APOBEC](#), ▶ [breast cancer](#)

MPF (maturation protein factor/M-phase promoting factor): The MPF contains two subunits; a protein kinase (coded for by the *p34^{cdc2}* gene) and a B cyclin. Activation takes place (probably by phosphorylation at threonine 161 of the *p34^{cdc2}* protein) during M phase and deactivation is mediated by degradation of cyclin subunit during the rest of the cell cycle. MPF is deactivated also by phosphorylation at Thr-14 and Tyr-15 amino acid residues. These sites are dephosphorylated probably by the product of gene *p80^{cdc25}* or a homolog before the onset of mitosis. ▶protein kinases, ▶cyclin, ▶signal transduction, ▶*p34^{cdc2}*, ▶cell cycle, ▶APC; Frank-Vaillant M et al 2001 Dev Biol 231:279; Taieb FF et al 2001 Curr Biol 11:508.

MPF: Mating pair formation proteins of bacteria.

MPI (minimal protein identifier): The MPI serves as an index of protein identity on the basis of proteomics characteristics. ▶proteomics

MPK2: ▶p38

Mp1p: ▶See mitochondrial import

MPR: Mannose-6-phosphate receptor.

Mps: A kinetochore-associated kinase required for maintaining the anaphase checkpoint until the microtubules are attached to the kinetochore. It acts before the anaphase promoting complex. Mps1 participates also in the duplication of the centrosome in cooperation with Cdk2. ▶kinetochore, ▶checkpoint, ▶anaphase, ▶APC, ▶Cdk2, ▶centrosome; Abrieu A et al 2001 Cell 106:83; Fisk HA, Winey M 2001 Cell 106:95.

MP-Score: The mean sum of pairs score for a column in an alignment of motifs. In other words, the value of the SP-score divided by the total number of, e.g., amino acids. The SP-score is the sum of pair scores for a column in a multiple alignment. ▶motif

MPSS (multiple parallel signature sequencing): A system biology approach determining libraries of cDNAs from normal and diseased tissues. ▶cDNA, ▶massive parallel signature sequencing, ▶transcriptome; Brenner S et al 2000 Nature Biotechnol 18:630.

MPT (mitochondrial permeability transition): MPT indicates protein release from mitochondria and apoptosis and may be detected by ICAT. ▶apoptosis, ▶ICAT; Bruno S et al 2002 Carcinogenesis 23:447.

MQM: Marker-QTL-marker. ▶QTL

M_r (relative molecular weight): Relative molecular mass of a molecule compared to that of the mass of a C¹² carbon atom. This is different from the gram molecular weight, traditionally used in chemistry. ▶dalton

MR (*Male recombination*) factor of *Drosophila* (map location 2–54): Apparently, a defective P element (▶hybrid dysgenesis) that cannot move, yet it can facilitate the movement of other P elements. Besides causing recombination in the male, it induces many of the symptoms of hybrid dysgenesis, including chromosomal aberrations, high mutation rate, and mitotic exchange. ▶male recombination, ▶hybrid dysgenesis

MRCA (most recent common ancestor): An evolutionary concept for divergence or coalescence. If MRCA is old, many mutations could occur around a particular locus. However, if MRCA is young, the genetic background to the locus most likely did not change much during evolution. Also, if a mutation is young, the frequency of the allele may be low, because there was not yet enough time for it to diffuse (unless the selection coefficient was very large and positive). This would mean that rare mutations are young and young mutations are rare. On the bases of these three parameters, statistical procedures can be used to estimate the age of MRCAs (Patterson NJ 2005 Genetics 169:1093). ▶evolutionary tree, ▶coalescence, ▶diffusion genetic

MRD (mismatch repair detection): In MRD, DNA fragments are cloned and inserted into bacterial plasmids, and bacteria are transformed by the heteroduplex constructs. If there is a mismatch, the growing bacterial colonies become white, whereas in case of no mismatch the colonies are blue. The reporter gene is *LacZa*. The template for repair is a hemimethylated double-stranded DNA. Mismatches activate repair and the unmethylated strand is degraded, whereas the methylated strand becomes the template for repair. The method can scan up to 10-kb fragments for mismatches that are below five nucleotides in length. A revised procedure more suitable for high throughput analysis uses the Cre/lox recombinase, a tetracycline resistance (Tet^R), and a streptomycin sensitive (Str^S) marker. Two vectors are constructed and one of them carries a 5-bp deletion for the *Cre* gene. In other respects, the two vectors are identical. DNA fragments cloned in the active Cre⁺ vector are propagated in a bacterial strain, which is dam methylase free. The two clones are made only to be used as standard panels for testing human DNA samples. Human DNA fragments from each individual to be tested are first amplified and then pooled. Linearized methylated DNAs from the Cre-deletion and the Cre⁺ unmethylated DNA are combined in one vessel and single stranded PCR-amplified DNA is added. Subsequently, Taq ligase is added to generate hemimethylated, closed heteroduplex circles. The remaining linear strands are

removed by exonuclease III digestion. The heteroduplexes are cloned into an *E. coli* strain (carrying Str^R in its chromosome) carrying an F' plasmid with Tet^R and Str^S cassettes, each, flanked by two lox sites. The DNA strands, without mismatch, replicate normally in the bacterium and both types of plasmids survive. The Cre^+ protein mediates recombination between the two lox sites and as a consequence, the Tet^R as well as the Str^S genes are removed. The bacterial cell thus becomes tetracycline-sensitive but because of the presence of the chromosomal Str^R gene, it will thrive on streptomycin but not on tetracycline media. The mismatch in the heteroduplex will be repaired and the unmethylated Cre^+ strand will be degraded. The inactive Cre strand will, however, be used as a template for replication and thus, the intact Tet^R and Str^S cassettes will stay functional and cells carrying them will remain tetracycline-resistant and streptomycin-sensitive. The tetracycline and streptomycin resistant cells are propagated on Petri plates and their restricted DNA content can be assayed by gel electrophoresis. [▶ mismatch repair](#), [▶ lactose](#), [▶ Cre/lox](#), [▶ tetracycline](#), [▶ streptomycin](#), [▶ dam methylase](#), [▶ PCR](#), [▶ electrophoresis](#), [▶ restriction enzymes](#); Faham M, Cox DR 1995 *Genome Res* 5:474; Faham M et al 2001 *Hum Mol Genet* 10:1657.

MRE11: MRE11 mediates double-strand break repair in somatic cells in cooperation with Ku. In meiosis, it is expressed without Ku and apparently mediates repair of the recombined DNA strands. Its defects may cause symptoms of the Nijmegen breakage syndrome and ataxia telangiectasia. Mre11, Rad50, and Xrs2 complexes are important for DNA damage control, maintenance of telomere length, cell cycle checkpoint control, and meiotic recombination (Ghosal G, Muniyappa K 2005 *Nucleic Acids Res* 33:4692). mRNA: Messenger RNA carries genetic information from DNA for the sequence of amino acids in protein. Its half-life in prokaryotes is about 2 min, in eukaryotes 6–24 hr, or it may survive for decades in trees. In individual cells, the life of the mRNA may vary by an order of magnitude (Grunberg-Manago M 1999 *Annu Rev Genet* 33:193). Unstable mRNAs even in eukaryotes may last only for a few minutes. The mRNA is produced by a DNA-dependent RNA polymerase enzyme, using the sense strand of the DNA as template, and it is complementary to the template. The mRNA is derived from the primary transcript by processing, including the removal of introns (in eukaryotes). The size of the mRNA molecules varies a great deal because the size of the genes encoding the polypeptides is quite variable. Upstream of the coding sequences of the mRNA there are several regulatory sequences (G box, CAAT or AGGA box, etc.), which are important for transcription but are not included in the mRNA. Transcription begins by the recognition and attachment of the transcriptase to a TATA box and the assembly of the transcription complex. The eukaryotic mRNA is capped with a methylated guanylic acid after transcription. Preceding the first amino acid codon (Met in eukaryotes and fMet prokaryotes), there is an untranslated leader sequence that helps in the recognition of the ribosome. In prokaryotes, the leader includes the Shine-Dalgarno sequence which assures a complementary sequence on the small ribosomal unit. In eukaryotes, such a sequence is not known; however, usually there is a AG—CCAUGG preferred box around the first codon and the ribosomal attachment is relegated to “scanning” for it in the leader. The structural genes then follow that in eukaryotes have been earlier spliced together from a highly variable number of exons. In the eukaryotic mRNA, there are untranslated sequences also at the 3' end that include a polyadenylation signal (most commonly AAUAAA) to improve stability of the mRNA by post-transcriptional addition of over hundred adenylic residues. This signal is used also for discontinuing transcription. In prokaryotes, either a rho protein-dependent palindrome or a rho-dependent GC-rich palindrome or a polyU sequence serves the same purpose. The number of mRNA molecules per cell varies according to the gene and the environment. In yeast cells, under good growing condition, 7 mRNA molecules were detected with a half-life of about 11 minutes, indicating that the formation of one mRNA molecule required about 140 seconds. The maximal transcription initiation rate for mRNA in yeast was found to be 6–8 second. The level of mRNA is frequently used for the assessment of proteins. The estimate so obtained may be biased, however, because

proteins may be in dynamic state subject maturation and degradation, and many proteins are regulated by alternative splicing of the mRNA and also by post-translational processing. The cellular distribution of mRNAs can be monitored by nuclease resistant molecular beacons used to monitor the path of the mRNA within the nucleus and its passing through the nuclear pores (Bratu DP et al 2003 Proc Natl Acad Sci USA 100:13308); (Bratu DP et al 2003 Proc Natl Acad Sci USA 100:13308). The movement of the mRNA and attached proteins may be stalled within the chromatin and to switch to the mobile phase requires ATP (Vargas D Y et al 2005 Proc Natl Acad Sci USA 102:17008). ►introns, ►RNA polymerase II, ►transcription factors, ►transcription complex, ►open promoter complex, ►Hogness box, ►Pribnow box, ►UAS, ►up promoter, ►G-box, ►GC box, ►enhancer, ►leader sequence, ►cap, ►Shine-Dalgarno box, ►mRNA tail, ►transcription termination in eukaryotes, ►decapping, ►transcription termination in prokaryotes, ►regulation of gene activity, ►monocistronic mRNA, ►operon, ►regulon, ►mRNA degradation, ►aminoacyl-tRNA synthetase, ►mRNA targeting, ►RNA non-coding, ►RNA surveillance, ►ribonuclease E, ►ribonuclease III, ►polynucleotide phosphorylase, ►degradosome, ►polyA polymerase, ►polyadenylation signal, ►beacon molecular, ►Mlp1, ►PML39, ►half-life, ►PMAGE; Brenner S et al 1961 Nature [Lond] 190:576; Maquat LE, Carmichael GG 2001 Cell 108:173; Moore MJ 2005 Science 309:1514; mRNA and small RNA of some plants: <http://mpss.udel.edu/>, coding potential of RNA transcripts: <http://cpc.cbi.pku.edu.cn/>.

mRNA CAP: ►cap

mRNA Circularization: The 5' and 3' ends of messenger RNA may be joined through the transcription initiation polypeptides eIF-4G, eIF-4E, and PABp, and this structure favorably modulates translation initiation and possibly prevents the truncation of the message and the polypeptide. The rotavirus mRNA, which has a GUGACC rather than a poly(A) tail, uses a special binding protein NSP3 and probably employs this structure to suppress host protein synthesis. ►PABp, ►polyadenylation signal; Mazumder B et al 2001 Mol Cell Biol 21:6440.

mRNA Degradation: mRNA degradation is not an incidental random process but it is under precise genetic control. The decay in eukaryotes may begin by the shortening or removal of the poly(A) tail, that is followed by removal of the Cap and digestion by 5'→3' exoribonucleases (encoded by *XRN1*, *HKE1*). The decay by 3'→5' exonuclease is of minor importance. The poly(A) tail is removed by the

PAN 3'→5' exonuclease but requires for activity the PABP (poly(A)-binding protein) and other proteins. The decapping is mediated by pyrophosphatases. The degradation is predominantly cytoplasmic although it may take place in the nucleus before the transfer to the cytoplasm. Most frequently, those mRNAs are attacked that have a termination codon 50–55 nucleotide upstream of the last exon–exon junction. AU-rich elements (AURE) and other factors in the downstream regions regulate the decay process. Decay regulatory purine-rich elements (180–320 base) reside also within the coding region. The histone mRNAs lack poly(A) tail and their stability depends on 6-base double stranded stem and a 4-base loop, and their stability depends also on the 50-kDa SLBP (stem-loop-binding protein) and other similar proteins. The destabilization of these mRNAs depends on the process of translation, and probably on the association of the stem-and-loop proteins with the ribosomes, and it appears to be auto-regulated also by histone(s). The degradation of the mRNA is initiated by defects in the process of the translation or by encountering nonsense codons, wrong splicing, upstream open reading frames (uORFs), and transacting protein factors in the cytoplasm and the nucleus. *RNA surveillance* (non-sense-mediated decay) disposes defective mRNAs. Similarly, if the mRNA is elongated beyond the normal stop signal, *non-stop decay* destroys it. If eukaryotic mRNA stalls during the process of translation, endonucleolytic cleavage takes place leading to *no-go decay*. The latter requires the presence of Dom34p and Hbs1p protein factors that resemble eRF1 and eRF3 translation termination factors (Doma MK, Parker R 2006 Nature [Lond] 440:561). Steroid hormones, growth factors, cytokines, calcium, and iron also affect mRNA stability. Cytokine and proto-oncogene mRNAs are degraded after binding the AUF1 protein to the 3' untranslated AU-rich sequences. This AU factor forms complexes with heatshock proteins, translation initiation factor eIF4G, and a polyA-binding protein. When the AUF1 is dissociated from eIF4G, AU-rich mRNA is degraded. Exo- and endoribonucleases, regulated by various factors, may also be involved in processing and also in protecting mRNA. Viral infections may rapidly destabilize host mRNAs without affecting the rRNAs and tRNAs. Premature termination of translation may account for Fanconi anemia Duchenne muscular dystrophy, Gardner syndrome, ataxia telangiectasia, breast cancer, polycystic kidney disease, desmoid disease, etc. A method exists for assessing the dynamics of the steady-state level and degradation of mRNA by the use of the cellular pyrimidine salvage pathway and affinity-chromatographic isolation of thiolated mRNA (Kenzelmann M et al 2007 Proc Natl

Acad Sci USA 104:6164). ►mRNA surveillance, ►non-stop decay, ►AMD, ►NMD, ►mRNA, ►polyA mRNA, ►exonuclease, ►endonuclease, ►nonsense codon, ►histones, ►Cap, ►transcription termination, ►mRNA tail, ►URS, ►transcription factors, ►eIF4G, ►heat-shock proteins, ►polyA mRNA, ►ubiquitin, ►RNAi, ►exosome; Ross J 1995 Microbiol Rev 59:423; Wilson GM et al 2001 J Biol Chem 276:8695; Wilusz CJ et al 2001 Nature Rev Mol Cell Biol 2:237; Chen C-Y et al 2001 Cell 107:451; van Hoof A, Parker R 2002 Current Biol 12:R285, degradation pathway in yeast: Kuai L et al 2005 Proc Natl Acad Sci USA 102:13962.

mRNA Display: An entirely in vitro technique for the selection of peptide aptamers to protein targets. The binding of the aptamers does not require disulphide bridges or special scaffold (e.g., antibody), yet the affinities are comparable to those of monoclonal antibody-antigen complexes. The polypeptides are linked to their mRNA in vitro, while stalling the translation on the ribosomes with the aid of puromycin, which attaches to the 3'-end of the mRNA. The mRNA-peptide fusions are then purified and selected in vitro. The procedure is highly efficient and permits selection in libraries of about 10^{13} peptides. It obviates the need for transformation, a disadvantage of phage display. ►aptamer, ►phage display, ►puromycin, ►RNA display; Wilson DS et al 2001 Proc Natl Acad Sci USA 98:3750.

mRNA Migration: After synthesis and release from the nucleus, the mRNA is not translated until it reaches its subcellular destination for translation. The localization is mediated by binding the onco-fetal protein ZBP1 (Zipcode binding protein 1) to a conserved 54-nucleotide element (Zip code) in the 3'-untranslated region of the β -actin mRNA. ZBP1 promotes translocation of actin to the periphery of the cell. Src protein kinase promotes translation by phosphorylating a key tyrosine residue (Tyr³⁹⁶) required for ZBP1 binding to mRNA (Hüttelmaier S et al 2005 Nature [Lond] 438:512). ►actin

mRNA Leader: ►leader sequence

mRNA Surveillance (nonsense-mediated decay, NMD): RNA transcripts containing premature stop codons or other defects are more liable to destruction by specific exonucleolytic proteins than normal ones. In yeast, the decay begins at the cap-binding protein or at the eIF4E translation initiation factor (Gao O et al 2005 Proc Natl Acad Sci USA 102:4258). The decay is generally initiated at the 5' or at the 3' end, but in *Drosophila* it starts in the vicinity of the nonsense codon (Gatfield D, Izaurralde E 2004 Nature [Lond] 429:575). Prematurely terminated mRNA molecules

may cause about 1/3 of the human hereditary diseases. In human cells, three proteins, hUpf1 (cytoplasmic ATP-dependent RNA helicase), hUpf2 (perinuclear), and hUpf3b (nuclear export-import signals shuttle between nucleus and cytoplasm), are involved. The NMD complex is formed apparently already in the nucleus at the exon-exon junctions, and triggers destruction of mRNA in the cytoplasm beginning downstream of the translation termination site. In *Caenorhabditis*, seven genes (*Smg*) are involved in NMD. Drugs (e.g., gentamycin) in cultured cells of the patients can inhibit the NMD pathway and the nonsense transcripts can be stabilized. The drug-induced changes are than revealed in normal and test systems with the aid of microarray hybridization. By identifying NMD inhibition, human disease genes can be recognized. This way, map location and biological function of the disease genes can be determined even when no *a priori* information is available. Some mutations causing NMD can be corrected by the application of appropriate drugs and the shortened polypeptide chain may be sufficient to alleviate defects normally causing hereditary disease. ►mRNA, ►mRNA degradation, ►alternative splicing, ►microarray hybridization, ►toeprinting, ►eIF-4E; Hilleren P, Parker R 1999 Annu Rev Genet 33:229; Lykke-Andersen J et al 2000 Cell 103:1121; Noensie EN, Dietz HC 2001 Nature Biotechnol 19:413; Amrani N et al 2004 Nature [Lond] 432:112; suppression of NMD for trapping mouse stem cells: Shigeoka T et al 2005 Nucleic Acids Res. 33(2):e20.

mRNA Tail: ca. 200 adenylate residues generally tails mature mRNAs of eukaryotes. This is not the end of the primary transcript; transcription may continue by a thousand or more nucleotides beyond the end of the gene. Polyadenylation requires that the transcript be cut by an endonuclease and then a poly-A RNA polymerase attaches to this poly-A tail, which is probably required for stabilization of the mRNA. Several of the histone protein genes do not have, however, a poly-A tail. Other histone mRNAs, which are not involved with the mammalian cell cycle and histone mRNAs of yeast and *Tetrahymena*, are polyadenylated. The common post-transcriptional polyadenylation is signaled generally by the presence near the 3'-end an AATAAA sequence, which is followed two dozen bases downstream by a short GT-rich element. Polyadenylation takes place within the tract bound by these two elements. Within most gene tracts, AATAAA occur at more upstream locations but they are not used for poly-A tailing. Several genes may have alternative polyadenylation sites, however, and thus can be used for the translation of different molecules, e.g., for membrane-bound or

secreted immunoglobulin, respectively. The polyadenylation signal may also have a role in signaling the termination of transcription, no matter how much further downstream that takes place. In the nonpolyadenylated histone genes, there is a 6-base pair palindrome that forms a stem for a 4 base loop near the 3'-end of the mRNA, and it is followed further downstream by a short polypurine sequence. The latter may pair with a U7 snRNP that facilitates termination. The U RNA transcripts of eukaryotic RNA polymerase II are not polyadenylated, either. The formation of an appropriate 3'-tail requires that it would be transcribed from a proper U RNA promoter and the transcript would have the 5' trimethyl guanine cap. The 3'-end of U1 and U2 RNAs is formed by the signal sequence GTTN₀₋₃AAAPUAGA [PU any purine, PY any pyrimidine] near the end. ▶transcription termination, ▶decapping, ▶polyadenylation signal, ▶polyA polymerase; Hilleren P et al 2001 Nature [Lond]:413:538.

mRNA Targeting: In order that proteins required for differentiation and morphogenesis would be available at the location needed, the mRNA generally carries a relatively long 3'-UTR (untranslated region). These long sequences appear to provide means for binding multiple proteins while being transported to the target sites. Additional 'zip codes' may be located in the 5'-untranslated sequences. During the process, the mRNA is bound and stabilized at the "ordained" sites from where the translated product may diffuse (in a gradient). ▶morphogenesis, ▶compartmentalization, ▶differentiation; Jansen R-P 2001 Nature Rev Mol Cell Biol 2:247.

mRNA, Transgenic: The result of trans-splicing of the transcripts. ▶trans-splicing; Finta C, Zaphiropoulos PG 2002 J Biol Chem 277:5882.

mRNA Turnover: ▶mRNA degradation

mRNP: The messenger ribonucleoprotein is a repressed mRNA. It is found in the eukaryotic cytoplasm and stored until later translation. In the female gametocyte of *Plasmodium*, this translational repression is mediated by an RNA helicase (DOZI, development of zygote inhibited) as a means of sexual development. Mutation in DOZI inhibits the formation of mRNAP and 370 transcripts are degraded. ▶mRNA, ▶gametocyte, ▶*Plasmodium*; Mair GR et al 2006 Science 313:667.

MRP (mitochondrial RNA processing): An RNase, which cleaves the RNA transcribed on the H strand of mtDNA at the CSB elements. MRP seems essential for normal exit from cell cycle at the end of mitosis

(Cai T et al 2002 Genetics 161:1029). MRP designates frequently also mitochondrial ribosome proteins. ▶CSB, ▶DNA replication mitochondria, ▶mtDNA, ▶ribosomal RNA, ▶ribosomal protein, ▶ribonuclease P, ▶Rex, ▶chondrodysplasia McKusick type; Ridanpaa M et al 2001 Cell 104:195.

MRP (matrix representation with parsimony): A method for constructing composite phylogenetic trees base on published data. The source phylogenetic information is encoded as a series of binary characters that represent the branching pattern of the original trees. The data matrix of the phylogenies is evaluated by parsimony and integrated into a composite tree. ▶evolutionary tree, ▶maximum parsimony; Bininda-Emonds OR 2000 Mol Phylogenet Evol 16:113.

MSAFP (maternal serum α -fetoprotein): MSAFP analysis may detect prenatally chromosomal aneuploidy, (trisomy), and open neural-tube defects between the first 15–20 weeks of pregnancy. Oxidation products of estradiol, estrone (estriol), and chorionic gonadotropin generally accompany the high level of this protein. ▶[fetoprotein](#), ▶[gonadotropin](#), ▶[trisomy](#), ▶[Turner syndrome](#), ▶[Down syndrome](#); Ochshorn Y et al 2001 *Prenat Diagn* 21:658; Miller R et al 2001 *Fetal Diagn* 16(2):120.

MSCI (meiotic sex chromosome inactivation): Silences unpaired (unsynapsed) chromosome regions in yeast and also in mouse during both male and female meiosis. The tumor suppressor protein BRCA1 is implicated in this silencing, mirroring its role in the meiotic silencing of the X and Y chromosomes in normal male meiosis. These findings impact the interpretation of the relationship between synaptic errors and sterility in mammals (Turner JM et al 2005 *Nature Genet* 37:11; Turner JM et al 2006 *Dev Cell* 10:521; MSUC).

MSCRAMM (microbial surface components recognizing adhesive matrix molecule): Microbial protein(s) recognizing host fibronectin-, fibrinogen-, collagen-, and heparin-related polysaccharides, important for host invasion, colonization, and as virulence factors. ▶[heparin](#), ▶[receptin](#); Patti JM et al 1994 *Annu Rev Microbiol* 48:585.

msDNA (multicopy single-stranded DNA): msDNA is formed in bacteria, which contain a reverse transcriptase and is associated with this enzyme. This DNA has a length of 162 to 86 bases and it may be repeated a few hundred times. The 5' end of the msDNA is covalently linked by a 2'-5'-phosphodiester bond to an internal G residue and thus forms a branched DNA-RNA copolymer of stem-and-loop structure. In some cases, because of processing, the msdRNA does not form a branched structure and exists only as a single-stranded DNA. The 5'-region of the msDNA is part of internal repeats within the copolymer. The system is transcribed from a single promoter and thus constitutes an operon. ▶[retron](#), ▶[reverse transcription](#); Lampson B et al 2001 *Progr Nucleic Acid Res Mol Biol* 67:69.

msdRNA: ▶[msDNA](#); Lima TM, Lim D 1997 *Plasmid* 38:25.

MSF (mitochondrial import stimulating factor): The MSF selectively binds mitochondrial precursor proteins and causes the hydrolysis of ATP. The MSF-bound precursor is made up of at least four proteins: Mas-20p, -22p, -70p, -37p. ▶[mitochondria](#), ▶[mitochondrial import](#); Hachiya N et al 1993 *EMBO J* 12:1579.

MSH: ▶[melanocyte stimulating hormone](#), ▶[hereditary non-polyposis colorectal cancer](#)

MSH2 (2p22-p21): A homolog of the bacterial MutS mismatch repair gene (Mazur DJ et al 2006 *Mol Cell* 22:39). ▶[mismatch repair](#)

MSH5/MSH4: MSH5/MSH4 are encoded in the central MHC class III region, and their obligate heterodimerization have a critical role in regulating meiotic homologous recombination and antibody gene switching (Sekine H et al 2007 *Proc Natl Acad Sci USA* 104:7193).

MSI: Microsatellite instability. ▶[microsatellite](#)

mSin: mSin proteins are transcriptional co-repressors. ▶[co-repressor](#), ▶[nuclear receptors](#); Ayer DE et al 1996 *Mol Biol Cell* 16:5772.

MSK: An enzyme of the MAPK family, closely related to RSK, and involved in phosphorylation of Histone 3 and thereby, in chromatin remodeling. ▶[chromatin remodeling](#), ▶[RSK](#)

Msl (male-specific lethal): At least five of the Msl genes exist in *Drosophila* that along with *Mle* (maleless) assure that a single X-chromosome in the male carries out all the functions at approximately the same level (dosage compensation) as two X-chromosomes in the female *Drosophila*. *Msl-1*, (2–53.3) and *Msl-2* (2–9.0) are located in the 2nd chromosome but similar genes are found also along the X-chromosome. Normally, the male chromatin is highly enriched in a histone 4 monoacetylated at lysine-16 (H4Ac16). Mutation at this lysine alters the transcription of several genes. Mutation in *Msl* genes prevents the accumulation of H4Ac16 in the male X-chromosome. Msl-2 protein by containing a Zinc-binding RING finger motif may specifically recognize X-chromosomal sequences and this way distinguishes between X and autosomes. The *Msl* complexes contain at least two RNAs on the X: roX1 (3.7 kb) and roX2 (0.6 kb). These RNAs, similarly to *Xist* RNAs in mammals, spread along over 1 Mbp of the chromosome although not as broadly as *Xist*, which may span over >100 Mbp. ▶[dosage compensation](#), ▶[Mle](#), ▶[ring finger](#), ▶[Xist](#), ▶[histone acetyltransferase](#); Larsson J et al 2001 *Proc Natl Acad Sci USA* 98:6273; Smith ER et al 2001 *J Biol Chem* 276:31483; Park Y et al 2002 *Science* 298:1620.

MS/MS: Tandem mass spectrometer. It can be used as an automatable tool for the diagnosis of amino acid sequence in proteins, etc. ▶[mass spectrometer](#), ▶[proteomics](#)

Msp I: Restriction endonuclease with recognition site C↓CGG.

MS-RDA (methylation-sensitive representational difference analysis): A subtractive hybridization method designed for the detection of differences in methylation

patterns among genes. ►methylation of DNA, ►subtractive cloning, ►differential hybridization mapping, ►RDA; Ushijima T et al 1997 Proc Natl Acad Sci USA 94:2284.

Mss (mammalian suppressor of Sec4): A guanosine-nucleotide exchange factor, regulating RAS GTPases. ►Ypt1, ►Rab, ►GTPase, ►RAS

MSUC (meiotic silencing of unsynapsed chromosomes): In MSUC, any chromosome region unsynapsed during pachytene of male and female mouse meiosis is subject to transcriptional silencing (Turner JM et al 2006 Dev Cell 10:521). Silencing seems to be due to extensive replacement of nucleosomes within unsynapsed chromatin and results in the exclusive incorporation of the histone H3.3 variant, which appears to be associated with transcriptional activity (van der Heijden GW et al 2007 Nature Genet 39:251). ►MSCI, ►silencer

MSUD (meiotic silencing by unpaired DNA): In MSUD, DNA unpaired in meiosis silences all homologous sequences including genes that are paired. MSUD requires the function of an RNA-dependent RNA polymerase. The mRNA is degraded after transcription. ►co-suppression, ►silencer, ►MSCI, ►quelling; Shiu PKT et al 2001 Cell 107:905; Shiu PKT et al 2006 Proc Natl Acad Sci USA 103:2243.

MSV (*msv*): ►Moloney mouse sarcoma virus

MSX (muscle segment homeobox, *msh*): Pleiotropic loci in humans (MSX1, 4p16.1) and MSX2 (5q34-q35) and homologous genes in mice control craniofacial (skull, teeth, etc.) development. ►pleiotropy, ►craniosynostosis, ►tooth-and-nail dysplasia; Milan M et al 2001 Development 128:3263; Cornell RA, Ohlen TV 2000 Curr Opin Neurobiol 10:63.

MTA: 5'-methylthioadenosine, one of the methyl donors in biological methylation.

MTA α : Yeast mating type α gene. ►mating type determination in yeast

MTA *a*: Yeast mating type *a* gene. ►mating type determination in yeast

MTD (maximum tolerated dose): The maximum tolerated dose of a treatment is that, which does not affect the longevity of the animal (except by cancer if the agent is a carcinogen) or does not decrease its weight under long exposure by more than 10%. MTD has been used in classification of carcinogens; in some instances at such high doses certain chemicals appear carcinogenic, however, under the conditions of normal use they may not pose a risk. Another potential problem is that genetic differences among test animals and humans may affect the sensitivity or susceptibility to the agents. ►bioassays in genetic toxicology; Leung DH, Wang YG 2002 Stat Med 21:51.

mtDNA (mitochondrial DNA): mtDNA in mammals consists of generally 5–6 small 16.5×10^3 bp mtDNA rings per organelle, but there are hundreds or thousands of mitochondria per cell. The yeast mtDNA genome is circular and 17–101-kb. In *Paramecium*, the mtDNA is linear and 40 kb. In about 1/3 of the yeasts and many other species (protozoa, fungi, algae), mtDNA may be linear. In plants, it varies in the range of 200 to 2,500-kbp, and occurs in variable size of mainly circular molecules, although smaller linear mtDNAs also exist and show inverted terminal repeats (Ward BL et al 1981 Cell 25:793). The mtDNA genome of *Plasmodium falciparum* is only 6-kbp, that of the plant *Arabidopsis* contains 366, 924-bp, and hexaploid wheat is 452,528 bp. More than 80% of the plant mtDNA is non-coding, whereas in protists only ~10% is non-coding. The human mtDNA genome contains 16,596 base pairs, is similar to that of other mammals, encodes 13 proteins, and transcribes two ribosomal genes and a minimal (22) set of tRNAs. The 13 proteins are: ATP synthetase subunits 6 and 8, cytochrome oxidase subunits I, II, III, apocytochrome b, and NADH dehydrogenase subunits 1–6 and 4L. A data set of 827 carefully selected sequences shows that modern humans contain extremely low levels of divergence from the mitochondrial consensus sequence, differing by a mere 21.6 nt sites on average. Fully 84.1% of the human mitochondrial genome was found to be invariant (Carter RW 2007 Nucleic Acids Res 35:3039).

Among the metazoan mtDNAs, some variations exist in gene number and the base composition of the coding strands also vary. *Reclinomonas* protozoons encode 97 genes by the mtDNA. Before the small (~16 kbp) metazoan mtDNAs have evolved, the unicellular protists had larger and genetically more complex mitochondria (Burger G et al 2003 Proc Natl Acad Sci USA 100:892).

Arabidopsis borrows two tRNAs from the chloroplasts. The wheat mtDNA includes 55 genes with exons, including 35 coding for protein, 3 rRNA, and 17 tRNA. Three percent of the wheat mtDNA genes are of chloroplast origin, ~16% of the total mtDNA is genic, and intramolecular recombination is evident (Ogihara Y et al 2005 Nucleic Acids Res 33:6235).

The number of mitochondria in the eukaryotic cells may run into hundreds to thousands. The buoyant density of the mtDNA is surprisingly uniform among many species; it varies between 1.705 to 1.707 g/mL.

In the marine mussels (*Mytilus*), there is an M (transmitted by the male to the sons) and an F (transmitted by the female to sons and daughters) mitochondrial DNA resulting in high degree of heteroplasmy among the males.

The replication of the mouse mtDNA proceeds generally from two origins of replication, thus

forming D loops, a tripartite structure of two DNA, and a nascent RNA strand. Replication of the heavy strand begins at the single origin (O_H) and continues until the origin of the light chain (O_L) is reached. Then the “lagging” strand replication is initiated in the opposite direction (for an overview of the human mtDNA map see p. 1,261). Another major D-loop originates at position 57 in several human cell lines. This replication type is responsible for the maintenance of mtDNA under steady-state conditions, whereas the other D-loop origin is more important for the recovery of mtDNA after depletion or for accelerating mtDNA replication in response to physiological demands (Fish J et al 2004 *Science* 306:2098). Restriction fragments including the replication forks when studied by 2-dimensional gels reveal structures that are called “Y arc”. In vertebrates, only a single DNA polymerase (polymerase γ) is involved in replication (Iyengar B et al 2002 *Proc Natl Acad Sci USA* 99:4483). This enzyme has two subunits; the larger (~125 to ~140-kDa) is involved in polymerization and the smaller (35–40-kDa) subunit may have a role in the recognition of the DNA replication primer and may function as a processivity clamp. The smaller, the accessory subunit, shares structural homology with the aminoacyl-tRNA synthetases. The large subunit also has a 3'→5'-exonuclease activity, assuring the high fidelity of DNA synthesis. Replication also in mitochondria requires a number of accessory proteins. The origin of replication of the light chain is at some distance from that of the heavy chain. The replication is regulated by the mtTFA protein, which also assures proper maintenance of the DNA and regulates transcription. The mutation rate of the mtDNA, despite the exonuclease function of polymerase γ , is an order of magnitude higher than that of the nuclear DNA. This higher rate has been attributed to oxygen, generated by oxidative phosphorylation. DNA repair may take place by nucleotide excision, mismatch repair, and alkyltransferase, but some aflatoxin B1, bleomycin, and cisplatin damage as well as pyrimidine dimers cannot be repaired efficiently.

In animals the heavy strand codes for 2 rRNAs, for 14 tRNAs, and for 12 polypeptides of the respiratory chain (ATP synthase, cytochrome b, cytochrome oxidase, 7 subunits of NADH dehydrogenase). In human mtDNA, the rRNA termination factor (mTERF) binds—by forming a loop—to both the termination and initiation sites of the two rRNA tracts and also drives mt rRNA synthesis (see Fig. M127) (Martin M et al 2005 *Cell* 123:1227; see diagram drawn after the electronmicrographs of Martin et al).

The plant mtDNA may encode three rRNAs and 15–20 tRNAs. The heavy chain of the mammalian mtDNA may be transcribed in a single polycistronic

unit and subsequently cleaved into smaller functional units. There are also abundant shorter transcripts of the heavy chain of the mtDNA. The light DNA strands of vertebrates are transcribed into eight tRNAs and into one NADH dehydrogenase subunit. The tRNA genes are scattered over the genome. The small mammalian mtDNA is almost entirely functional, and only a few (3–25) bases lie between the genes without introns, and some genes overlap. The promoter sequences are very short and are embedded in non-coding regions. The human mtDNA employs two forms of transcription factors that bear structural similarities to rRNA modifying enzymes (see Fig M128). These two factors (TFBM1 and TFBM2, the latter being much less efficient) bind to the core RNA polymerase (PolRMT), which can recognize the two promoter sites (LSP and HSP). TFAM is the protein that binds upstream to both promoters, unwinds the DNA template, and facilitates bidirectional transcription (Shoubridge EA 2002 *Nature Genet* 31:227). The upstream leader sequence is minimal and the typical eukaryotic cap is absent. In addition to the AUG initiator codon, AUA, AUU, and AUC may start translation as methionine codons. The genetic code dictionary of mammalian and fungal (yeast) mitochondria further differs somewhat from the “universal code”. The UGA stop codon means tryptophan, the AUA isoleucine codon represents methionine in both groups, whereas the CUA leucine

Figure M127. rRNA termination factor in mitochondria

Figure M128. Arabidopsis mtDNA (outer circle) relative to mammalian mtDNA (inner circle)

codon in yeast mtDNA spells threonine (but in *Neurospora* mtDNA it is still leucine), and the AGA and AGG arginine codons are stop codons in mammalian mtDNA. Other coding differences may still occur in other species. Some mtDNA genes have no stop codons at the end of the reading frame but a U or UA terminate the transcripts after processing that may become, by polyadenylation, a UAA stop signal. Since mitochondria have only 22 tRNAs, the anticodons must use an unusual wobbling mechanism. The two-codon-recognizing tRNAs can also form a G*U pairing, and the four-amino-acid codon sets are base-paired either by two nucleotides only, or the 5' terminal U of the anticodon is compatible with any other of the 3' bases of the codon. Nuclear mRNA may not be translated in the mitochondria because of the differences in coding. Mitochondrial translation does not use the Shine-Dalgarno sequence for ribosome recognition in contrast to prokaryotes. Rather, it depends on translational activator proteins that connect the untranslated leader to the small ribosomal subunit. Plant mitochondria utilize the universal code.

The fission yeast and *Drosophila* mtDNAs are just slightly larger (19 kb) than that of mammals. The mtDNA of the budding yeast is about 80 kb, yet its coding capacity is about the same as that of the mammalian mtDNA. The large mitochondrial DNA is rich in AT sequences and contain introns. Some yeast strains have the same gene in the long form (with introns) while other strains in the shorter form (without intron). The introns may have maturase functions in processing the transcripts of the yeast genes that harbor them (cytochrome b) or they may be active in processing the transcripts of other genes (e.g., cytochrome oxidase). The 1.1-kb intron of the 21S rDNA gene contains coding sequences for a site-specific endonuclease that facilitates its insertion into some genes lacking this intron as long as they contain the specific target site (5'-GATAACAG-3'). Thus, this intron is also an insertion element.

For transcription of the vertebrate mtDNA the transcription factor mtTFA (a high-mobility group protein) must bind upstream (−12 to −39 bp) to the promoter to unwind the DNA for the mtRNA polymerase, which binds downstream. The distance between these two binding sites is important.

The *Saccharomyces* mtDNA genes are replicated from several (7 or more) scattered replicational origins, each containing 3 GC-rich segments separated by much longer AT tracts. Transcription is mediated by a mitochondrial RNA polymerase (similar to T-odd phage polymerases) that is coded, however, within the nuclear DNA. The conserved 5'-TTATAAGTAPuTA-3' promoter is positioned within nine bases upstream from the transcription initiation site. Unlike the much smaller mammalian mtDNA genes, yeast genes have more or

less usual upstream and 3' sequences. The much more compact mammalian or fission yeast genes do not use upstream regulatory sequences (UTRs). In the mtDNA, a 13-residue sequence embedded in the tRNA^{Leu(UUR)}, a 34-kDa protein, (mTERM) is bound and the complex is required for the termination of transcription. Transcription initiation also requires—besides sc-mtTFA—the protein sc-mtTFB. It seems that the primers for the heavy chain transcription are synthesized on the light chain of the mtDNA. Mammalian light chains contain three conserved sequence blocks (CSBs) serving apparently as primers for the transcription of the heavy chain. These seem to be analogous to the GC-rich segments of yeast. In yeast for the transcription of mtDNA heavy chain, a R loop is also formed. Near the origin of the heavy chain there is an RNase, specific (RNase MRP) for processing the 3'-OH ends of the origin-containing RNAs.

The rRNA genes, unlike in the nuclear genomes, are separated by other coding sequences. Yeast mtDNA encodes at least one ribosomal protein. In mammals, all mitochondrial ribosomal proteins are coded in the nucleus and imported into this organelle. The majority of the other proteins are also imported. Nuclear proteins mediate the translational control locus by specific or global manners.

The transport of proteins through the mitochondrial membrane takes place in several steps. The NH₂ terminus passes into the inner membrane through the protein import channel. The mitochondrial heatshock protein 70 (mtHsp70) stabilizes the translocation intermediate in an ATP-dependent process. The traffic may be in two ways, and it may be a passive transport.

The mtDNA of plants is much larger than that of other organisms, varying between 208 to 2,500 kbp. The mtDNA of *Arabidopsis* is 366,924 bp and contains 57 genes (Unsold M et al 1997 Nature Genet 15:57). The mtDNA of plants frequently exists in multiple size groups. This DNA is interspersed with large (several thousand kb) or smaller (200–300 kb) repeated sequences. Recombination between these direct repeats of a “master circle” may generate in stoichiometric proportion smaller, subgenomic DNA rings. In species without these repeats (e.g., *Brassica hirta*), subgenomic recombination does not occur. The very small mtDNA molecules are called plasmids. Plasmids, *S-1*, and *S-2* share 1.4-kb termini. These plasmids may integrate into the main mtDNA.

The variety and the number of repeats may vary in the different species and some species (*Brassica hirta*, *Marchantia*) may be free of recombination repeats. The recombination repeats may contain one or more genes. The repeats display recombination within and between the mtDNA molecules. These events then generate chimeric sequences, deficiencies, duplications, and a variety of rearrangements.

Recombination between direct repeats tosses out DNA sequences between them and generates smaller circular and possibly linear molecules. The 570-kb maize mtDNA “master circles” may have six sets of repeats, whereas in the T cytoplasm the repeats are quite complex. The size of the repeats may be 1 to 10-kb. Not all of them promote recombination and even the recombination repeats may vary in different species. Plant mitochondria may also contain single and double-stranded RNA plasmids. The latter may be up to 18-kb size. The single-stranded RNA plasmids may be replication intermediates of the double-stranded ones. The base composition of some is different from that of the main mtDNA and appears to be of foreign (viral) origin.

It has been reported that passage of cells thorough in vitro culturing (tissue culture) may incite rearrangements in the mtDNA genome. This phenomenon may be the result, however, of different amplification of preexisting alterations. Formation of cybrids may also result in new combinations of the mtDNAs (►somaclonal variation). The mitochondrial protein complexes may be organized by chaperone-like mitochondrial proteases.

Some of the DNA sequences in the plant mitochondria are classified as “promiscuous” because they occur in the nuclei and in the chloroplasts too. These promiscuous DNA sequences may contain tRNA (tRNA^{Pro}, tRNA^{Trp}) and 16S rRNA genes. Into the human nuclear DNA, mtDNA has been inserted several times during evolution and is detectable mostly as pseudogenes. It has been estimated that mtDNA sequences are translocated into the nuclear chromosomes at the high frequency of 1×10^{-5} per cell generation. With the aid of biolistic transformation any type of DNA sequence can be incorporated into organellar genetic material, including mtDNA. The plant mitochondrial tRNAs may be encoded by mtDNA, nuclear DNA, or plastid DNA directly, or by plastid DNA inserted into the mtDNA. Plant mitochondria may code for some mitochondrial ribosome proteins. These ribosomal proteins may be different in different plant species. The liverwort mtDNA genome is very large and contains at least 94 genes.

Human mtDNA was also used for evolutionary studies to trace the origin of the present-day human population to a common female ancestral line, the so-called phylogenetic Eve. Restriction fragment length polymorphism carried out on the mtDNA of 147 people, representing African, Asian, Australian, Caucasian, and New Guinean populations indicated an evolutionary tree by the maximal parsimony method. Accordingly, it appeared that Eve lived about 200,000 years ago in Africa because that population was the most homogeneous in modern times and other populations shared the most common mtDNA

sequences with these samples. The advantage of the mtDNA for these studies was that mitochondria are transmitted through the egg and thus recombination with males would not alter its sequences. Later studies have shown, however, that in mice (and probably in humans) a small number of mitochondria are transmitted also through the sperm. Therefore some of the conclusions of the original study regarding the time and population scales may require revision, although the basic ideas about the human origin may be correct. The unique descent of males can be traced through the Y chromosome. The original human mtDNA sequence (‘Cambridge reference’ Anderson S et al 1981 Nature [Lond] 290:457) has numerous errors because of variations particularly in the control region. These errors may affect demographic/population genetics conclusions and may lead to serious bias in forensic evaluations (Forster PM et al 2003 Ann Hum Genet 67:2).

In vitro in heteroplasmic cells, the mutant mtDNA replication could be inhibited by peptide nucleic acid, complementary to the mutant sequences. Mitochondria depend, either on the salvage pathway for deoxyribonucleotides or on special transporters to provide these DNA precursors. Human mitochondria have only two deoxyribonucleoside kinases. The thymidine kinase phosphorylates both deoxythymidine and deoxycytidine. The deoxyguanosine kinase phosphorylates both deoxypurine nucleosides.

Mutations can cause mtDNA depletion in humans and include: TP, which is associated with mitochondrial neurogastrointestinal encephalopathy (MNGIE, 22q13.32-pter); TK2 (16q22), encoding thymidine kinase, which causes mitochondrial myopathy2; DGUOK (2p13) that codes for a deoxyguanine kinase, associated with liver failure; POLG (5q25) that is responsible for Alpers progressive infantile poliodystrophy; MPV17 (2p23-p21) that can cause neurohepatopathy; and SUCLA2 (succinate-co-enzyme-A ligase, 13q12.2-q13), which causes encephalomyopathy (Ostergaard E et al 2007 Am J Hum Genet 81:383).

MTF (mouse tissue factor): A membrane protein initiating blood clotting.

mtFAM (mitochondrial transcription factor, Tfa, TCF6): A high mobility group nuclear gene product controlling transcription and replication in the mammalian mitochondria and possibly affecting transcription also in the nucleus. It is also indispensable for embryogenesis. Heart-specific local mutation (deletion) in mtFAM in mice leads the expression of heart anomalies appearing in Kearns-Sayre syndrome in humans. ►mtDNA, ►mitochondrial genetics, ►high mobility group proteins, ►mitochondrial diseases in humans

MTHF: ►photolyase

Mtj1: A transmembrane murine chaperone with homology to DnaJ and Sec63. ►DnaJ, ►Sec63

MTOC: microtubule organizing centers are formed early in the 16-cell stage within the cyst that gives rise to the primary oocyte and nurse cells. ►microtubule organizing center, ►centromere, ►spindle, ►spindle pole body, ►centrosome, ►maternal effect genes, ►oocyte; Rieder CL et al *Trends Cell Biol* 11:413.

MtODE: A mitochondrial AP lyase that cleaves double-stranded DNA at 8-oxoguanine sites and repair oxidative damage. ►oxidative DNA damage, ►AP lyase; Croteau DL et al 1997 *J Biol Chem* 272:27338.

mtPTP (mitochondrial transition pore): An opening on the mitochondrial inner membrane through which mitochondrial proteins can be released to the cytosol and may initiate, e.g., apoptosis. ►apoptosis, ►AIF

M-Tropic (e.g., virus): Homes on macrophages. ►tropic

MTS1 (multiple tumor suppressor): The *MTS1* gene encodes an inhibitor (p16) of the cyclin-dependent kinase 4 protein. When it is missing or inactivated by mutation, cell division may be out of control. *MTS1* is implicated in melanoma and pancreatic adenocarcinoma. ►p16, ►melanoma, ►tumor suppressor, ►pancreatic adenocarcinoma

MTT Dye Reduction Assay: The MTT dye reduction assay measures cell viability by spectrophotometry.

mtTF: The mitochondrial transcription factor. ►transcription factors, ►transcription complex, ►mtDNA

MtGENDO: mtGENDO refers to oxidative damage-specific mitochondrial AP lyases. It cleaves TG mismatches in double-stranded DNA. It does not recognize 8-oxodeoxyguanine or uracil sites. ►oxidative DNA damage, ►MtODE, ►AP lyase; Stierum RH et al 1999 *J Biol Chem* 274:7128.

Mu (*Mutator*): A transposable element system of maize increases the frequency of mutation of various loci by more than an order of magnitude (10^{-3} – 10^{-5}). About 90% of the mutations induced carry a *Mu* element. Their copy number in the genome may be 10–100. The element comes in various sizes but the longest are less than 2-kb. The shorter elements appear to have originated from the longer by internal deletions. There are relatively long (0.2-kb) inverted repeats at the termini, and 9-bp direct repeats are adjacent to them. The inverted terminal repeats are conserved among the at least five different classes of *Mu* elements, although the sequences in between them may be quite different. The *Mu* elements appear to transpose (in contrast to other maize transposable elements) by a replicative type of mechanism. The two best-studied forms, *Mu1* (1.4-kb) and *Mu1.7* (1.745-kb), were identified also in circular extrachromosomal states. When *Mu* is completely methylated, the mutations caused by it become stable. Less than complete methylation of the element and some other sequences (e.g., histone DNA) are associated with mutability. *Mu* is regulated by MuDR regulatory transposon (4.9-kb) carrying the *mudrA* and *mudrB* genes with transcripts of 2.8-kb and 1.0-kb, respectively. The MuDR element frequently suffers deletions limited to the MURB region. Mutator-like elements (MULEs) with substantial variations in structure and size have been discovered also in *Arabidopsis*. These 22 mutator elements are normally dormant in *Arabidopsis* but a mutation that decreases DNA methylation (DDM1) activates them. ►transposable elements, ►insertional mutation, ►controlling elements, ►hybrid dysgenesis, ►methylation of DNA; Singer T et al 2001 *Genes Dev* 15:591; Miura A et al 2001 *Nature [Lond]* 411:212; Yin Z, Harsdhey RM 2005 *Proc Natl Acad Sci USA* 102:18884.

Mu Bacteriophage: A 37-kbp temperate bacteriophage. Its linear double-strand DNA is flanked by 5-bp direct repeats. Transcription of the phage genome during the lytic phase requires the *E. coli* RNA polymerase holoenzyme. During replication, it may integrate into different target genes of the bacterial chromosome and thus, may cause mutations (as the name indicates). *Mu* may integrate in more than one copy

and if the orientation of the prophage is the same, it may cause deletion, or if the orientation of the two Mu DNAs is in reverse, inversion may take place by recombination between the transposons. The phage carries three terminal elements at both left and right ends where recombination with the host DNA takes place. There is a transpositional enhancer (internal activation sequence) of about 100-bp at 950 bp from the left end. This left-enhancer-right complex is called LER. The 75-kDa transposase binds to the two ends and to the enhancer. A complex of nucleoproteins, the transposome, mediates the transposition. The transposome includes four subunits of the MuA transposase and each contains a 22-base pair recognition site. These recognition sites—in case there is a shortage of Mu DNA—may recruit non-Mu DNA and then can transpose it too. In the presence of bacterial binding proteins (HU and IHF), a stable synaptic complex (SSC) is formed. Then at the 3'-ends, Mu is cleaved by the transposase and they form the Cleaved Donor Complex (CDC). Transesterification at the 3'-OH places Mu into the host DNA. In the Strand Transfer Complex (STC), the 5'-ends are still attached to the old flanking DNA but the 3'-ends are joined to the new target sequences and a cointegrate is generated by replication or nucleolytic cleavage separates Mu from the old flanks and then the gaps are repaired and the transposition is completed. ▶ **mini Mu**, ▶ **transposons**, ▶ **mutator phage**, ▶ **cointegrate**, ▶ **transposition site**; Bukhari AI 1976 *Annu Rev Genet* 10:389; Abbes C et al 2001 *Can J Microbiol* 47 (8):722; Goldhaber-Gordon I et al 2002 *J Biol Chem* 277:7694; Pathania S et al 2002 *Cell* 109:425.

Mucins: Glycosylated protein components of the mucosa that lubricate the intestinal tract. Mutation in the genes involved may lead to cancer. ▶ **D-amino acids**; Velcich A et al 2002 *Science* 295:1726; Hollingsworth MA, Swanson BJ 2004 *Nature Rev Cancer* 4:45.

Muckle-Wells Syndrome: Dominant (1q14) inflammatory disease accompanied by fever, abdominal pain, and urticaria (red or pale skin eruptions). Progressive nerve deafness and amyloidosis may follow. This, and two other diseases, involve mutations in the CIAS1 gene (cold autoinflammatory response) at the NALP locus. Cryopyrin (Nod family protein), along with CAIS1, regulates the inflammatory response (Dowds TA et al 2003 *Biochem Biophys Res Commun* 302:575; Sutterwala FS et al 2006 *Immunity* 24:317). ▶ **amyloidosis**, ▶ **deafness**, ▶ **urticaria familial cold**, ▶ **cold hypersensitivity**, ▶ **hydatiform mole**, ▶ **inflammasome**

Mucopolidoses (ML): ML include a variety of recessive diseases connected to defects in lysosomal enzymes.

ML I is a neuroaminidase deficiency and ML II is an N-acetylglucosamine-1-phosphotransferase deficiency (human chromosome 4q21-q23). This enzyme affects the targeting of several enzymes to the lysosomes. Congenital hip defects, chest abnormalities, hernia, and overgrown gums, but no excessive excretion of mucopolysaccharides are observed. ML III is apparently allelic to ML II although the mutant sites seem to be different. MP III (pseudo-Hurler polydystrophy) also has similarity to the Hurler syndrome (▶ **mucopolysaccharidosis**), although the basic defects are not identical. MP III A is a heparan sulfate sulfatase deficiency (▶ **mucopolysaccharidosis**, ▶ **Sanfilippo syndrome A**), whereas MP IIIB is basically the Sanfilippo syndrome B (▶ **mucopolysaccharidosis**). MP IV (19p13.2-p13.3) is a form of sialolipidosis with typical lamellar body inclusions in the endothelial cells that permit prenatal identification of this disease that may cause early death. ▶ **mucopolysaccharidosis**, ▶ **Hurler syndrome**

Mucopolysaccharidosis (MPS): Hurler syndrome (*MPS I*) recessive 22pter-q11 deficiency of α -L-iduronidase (IDUA) resulting in stiff joints, regurgitation in the aorta, clouding of the cornea, etc. The latest chromosomal assignment of MPS1 is 4p16.3. The IDUA protein (about 74 kDa) includes a 26-aminoacid signal-peptide. The *MPS II* (*Hunter syndrome*, I-cell disease) is very similar to *MPS I*, but it is located in human chromosome Xq27-q28. The symptoms in this iduronate sulfatase deficiency are somewhat milder and the clouding of the cornea is lacking. Dwarfism, distorted face, enlargement of the liver and spleen, deafness and excretion of chondroitin, and heparitin sulfate in the urine are additional characteristics. The following MPSs are controlled by autosomal recessive genes and the deficiencies involve: *MPS IIIA* (Sanfilippo syndrome A; human chromosome 17q 25.3) heparan sulfate sulfatase, in *MPS IIIB* (Sanfilippo syndrome B, in human chromosome 17q21) N-acetyl- α -D-glucosaminidase, in *MPS IIIC* acetylCoA: α -glucosaminide-N-acetyltransferase, *MPS IIID* (Sanfilippo syndrome D, 12q14) N-acetylglucosamine-6-sulfate sulfatase, in *MPS IVA* (Morquio syndrome A, 16q24.3) galactosamine-6-sulfatase, in *MPS IVB* (Morquio syndrome B) β -galactosidase, in *MPS VI* (Maroteaux-Lamy syndrome, 5q11-q13) N-acetylgalactosamine-4-sulfatase (arylsulfatase B), in *MPS VII* (Sly syndrome, 7q21.11) β -glucuronidase, and in *MPS VIII* (DiFerrante syndrome) glucosamine-3-6-sulfate sulfatase. The Hurler syndrome and Sly disease may be treated by implantation of neo-organs, tissues of skin fibroblasts secreting β -glucuronidase, or α -L-iduronidase, respectively. ▶ **mucopolidoses**, ▶ **iduronic acid**, ▶ **heparan sulfate**, ▶ **glucuronic acid**, ▶ **arylsulfates**, ▶ **hyaluronidase**

deficiency, ►coronary heart disease, ►eye diseases, ►deafness, ►miniorgan, ►geleophysic dysplasia, ►enzyme replacement therapy

Mucosal Immunity: The mucosal membranes (in the gastrointestinal tract, nasal, respiratory passages, and other surfaces that have lymphocytes) are supposed to trap 70% of the infectious agents. The mucosal cells rely on immunoglobulin A (IgA) rather than IgG used by the serum. In the gastrointestinal system are located the Peyer's patches that trap infectious agents and pass them to the antigen-presenting cells, T and B cells. The B cells generate the IgA anti-bodies. Concomitantly, the released antigen may stimulate the formation of IgG too. Providing attenuated forms of the pathogen (e.g., *Vibrio cholerae*) orally can trigger the mucosal immunity system. Another approach is to deliver the antigens by bacteria that more effectively stimulate simultaneously both IgA and IgG production. Other delivery systems may use a biodegradable poly (DL-lactide-co-glycolide), PLG, or liposomes. The oral polio vaccine has been quite successful because it provides lasting protection but most of oral vaccines are short in this respect. ►Peyer's patch, ►antigen-presenting cell, ►T cell, ►B cell, ►immunoglobulins, ►antigen, ►immune system, ►vaccines, ►plantibody; Simmons CP et al 2001 Semin Immunol 13(3):201.

Mucosulfatidosis: A multiple sulfatase deficiency with excessive amounts of mucopolysaccharides and sulfatides in the urine. Multiple sulfatase deficiency encoded by SUMF, causing a lysosomal storage disease, results from the lack or co- or post-translational replacement of cysteine by 2-amino-3-oxopropionic acid in several sulfatases (Schmidt B et al 1995 Cell 82:2712; Landgrebe J et al 2003 Gene 316:47). The numerous human sulfatases share common domains. The defect results in abnormal development and early childhood death because of abnormal signaling by gene WNT (Dhoot GK et al 2001 Science 293:1663). Another sulfatase (RsulfFP1) normally mediates proteoglycan signaling by desulfation (Ohto T et al 2002 Genes Cells 7:521). Some of the symptoms of sulfatase deficiency are shared by leukodystrophy, Maroteaux-Lamy, Hunter, Sanfilippo A, and Morquio syndromes, as well as by ichthyosis. Several sulfatase genes occur in bacteria to animals but few in plants. Heterologous bone transplantation, somatic cell gene transfer, and enzyme replacement offer therapeutic potentials in several sulfatase deficiency diseases. (See diseases mentioned in separate entries, ►genetic engineering; Diez-Roux G, Ballabio A 2005 Annu Rev Genomics Hum Genet 6:355).

Mud: A transposon modified (derived) from bacteriophage Mu. ►Mu bacteriophage

MudPIT (multidimensional protein identification technology): A method for the study of complex protein mixtures. Multidimensional liquid chromatography is followed by mass spectrometric analysis by digesting the cell lysate with the help of endoproteinase LysC, and then further purification. The databases are searched by SEQUEST algorithm. The peptide sequences can be used for the identification of proteins in a mixture. ►mass spectrum, ►MALDI-TOF, ►proteomics, ►SEQUEST; Washburn MP et al 2001 Nature Biotechnol 19:242; Smith RD et al 2002 Proteomics 2:513.

Muenke Syndrome (nonsyndromic coronal craniosynostosis): Primarily a skull bone fusion disorder that sometimes affects finger and toe development. It is generally caused by mutation affecting the proline²⁵⁰ site in the fibroblast growth factor receptor 3 (FGFR3) gene at 4p16.3. Its incidence is higher in women than in men. ►craniosynostosis syndromes

Muir-Torre Syndrome: A familial autosomal dominant disease involving skin neoplasias, apparently due to hereditary defects in the genetic (mismatch) repair system. ►mismatch repair, ►colorectal cancer, ►Gardner syndrome, ►polyposis hamartomatous, ►hereditary nonpolyposis colorectal cancer

Mulatto: Offspring of white and black parentage. ►miscegenation

Mulberry (*Morus* spp): fruit tree; $x = 14$. *M. alba* and *M. rubra* are $2n = 28$ whereas the Asian *M. nigra* is $2n = 38$.

Mulibrey Dwarfism: ►dwarfism [Mulibrey nanism]

Mule: ►hinny

MULE (Mcl ubiquitin ligase E3): Mcl-1 is an anti-apoptotic member of the Bcl protein family controlling DNA-damage-induced apoptosis (Zhong Q et al 2005 Cell 121:1085). ►apoptosis, ►BCL

Mulibrey Nanism (MUL, 17q22-q23): An autosomal anomaly causing small size. It involves all or some of the SE characteristics: low birth weight, small liver, brain, eye, growth, triangular face, yellow eye dots, etc. The basic defect is in a Zinc-finger protein (RBCC), containing a ring finger, a B box, and a coiled-coil region. It appears to be a peroxisomal disorder. ►stature in humans, ►Zinc finger, ►B box, ►ring finger, ►coiled coil, ►peroxisome; Kallijärvi J et al 2002 Am J Hum Genet 70:1215.

Muller 5 Technique: ►Base

Muller's Ratchet: Genetic drift can lead to the accumulation of deleterious mutations, particularly in asexual populations. By each mutation the ratchet (a toothed wheel) may click by one notch. The

expected time of losses of individuals with successive minimal number of mutations depends on the absolute number of individuals with minimal number of mutations: $N_m = q_m$ where q is their expected frequency and N = effective population size. Muller's ratchet may operate during the evolution of transposons and retroviruses and fix shorter sequences than the initial elements and establish elements that would depend on trans-acting elements for transposition. In case the number of non-deleterious mutations is small (n_0), the equilibrium value $n_0 = Ne^{-\mu/s}$ where N = effective population size, μ = expected number of deleterious mutations per genome, s = selection coefficient, e = base of natural logarithm. Conversely, the rapid mutations of retrotransposons may eliminate elements that would lose their transposase and thus can escape the Muller's ratchet. Deleterious mutations may be eliminated by reversions, by compensating new mutations, or by genetic recombination. The original hypothesis (Muller H J 1932 Amer Nature 66:118) suggested the advantage of the evolution of sex and recombination as a means to purify the population from deleterious mutations. ► **Y chromosome**, ► **genetic drift**, ► **transposable elements**, ► **retrovirus**; Gabriel W, Bürger R 2000 Evolution Int J Org Evolution 54:1116; Gordo I, Charlesworth B 2000 Genetics 156:2137.

M

Müllerian Ducts: Gonadal cells begin to develop before the mouse embryo is two-weeks old. From the unspecialized primordial cells in the male, the Wolffian ducts develop, and from those in the female, the Müllerian ducts. Initially, however, both sexes form both of these structures and appear bisexual but later, according to sex—one or the other—degenerates. The Müllerian inhibiting substance (MIS, Jost factor) causes the degeneration of the Müllerian ducts. This is a member of the TGF- β (transforming growth factor family of proteins) or is the AMH (anti-Müllerian hormone) and it is encoded in human chromosome 19p13-p13.2. Defect in the AMH receptor causes pseudohermaphroditism with uterine and oviductal tissues in males observed in PMDS (persistence of Müllerian duct syndrome). MIS regulates NF κ B signaling and breast cancer cell growth in vitro and can induce apoptosis in ovarian and cervical cancer cell lines (Renaud EJ et al 2005 Proc Natl Acad Sci USA 102:111). In mammals, the Wnt-4 signaling is required for ovarian morphogenesis. ► **gonad**, ► **Wolffian ducts**, ► **SRY**, ► **SF-1**, ► **sexual dimorphism**, ► **TGF**, ► **pseudohermaphroditism**; Segev DL et al 2001 J Biol Chem 276:26799; Bédécarrats G et al 2003 Proc Natl Acad Sci USA 100:9348.

Müllerian Inhibitory Substance (Jost factor): ► **Müllerian duct**

Müllerian Mimicry: In Mullerian mimicry, two monomorphic species share morphological similarities signaling a defense (e.g., distastefulness, poisonousness) to predators, and both benefit from the trait. Similar mimicry occurs in various species. A single gene locus may be shared among the different *Heliconius* species (see Fig. M129). ► **Batesian mimicry**; Kapan DD 2001 Nature [Lond] 409:338; Joron M et al 2006 PLoS Biol 4(10:e303).

Figure M129. *Heliconius* species of different geographical areas display Müllerian mimicry. From top to bottom: southern Ecuador, southern Brazil, northern Ecuador, western Brazil, Peru. (Courtesy of Fred Nijhout, Duke University)

Multibreed: A population including purebred and crossbred groups. ► **pure-breeding**, ► **cross breeding**

Multicase (multiple computer automated structure evaluation): Multicase relies on information of molecular fragments as descriptors of potential biological (carcinogenic) activity of chemicals. It compares the structure–activity relationship among many compounds in order to find commonality. ► **CASE**, ► **SAR**, ► **biophore**; Cunningham AR et al 1998 Mutation Res 405:9.

Multicellular Organisms: In a multicellular organism, the cells of an individual are coordinated for different function(s) and situated closely enough to ensure interaction. A bacterial colony is formed from many cells but these cells are not coordinated even when they display patterned growth. The multicellular condition apparently evolved repeatedly during evolution. The structural condition for evolution of a multicellular system was apparently the synthesis of

an adhesive polymer matrix needed for cell alignment (Vellicer GJ, Yu Y-t N 2003 Nature [Lond] 425:75). Evolution of multicellularity involved signal transmission, reception, and localized expression of specialized genes. Their main advantages are in feeding and dispersion. ►[quorum-sensing](#); Kaiser D 2001 Annu Rev Genet 35:103.

Multicompartment Virus: In a multicompartment virus, each individual viral particle may carry only part of the total genome and complementation between the particles can provide the full function. Such viral strategy permits a combinatorial advantage to the virus.

Multicomponent Virus: The genome of a multicomponent virus is segmented, i.e., its genetic material is in several pieces similarly to the chromosomes in eukaryotic nuclei. ►[bacteriophages](#)

Multicopy Plasmids: Multicopy plasmids have several copies per cell. ►[plasmid types](#)

Multidrug Resistance (MDR/ABCB1): Multidrug resistance is mediated by the multidrug transporter (MDT, 1,280 amino acids) phosphoglycoprotein that regulates the elimination (or uptake) of chemically quite different drugs from mammalian (cancer) cells in an ATP-dependent manner. MDR is generally carried by extrachromosomal elements in bacteria such as plasmids, transposons, and integrons. In cancer cells, the MDR gene is generally amplified as episomes and double-minutes. Intercellular transfer of phosphoglycoproteins can mediate acquired drug resistance (Levchenko A et al 2005 Proc Natl Acad Sci USA 102:1933). The MDR gene may be used for gene therapy by protecting the bone marrow from the effects of cytotoxic cancer drugs. The MDT gene controls a very broad base drug-resistance. The MRP (multidrug resistance associated protein) is a glutathione conjugate protein that belongs to the same family as MDR and may be expressed in cell lines where MDR function is usually limited. The bacterial multidrug resistance gene, *LmrA*, is very similar to the human gene and it is expressed in human cells when introduced by transformation. Besides gene mutation, MDR can be acquired also by rearrangement of the genome (aneuploidy) in cancer cells.

Whole-genome sequencing identified steps in the evolution of multidrug resistance in isogenic *S. aureus* isolates recovered periodically from the bloodstream of a patient undergoing chemotherapy with vancomycin and other antibiotics. After extensive therapy, the bacterium developed resistance, and treatment failed. Sequencing the first vancomycin susceptible isolate and the last vancomycin nonsusceptible isolate identified genome wide 35 point mutations in 31 loci (Mwangi MM et al 2007 Proc Natl Acad Sci USA 104:9451). ►[amplification](#), ►[multiple drug](#)

Multifactorial Cross: In a multifactorial cross, the mating is between parents, which differ at multiple gene loci.

Multifactorial Disease: Multifactorial disease is caused or controlled by more than single genes. Generally, the number of factors involved cannot be determined in a straight forward manner and environmental influences may be significant. ►[QTL](#), ►[sporadic](#)

Multiforked Chromosomes: In bacteria, replication of the DNA may start again before the preceding cycles of DNA synthesis have been completed and thus display multiple replication forks (see Fig. M130). ►[replication fork](#), ►[replication bidirectional](#), ►[DNA replication](#); diagram from Sueoka N 1975 Stadler Symp 7:71.

Figure M130. Multiforked chromosome of bacteria

Multifunctional Proteins: ►[one gene—one enzyme](#)

Multigene Family: In a multigene family, clusters of similar genes evolved through duplications and mutations and display structural and functional homologies. Some members of the families may be at different locations in the genome and some may be pseudogenes. ►[pseudogenes](#)

Multigenic: ►[polygenic inheritance](#)

Multi-Locus Probe (MLP): In a multi-locus probe, in DNA fingerprinting alleles of more than one locus are examined simultaneously. ►[DNA fingerprinting](#)

Multi-Locus Sequence Typing: Multi-locus sequence typing detects allelic variations (mutations and recombination) within about 450 bp internal sequences of seven bacterial housekeeping genes. Since the integrity

of housekeeping gene function is generally vital, most of the alterations detected are neutral. ▶[DNA typing](#), ▶[housekeeping genes](#); Feil EJ et al 2000 *Genetics* 154:1439.

Multimap: A computer program for linkage analysis using lod scores. ▶[lod score](#)

Multimeric Proteins: Multimeric proteins have more than two polypeptide subunits.

Multinomial Distribution: Multinomial distribution may be needed to predict the probability of proportions: $P = \frac{n!}{r_1!r_2!\dots r_z!} (a)_1^r (b)_2^r \dots (z)_z^r$ where P is the probability r_1, r_2, \dots, r_z stand for the expected numbers in case of a, b...z theoretical proportions and n = the total numbers. Example: in case of codominant inheritance and expected 0.25 AA, 0.50 AB, and 0.25 BB, the probability that in an AB x AB mating we would find in F2 among five progeny 2AA, 2AB, and 1 BB is: $P = \frac{5!}{2!2!1!} (0.25)^2 (0.50)^2 (0.25)^1 = \frac{120}{4} (0.0625) (0.25) (0.25) = 30(0.00391) \approx 0.117$. binomial distribution, distribution)

Multiparental Hybrid: A multiparental hybrid can be generated by fusion of two or more different embryos of different parentage at the (generally) 4 - 8 cell stage and then reimplantation at (generally) the blastocyst stage into the uterus of pseudo-pregnant foster mouse. Such hybrids may appear chimeric if the parents were genetically different and can be used advantageously for the study of development (see Fig. M131). ▶[allophenic](#), ▶[pseudo-pregnant](#), ▶[triparental human embryo](#)

Figure M131. Hexaparental mother mouse displaying yellow, black and white sectors (at right). It was obtained by aggregation of three strains in vitro that were implanted into a pseudopregnant female. Her offspring are at left. (Courtesy of RM Petters & CL Markert)

Multiparous: An animal species that usually gives birth to multiple offspring by each delivery; a human female that gives birth to twins at least twice.

Multipaternal Litter: A multipaternal litter is produced if the receptive multiparous female mates during estrus with several males. ▶[estrus](#), ▶[superfertilation](#), ▶[last-male sperm preference](#)

Multiphoton Microscopy: A non-invasive fluorescence microscopy for various tissues. Molecular excitation by two simultaneous absorptions of two photons provides intrinsic three-dimensional resolution of laser scanning fluorescence microscopy (Denk W et al 1990 *Science* 248:73). ▶[microscopy](#), ▶[laser scanning cytometry](#); Zipfel WR et al 2003 *Nature Biotechnol* 21:1369.

Multiple Alleles: More than two different alleles at a gene locus. The number of different combinations at a particular genetic locus can be determined by the formula $[n(n + 1)]/2$ where the number of different alleles at the locus is n . ▶[allelic combinations](#)

Multiple Birth: ▶[twinning](#)

Multiple Cloning Sites (MCS): ▶[polylinker](#)

Multiple Cross Mapping (MCM): A procedure for chromosomal localization of quantitative trait and complex loci using several inbred strains of mice. The technique can identify linked modifiers. ▶[QTL](#), ▶[modifier gene](#); Hitzemann R et al 2002 *Genes Brain & Behavior* 1(4):214; Park Y-G et al 2003 *Genome Res* 13:118.

Multiple Crossovers: Multiple crossovers are genetically detectable only when the chromosomes are densely marked. In the absence of interference, the frequency of multiple crossovers is expected to be equal to the products of single crossovers. ▶[coincidence](#), ▶[mapping](#), ▶[mapping function](#)

Multiple Drug Resistance (MDR): MDR is based on several mechanisms such as active detoxification system, improved DNA repair, altered target for the drugs, decreased uptake, increased efflux, and inhibition of apoptosis. The MDR genes control multiple drug resistance in mammals. The 27 exon MDR1 locus (human chromosome 7q21.1) encodes a phosphoglycoprotein and controls drug transport and drug removal ('hydrophobic vacuum cleaner' effect). A repressor binding to a -100 to -120 GC-rich sequence regulates the MDR1 gene. At -70 to -80 is a Y box (binding site of the NF-Y transcription factor). This area overlaps with the binding site of Sp1. There is also a 13-bp sequence (IN) surrounding the transcription initiation site and promoting the accuracy of transcription. If tumors have high expression of this gene, the prognosis for

chemotherapy is not good. Upon drug treatment, the activity of the MDR protein may increase several-fold. The MDR activity can be suppressed by some calcium channel blockers, antibiotics, steroids, detergents, antisense oligonucleotides, anti-MDR ribozymes, etc. Non-P-glycoprotein-mediated MDR has also been restricted by MRP (a multiple-drug-resistance-related glycoprotein), encoded in human chromosome 16p13.1. The MDR gene targeted to special tissues of transgenic animals by tissue-specific promoters may protect these tissues (e.g., bone marrow) during cancer chemotherapy. Also, the MDR transgenic cells may display selective advantage and thus be advantageous during the curing process. In mouse tumors like in human tumors, the response to drugs of individual tumors varies, but eventually they all become resistant to the maximum tolerable dose of doxorubicin or docetaxel. The tumors also respond well to cisplatin but do not become resistant, even after multiple treatments in which tumors appear to regrow from a small fraction of surviving cells. Classical biochemical resistance mechanisms, such as up-regulated drug transporters, appear to be responsible for doxorubicin resistance, rather than alterations in drug-damage effector pathways (Rottenberg S et al 2007 Proc Natl Acad Sci USA 104:12117). ▶ABC transporter, ▶cancer therapy, ▶chemotherapy, ▶multidrug resistance, ▶drug intersection, ▶transcription factors, ▶Sp1, ▶promoter, ▶epistasis; Gottesman MM et al 1995 Annu Rev Genet 29:607; Litman T et al 2001 Cell Mol Life Sci 58(7):931; review: Higgins CF 2007 Nature [Lond] 446:749.

Multiple Endocrine Neoplasia (MEN): ▶endocrine neoplasia

Multiple Epiphyseal Dysplasia (MED): An osteochondrodysplasia causing short stature and early onset osteoarthritis. Mutations in a cartilage oligomeric-matrix protein (a pentameric 524-kDa glycoprotein, COMP, 19p13.1), and in collagen IX (COL9A2, 1p33-p32.2, COL9A3, 20q13.3) cause MED. ▶osteochondromatosis, ▶osteoarthritis, ▶collagen, ▶Ehlers-Danlos syndrome, ▶pseudoachondroplasia, ▶COMP, ▶thrombospondin; Briggs MD et al 1995 Nature Genet 10:330.

Multiple Hamartoma Syndrome (MHAM, PTEN, MMAC1): Hamartomas are groups of proliferating, somewhat disorganized, mature cells—occurring under autosomal dominant control—on the skin, breast cancer, thyroid cancer, mucous membranes, and gum, but may be found also as polyps in the colon or other intestines. The lesions may become malignant. The symptoms may be associated with a number of other defects. The Cowden disease was assigned to human chromosome 10q22-q23. The Bannayan-Riley-Zonona syndrome resembles Cowden disease

and maps to the same location. The molecular basis is a dual function phosphatase with similarity of tensin. Another form involving megaloccephaly and epilepsy symptoms is the Lhermitte-Duclos disease. ▶cancer, ▶breast cancer, ▶tensin, ▶PTEN, ▶Bannayan-Riley-Zonona syndrome; Backman SA et al 2001 Nature Genet 29:396; Kwon C-H et al *ibid.* pp 404.

Multiple Hit: In a multiple hit, the mutagen causes mutation at more than one genomic site. ▶kinetics

Multiple Myeloma: A bone marrow tumor-causing anemia and decrease in immunoglobulin production, frequently accompanied by the secretion of the Bence-Jones proteins. Multiple myeloma may be genetically determined as it may appear in a familial manner. In some forms that have independent origin, within the same family or even within the same person, the protein may show some variations. It can be also induced in isogenic mice by injection of paraffin oil into the peritoneal cavity. Such animals may produce large quantities of the light chain immunoglobulin that can be subjected to molecular analysis. Such globulins are not necessarily monoclonal although from single transformation essentially similar molecules are expected. Multiple myeloma is also called amyloidosis encoded by a gene in human chromosome 11q13. Translocation of the IgH (14q32) immunoglobulin H gene to the amyloidosis locus or to the fibroblast growth factor receptor 3 (4p16.3) may also evoke multiple myeloma. The lymphocyte-specific interferon regulatory factor 4 (6p25-p23) may also be involved. The cyclin D1 protein mediating cell cycle events and the expression of oncogenes also occurs at the 11q13 location. ▶Bence-Jones proteins, ▶immunoglobulin, ▶monoclonal antibody, ▶macroglobulinemia, ▶cyclin D, ▶interferon; Kuehl WM, Bergsagel PL 2002 Nature Rev Cancer 2:175.

Multiple Regression: A continuous variable, say y regresses to other variables such as x_1, x_2, \dots, x_n . The expected value is: $E(y) = b_0 + b_1x_1 + \dots + b_nx_n$ where the b regression coefficients are generally estimated by least squares. ▶correlation, ▶least squares, ▶regression

Multiple Sclerosis (MS): a disease caused by loss of myelin from the nerve sheath or even defects of the gray matter. It is called multiple because it frequently is a relapsing type of condition involving incoordination, weakness, and abnormal touch sensation (paresthesia) expressed as a feeling of burning or prickling without an adequate cause. Myelin oligodendrocyte glycoprotein (MOG) is expressed in the central nervous system oligodendrocytes and in the outermost myelin lamellae. Anti-MOG antibodies have proven effective in destroying multiple sclerosis (demyelination) in some animal models. There is now

evidence that IgG binding to MOG can detect the disease at the preclinical early inflammatory stage in humans and marmoset monkeys (Lalive PH et al 2006 Proc Natl Acad Sci USA 103:2280).

The exact genetic basis is not clear. It may be determined polygenically or it may be recessive; in both cases with much reduced penetrance. It is associated with defects of the HLA-DQ and HLA-DR system in white as well as in American black populations (Oksenberg JR et al 2004 Am J Hum Genet 74:100). There is molecular evidence that in some forms α -B-crystalline, a small heatshock protein, is formed as an autoantigen. Viral initiation has also been considered. MS is basically an autoimmune disease. Encephalitogenic antigens and adjuvants induce *experimental allergic encephalomyelitis* in mice and the condition significantly modified autoimmune susceptibility in both females and males by the Y chromosome derived from the father and grandfather (Teuscher C et al 2006 Proc Natl Acad Sci USA 103:8024). In a rodent model, blocking cytosolic phospholipase A₂ (cPLA₂) may alleviate the condition if the disease has not progressed too far. The controls may reside in the thymus where the T lymphocytes develop. Also damage in the white matter of the central nervous system may be responsible. It appears that MS is induced by damage to the blood-brain barrier (BBB), caused by inflammatory cytokines (TFN, IFN- γ). Among close relatives the incidence may be 20 times higher than in the general population. The concordance between monozygotic twins is about 30%. HLA DR2 carriers have a four-fold increased relative risk. Females have almost twice the risk than males in the relapsing type but in the progressive MS male affliction is slightly more common. The prevalence in the USA is about 1/1,000 but it varies by geographical areas. The onset is between ages 20 to 40. Some of the symptoms may be shared with other diseases, and conclusive identification requires laboratory analysis of myelin. The synonym for MS is disseminated sclerosis. Several procedures have been suggested for the suppression or mitigation of the autoimmune reaction. Anti integrin $\alpha_4\beta_1$ agents (cognate antibodies, synthetic antagonists) may delay demyelination. In a mouse model, isolated neural precursor cells from the mouse brain was injected into the blood or the spinal fluid. These cells express the α_4 integrin protein, which may assist their movement from the blood to the brain where they differentiate into oligodendroglial cells and make myelin or may become neurons. As a consequence, the autoimmunological damage may be repaired (Pluchino S et al 2003 Nature [Lond] 422:688). Copaxone (Cop-1), and a synthetic copolymer of tyrosine, glutamate, alanine, and lysine may protect motor neurons against acute and chronic degeneration (Kipnis J, Schwartz M 2002 Trends Mol Med 8:319).

MS is under the control of several genes, yet linkage to 5p14-p12 with a lod score of 3.4 was found. The Pelizaeus-Merzbacher disease, a late onset multiple sclerosis-like disorder with an autosomal dominant expression, has been frequently confused with MS. Two principal regions in human chromosomes 17q22 and 6p21 (in the HLA area) control epistatically the susceptibility to MS. Besides these loci, chromosome 1 – centromere region also displays linkage with MS (lod score 4.9) or even stronger based on large African-European admixture populations (Reich D et al 2005 Nature Genet 37:1113). Genomewide association studies indicated linkage with the HLA region (6p21) and with interleukin receptor loci IL2RA (CD25, 10p15) and IL7RA (CD127, 5p13) and to a lesser degree with KIAA (multiple interacting proteins, 16p13) and CD58 (lymphocyte-associated antigen, 1p13) among other SNPs Ramagopalan SV et al 2007 New England J. Med. 357:2199. ▶myelin, ▶oligol, ▶epilepsy, ▶neuromuscular diseases, ▶autoimmune disease, ▶MHC, ▶HLA, ▶heatshock protein, ▶Pelizaeus-Merzbacher syndrome, ▶Addison-Schilder disease, ▶neurological diseases, ▶leukodystrophy, ▶HLA, ▶concordance, ▶twinning, ▶lod score, ▶TFN, ▶IFN, ▶BBB, ▶CD45; Klein L et al 2000 Nature Med 6:56; Smith T et al 2000 Nature Med 6:62; Barcellos LF et al 2001 Nature Genet 29:23; Schmidt S et al 2002 Am J Hum Genet 70:708; Keegan BM, Noseworthy JH 2002 Annu Rev Med 53:285.

Multiple Translocations: ▶translocation complex

Multiple Tumor Suppressor: ▶MTS1

Multiplex Amplifiable Probe Hybridization: Multiplex amplifiable hybridization uses PCR and electrophoresis for the detection of small deletions and duplications within genes. (See White S et al 2002 Am J Hum Genet 71:365).

Multiplexing: In multiplexing, several pooled DNA (or other) samples are sequenced/processed/analyzed simultaneously to expedite the process. ▶genome project

Multiplication Colony: Multiplication colony is an expansion by random mating of the foundation stock of inbred rodents for experimental use. ▶foundation stock, ▶inbred

Multiplication Rule: ▶joint probability

Multiplicative Effect: As per the multiplicative effect, alleles at more than one gene locus together have higher than simply additive contribution to the phenotype. In genetically determined disease, the relative risk with

two alleles is the square of the relative risk with only one allele. ►additive effects

Multiplicity of Infection: A single bacterial cell is infected by more than one phage particle. ►double infection

Multiplicity Reactivation: As per multiplicity reactivation, when bacterial cells are infected with more than one phage particle, each, that have been inactivated by heavy doses of DNA-damaging mutagens, the progeny may contain viable viruses because replication and/or recombination has restored functional DNA sequences. ►Weigle reactivation

Multipoint Cross: More than two genes are involved in a multipoint cross. (See <http://www.broad.mit.edu/ftp/distribution/software/>).

Multipolar Spindle: During mitosis, more than two poles exist under exceptional conditions, e.g., aneuploidy caused by fertilization by more than one sperm. Such a condition may be the result of centrosome defects in animals (see Fig. M132). Multiple centrosomes may be formed in case the tumor suppressor gene p53 is not functioning. ►mitosis, ►centrosome, ►p53, ►spindle

Figure M132. Multipolar spindle in a starfish egg

Multipotent: Multipotency is an ability to develop into more than one type of cell or tissue. ►pluripotency, ►totipotency, ►regeneration

Multi-Regional Origin: ►out-of-Africa hypothesis

Multisite Gateway Technology: Invitrogen Gateway technology exploits the integrase/*att* site-specific recombination system for directional cloning of PCR products and the subsequent subcloning into destination vectors. One or three DNA segments can be cloned using Gateway or MultiSite Gateway, respectively (Magnani E et al 2006 BMC Mol Biol 7:46; <http://www.invitrogen.com/content.cfm?pageid=8012&sku=12537023>).

Multisite Mutations: Multisite mutations occur generally when an excessively large dose of a mutagen(s) is applied. Frequently, deletions or other chromosomal aberrations are included. ►mutation, ►chromosomal aberration, ►deletion

Multistranded Chromosomes: Multistranded chromosomes contain more than two chromatids, such as in the polytenic chromosomes produced by repeated replication without separation of the newly formed strands. In the early period of electronmicroscopic studies of ordinary chromosomes, apparent multiple strands were observed, and it was assumed that each chromosome has many parallel strands of DNA (see Fig. M133). This assumption could not be validated by subsequent investigations. Each chromatid has only a single DNA double helix that is folded to assure proper packaging. ►packing ratio, ►polytenic chromosomes, ►Mosolov model

Figure M133. Scanning electronmicrograph of a segment of polytenic salivary gland chromosome. (Courtesy of Dr. Tom Brady)

Multitasking: The multitasking computer program performs more than a single operation simultaneously.

Multivalent: Multivalent refers to the association of more than two chromosomes in meiosis I. ►meiosis

Multivariate Analysis: Multivariate analysis has many uses in genetics when a decision is needed to classify syndromes with overlapping symptoms and when the diagnosis requires quantitation. It may be also used to classify populations with similar traits. The assumption is that the variates X_1, \dots, X_k are distributed according to a multivariate normal distribution. The variance of X_i , σ_{ii} and the covariance of X_i and X_j are presumed to be identical in the two populations, but σ_{ii} or σ_{ij} are not the same from one variate to another or one pair of variates to another pair, respectively. The difference between the two means for X_i is $\delta_i = \mu_{2i} - \mu_{1i}$. Hence the *linear discrimination function* $\Sigma L_i X_i$ provides the lowest probability of

incorrect classification. The L_i values will be determined according to the procedure shown. The δ/σ is maximalized for minimization of the chance of misclassification. The *generalized squared distance* is $\Delta^2 = (\sum L_i \delta_i)^2 / \sum \sum L_i L_j \sigma_{ij}$ and L_i is obtained by a set of equations: $\sigma_{11}L_1 + \sigma_{12}L_2 + \dots + \sigma_{1k}L_k = \delta_1$, $\sigma_{k1}L_1 + \sigma_{k2}L_2 + \dots + \sigma_{kk}L_k = \delta_k$. ▶[discriminant function](#), ▶[covariance](#) [[look up at correlation](#)], ▶[Euclidean distance](#))

Multivariate Normal Distribution:

$$f(x_1, x_2, \dots, x_q) = (2\pi)^{-q/2} \left| \sum \right|^{-1/2} \exp -1/2(x - \mu)' \sum^{-1} (x - \mu)$$

Multivesicular Body (MSB): Proteins or peptides covalently tagged with ubiquitin(s) are sorted through the MVB pathway and delivered to lysosome for breakdown. ▶[ubiquitin](#)

MUM (maximum unique match): Indicates the homology of the nucleotide sequences between two DNA single strands.

MUMmer: A genome sequence alignment algorithm. ▶[algorithm](#); Delcher AL et al 2002 Nucleic Acids Res 30:2478.

Mummies: Dried animal or human bodies, preserved by chemicals and/or desiccation. They may contain proteins (blood antigens), and DNA sequences to carry out limited molecular analysis using PCR technology. ▶[ice man](#), ▶[ancient DNA](#), ▶[ancient organisms](#); Buckley SA et al 2004 Nature [Lond] 431:294.

Mumps: An infectious disease caused by paramyxovirus. It is spread through contact, sneezing, saliva, or through other body fluids, and generally affects children under 15. Swelling of the parotid (salivary) glands situated in front and below the ears is its primary target, but it may affect other organs such the ovaries, testes, pancreas, and brain. In the majority of cases, clinical treatment is not required. Vaccination is available.

MUNC18: A mammalian homolog of the Unc18 protein of *Caenorhabditis*, and binds syntaxin. Sec1/Munc18 activate SNARE fusion and are required for neurotransmitter release (Shen J et al 2007 Cell 128:183). ▶[syntaxin](#), ▶[snare](#), ▶[neurotransmitter](#)

Mung Bean Nuclease: A single-strand specific endonuclease.

Munchausen Syndrome: Medically, a psychological disorder of simulating disease in order to get attention. It was so named by Batshaw ML et al (1985 in New England J Med 312:1437) for some

patients simulating Torsion Dystonia (9q34), a neurological disorder involving involuntary motions. Freiherr/Baron von Münchhausen, a German raconteur published his fancy, mendacious adventures in a *Vademecum for Happy People* in 1760, which appeared in different editions and languages and made him a legend of tall stories. ▶[dystonia](#)

Muprinting: Analysis of the pattern of integration sites of Mu phage in large populations of bacteria. ▶[Mu bacteriophage](#), ▶[insertional mutation](#)

Murashige & Skoog Medium (MS1): MS1 for plant tissue culture is suitable for growing callus and different plant organs. Composition mg/L: NH_4NO_3 1650, KNO_3 1900, $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ 440, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 370, KH_2PO_4 170, KI 0.83, H_3BO_3 6.2, $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ 22.3, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ 8.6, $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ 0.25, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ 0.02, $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ 0.025, Ferric-EDTA 43, sucrose 3%, pH 5.7, inositol 100, nicotinic acid 0.5, pyridoxine.HCl 0.5, thiamin.HCl 0.4, indoleacetic acid (IAA) 1 – 30, and kinetin 0.04 – 10. Microelements, vitamins, and hormones may be prepared in a stock solution and added before use. For kinetin, other cytokinins may be substituted such as 6-benzylamino purine (BAP) or isopentenyl adenine (or its nucleoside), for IAA, naphthalene acetic acid (NAA), or 2,4-D (dichlorophenoxy acetic acid) may be substituted or a combination of the hormones may be used in concentrations that are best suited for the plant and the purpose of the culture. For solid media, use agar or gellan gum. Heat labile components are sterilized by filtering through 0.45 μm syringe filters. Variations of this medium are commercially available as a dry powder ready to dissolve but the pH needs to be adjusted. ▶[agar](#), ▶[gellan gum](#), ▶[syringe filter](#), ▶[Gamborg medium](#); Murashige T, Skoog F 1962 Physiol Plant 15:473.

Murine: Pertaining to mice (or rats).

Murine Leukemia Virus (MuLV): ▶[viral vectors](#)

Muscarinic Acetylcholine Receptors: Muscarinic acetylcholine receptors are activated by the fungal alkaloid, muscarine, a highly toxic substance, causing excessive salivation (ptyalism, sialorrhea), lacrimation (shedding tears), nausea, vomiting, diarrhea, lower than 60 pulse rate, convulsions, etc. Deficiency of the M3 receptor decreases appetite in mice and the animals stay lean. Antidote: atropine sulfate. ▶[signal transduction](#)

Muscular Atrophy: Peroneal muscular atrophy (of the fibula) may be classified as (i) demyelinating form and sensory neuropathy, (ii) axonal motor and sensory neuropathy and (iii) distal hereditary neuropathy or distal spinal muscular dystrophy. ▶[Werdnig-Hoffmann disease](#), ▶[Kennedy disease](#), ▶[Charcot-Marie-Tooth](#)

disease, ►olivopontocerebellar atrophy, ►dentatorubral-pallidoluysian atrophy, ►Machado-Joseph syndrome, ►spinal muscular atrophy, ►trinucleotide repeats

Muscular Dystrophy: A collection of anomalies involving primarily the muscle, and controlled by X and autosomal recessive or dominant genes. The most severe form is the (DMD) *Duchenne muscular dystrophy* in human chromosome Xp21.2 (12q21). Its transmission is through the females because the males affected do not reach the reproductive stage. Similar defects were observed also in animals. The prevalence is about 3×10^{-4} . The frequency of female carriers is about twice as high as the affliction of males. The onset is around age 3 and within a few years, the affected persons fail to walk and usually die by age 20. Mental retardation is common in this disease. The earliest diagnosis may be made by an abnormally high serum creatine phosphokinase (CPK) level at birth. Prenatal diagnosis is feasible and successful in about 90% of the cases. The dystrophin gene is one of the largest human genes involving more than two megabases (about half of the size of the entire genome of *E. coli*). This gene includes many introns with an average size of about 16 kb, whereas in the about 79 exons average size is only about 50 kb. In a tissue specific manner, it may chose among eight promoters located at different positions. The full-length dystrophin is ~427-kDa but the R dystrophin is 260, the B 140, the S 114, and the G 71-kDa. The pertinent promoter used 5' downstream to determine the length of the protein. All have the same C-terminal domain, except the 40-kDa apodystrophin-3, which has a truncated C-terminal synthrophin-binding domain. The gene in the muscles appears to use a promoter other than in the brain. The majority of the cases are deletions and other chromosomal defects, yet gene mutations (predominantly frameshifts) are common too because of the large size of the gene. Intragenic recombination frequency was estimated to be 0.12. Dystrophin connects F-actin through its N-terminus, and its C-terminus binds to a complex of glycoproteins and through them to the extracellular matrix and the sarcolemma (Bassett DI et al 2003 Development 130:5851). In DMD, the dystrophin protein may be entirely missing, whereas in the milder form of the diseases, the *Becker type* (BMD), the dystrophin protein is just shorter. With antisense technology (in a mouse model, using 2'-O methyl oligoribonucleotides), skipping of exon 23 induction altered the reading frame and the mRNA was translated into a protein resembling that of the Becker type dystrophin. Such a gene therapy significantly mitigated the symptoms of the disease (Mann CJ et al 2001 Proc

Natl Acad Sci 98:42; Goyenvall A et al 2004 Science 306:1796). Adeno-associated virus vector can deliver an antisense sequence, through the tail vein to rodents had beneficial therapeutic effects (Denti MA et al 2006 Proc Natl Acad Sci USA 103:3758). The dog model of DMD responded favorable to intra-arterial delivery of blood vessel-associated stem cells making the wild type protein (Sampaolesi M et al 2006 Nature [Lond] 444:574). Combining the effects of nitric oxide with nonsteroidal anti-inflammatory activity by using HCT 1026, (a nitric oxide-releasing derivative of flurbiprofen) (see Fig. M134) in murine models for limb girdle and Duchenne muscular dystrophies, significantly ameliorated the morphological, biochemical, and functional phenotype in the absence of secondary effects and slowed down disease progression. In addition, HCT 1026 enhanced the therapeutic efficacy of arterially delivered donor stem cells, by increasing 4-fold their ability to migrate and reconstitute muscle fibers (Brunelli S et al 2007 Proc Natl Acad Sci USA 104:264).

Figure M134. Flurbiprofen

The frequency of BMD is about 0.1 of that of DMD, and the patients may live until 35 and thus may have children. Apparently, allelic genes code for BMD and DMD. Deletions in the DMD gene may affect genes proximal to the centromere: CGD (chronic granulomatous disease), or the XK (McLeod syndrome) or the XP6 (retinitis pigmentosa) and distally GKD (glycerol kinase) or AHC (adrenal hyperplasia) may be affected. The two forms of the *Emery-Dreifuss dystrophy* affecting the shoulder muscles (scapulohumeral dystrophy) are autosomal (1q21-q23, encoding lamins A and C) and X-linked (Xq28, encoding emerin). In the *limb-girdle muscular dystrophy* (LGMD, 3 dominant, 8 recessive), the defects are in the sarcoglycan subunits; α -sarcoglycan is encoded in chromosome 17q12-q21, the β subunit is coded in chromosome 4q12, whereas the γ subunit was localized to 13q12. Mouse defective in α -sarcoglycan can be successfully treated by arterial delivery of mesangioblasts (stem cells) transduced by lentiviral vectors expressing the sarcoglycan gene (Sampaolesi M et al 2003 Science 3001:487). The human chromosome 4q35 region harbors the dominant genes, which are misregulated in FSHD (*facioscapulohumeral muscular dystrophy*). In FSHD, deletion is found in a 4q35 duplicated region (D4ZA) containing

a transcriptional silencer. Overexpression of FRG1 (but not the FRG2) gene in the region leads to the FSHD disease because of inappropriate alternative splicing of the pre-mRNA of mice (Gabellini D et al 2006 Nature 439:973). LGMD1A (human chromosome 5q) and LGMD2 (human chromosome 1q11-q21) are both the dominant forms. LGMDC (3q25) involves a defect in the plasma membrane protein caveolin-3. Chromosomes 2p13, 5q22.3–31.3, and 15q15 also encode LGMD subunits. The recessive (chromosome 9q31) *Fukuyama congenital muscular dystrophy* (FCMD) has a prevalence of $\sim 10^{-4}$ in Japan. It involves polymicrogyria (numerous small convolutions of the brain) due to defects of migration of the neurons and involves mental retardation. The mutation is caused by a ~ 3 -kbp insertion of a retrotransposal tandem repeat at the 3'-untranslated sequences of a gene encoding a secreted protein, fukutin. The recessive *Miyoshi myopathy* (2q13.2) has an early adulthood onset due to defect in the 6.9-kb cDNA encoding the dysferlin protein (named after dystrophy and fertility in *Caenorhabditis*). The *oculopharyngeal muscular dystrophy* (OPMD), a late adulthood onset disease of swallowing, dropping eye lids, and limb weakness is caused by 8–13 expansion of a (GCG)₆ tract specifying polyalanine encoded by the poly(a) binding protein 2 gene (PABP2) at human chromosome 14q11-q13. The symptoms of the muscular dystrophies display considerable variation in onset and severity of expression. The face and shoulder (fascioscapulohumeral) dystrophy is limited to the named body parts. The gene was assigned to human chromosome 4q35. The congenital dystrophy gene causing deficiency in the laminin $\alpha 2$ chain (merosin) around the muscle fibers was located to human chromosome 6q22-q23. Laminin- $\alpha 2$ -deficiency can be compensated for by agrin in mouse. Adeno-associated virus vector—introduced into multiple muscles—mediated overexpression of agrin and restored the structural integrity of the basal lamina of myofibers, inhibited interstitial fibrosis, and ameliorated the pathological symptoms by such somatic gene therapy in mice (Qiao C et al 2005 Proc Natl Acad Sci USA 102:11999). For improving plasmid-mediated integration of dystrophin, phage Φ C31 integrase was used in mouse model of gene therapy for Duchenne muscular dystrophy. Using luciferase expression vector, the integration can be modified in non-invasive manner (Bertoni C et al 2006 Proc Natl Acad Sci USA 103:419). The *Ullrich* (scleroatonic) *muscular dystrophy* is a recessive defect in collagen 6 (COL6A1, COL6A2, 21q22.3, COL6A3, 2q37). Mitochondria in cells from Ullrich patients, unlike those in myoblasts from healthy donors, depolarized upon addition of oligomycin and displayed ultrastructural alterations that were worsened by treatment with oligomycin. The increased apoptosis,

ultrastructural defects, and the anomalous response to oligomycin could be normalized by Ca^{2+} chelators, by plating cells on collagen VI, by treatment with cyclosporin A, or with the specific cyclophilin inhibitor methylAla3ethylVal4-cyclosporin, which does not affect calcineurin activity (Angelin A et al 2007 Proc Natl Acad Sci USA 104:991). Other types of muscular dystrophies may accompany symptoms of other human diseases. Dystrophin is a rod-like cytoskeletal protein, normally localized at the inner surface of the sarcolemma (the muscle fiber envelope). Dystrophin is attached within the cytoplasm to actin filaments and also to the membrane-passing β subunit of the dystroglycan (DG) protein while the α subunit of DG joins the basal lamina through the laminin protein (encoded in chromosome 6q22-q23). In the membrane, DG is associated with the β and γ subunits of sarcoglycan (SG); the α sarcoglycan is extracellularly attached to the other two subunits. In *Caenorhabditis*, the acetylcholine transporter SNF-6 mediates synaptic activity at the neuromuscular junctions. Improper clearing of acetylcholine in the mutants seems to contribute to muscular dystrophy pathogenesis (Kim H et al 2004 Nature [Lond] 430:891). In some LGMD patients, there is also a defect in the muscle-specific protease calpain-3, encoded in chromosome 15q15. [The LGMD disease is also called severe childhood autosomal recessive muscular dystrophy or SCARMMD]. In some of the SCARMMDs, the defect was associated with adhalin, a 50-kDa sarcolemma dystrophin-associated glycoprotein, encoded in human chromosome 17q. Bone marrow cells, which normally are precursors of cartilage, bone, and some parenchyma cells may differentiate into myotubes and have been considered as genetic therapeutic agents for the treatment of muscular dystrophy. Carriers of dystrophies can be *biochemically normalized* when from over-expressed positive cells the protein is diffused to the nearby negative cells. In case of *genetic normalization*, degenerated myonuclei are replaced by nuclei from dystrophin-positive *muscle satellite cells* (muscle stem cells). Gene therapy is possible by the injection of integrating vectors carrying the normal genes into muscle satellite cells that may fuse with the muscle fibers. Adenovirus vectors, however, do not integrate into the host nuclei and replicate only in extrachromosomal form. Therefore, after a variable period of time they may be lost. Retroviral vectors integrate and are stably expressed in the chromosomes. They can be introduced in vivo or ex vivo. Direct injection of supercoiled plasmid DNA may also be successful for transformation although such DNAs are not integrated into the host genome and frequently display variable expression. Another therapeutic approach is the injection of fusogenic, in vitro cultured myoblast cells that may cure in a mosaic pattern the host's defect.

Upregulation of the utrophin gene (6q24, its encoded protein is 65–80% homologous to dystrophin) has also been considered as a remedy. The utrophin gene is normally active only during embryonal development and then it falls dormant. ▶myotonic dystrophy, ▶Charcot-Marie-Tooth disease, ▶neuromuscular diseases, ▶muscular atrophy, ▶neuropathy, ▶lamins, ▶agrin, ▶RFLP, ▶apoptosis, ▶emerin, ▶myotubes, ▶gene therapy, ▶adenovirus, ▶viral vectors, ▶retroviral vectors, ▶myoblast, ▶sarcolemma, ▶dystrophin, ▶caveolin, ▶dysferlin, ▶mitochondrial diseases in humans, ▶contiguous gene syndrome, ▶antisense technologies, ▶readthrough, ▶Walker-Wagner syndrome, ▶collagen; Koenig M et al 1989 Am J Hum Genet 45:498; Arahata K 2000 Neuropathology Dystrophin S34-S41; Burton EA, Davies KE 2002 Cell 108:5; Durbeej M, Campbell KP 2002 Current Op Genet Dev 12:349; Chamberlain JS 2002 Hum Mol Genet 11:2355; Hauser MA et al 2002 Am J Hum Genet 71:1428, potential gene therapies: van Deutekom JCT, van Ommen G-JB 2003 Nature Rev Genet 4:774.

Mushroom: The fruit body of basidiomycete fungi. The mushroom is generally a genetic mosaic arising from mycelial fusion of two to several genetically compatible colonies. ▶basidiomycetes, ▶fungal life cycles

Mushroom Body: A central nerve (neuropil) complex in the insect brain and the pairs of mushroom bodies are implicated in olfactory memory recall and elementary cognitive functions. Mushroom bodies regulate sleep in *Drosophila* (Joiner WJ et al 2006 Nature [Lond] 441:757). ▶memory, ▶olfactogenetics; McGuire SE et al 2001 Science 293:1330.

Music of Macromolecules: <http://www.geneticmusic.com/dnamusic>; music of the genome: <http://www.pandora.com>.

Musical Talent: Pitch perception appears to be associated with an associative auditory area of the brain (asymmetry of the planum temporale). The immediate and correct recognition of the musical pitch, an auditory tone without an external reference, is rare autosomal dominant factor in the human populations and it is called the perfect or absolute pitch (AP). The heritability of musical ability appears high (70–80). The development of this ability is favored by early musical training. Whales and several species of birds use music somewhat similarly to humans (Gray PM et al 2001 Science 291:52). The neurobiological bases of human music perception and performance is discussed by Tramo MJ 2001 Science 291:54. ▶Bach, ▶Beethoven, ▶Mozart, ▶Strauss, ▶dysmelodia, ▶amusia, ▶prosody, ▶pitch; Baharloo S et al 1998 Am J Hum Genet 62:224 *ibid.* 67:755 2000; Peretz I et al 2002 Neuron

Mustard Gas (dichloroethyl sulfide, $[\text{ClCH}_2\text{CH}_2]_2\text{S}$): A radiomimetic, vesicant poison gas, used for warfare in World War I. ▶nitrogen mustards, ▶radiomimetic

Mustards (family of cruciferous plants): The taxonomy of this family is not entirely clear. The white mustard (*Sinapis alba*) is $2n = 24$. The black mustard (*Brassica nigra*) is $2n = 2x = 16$ and supposedly the donor of its genome to the Ethiopian mustard (*B. carinata*) $2n = 34$, $(2 \times [8 + 9])$, an amphidiploid that received 9 chromosomes from *B. oleracea* ($2n = 18$). The brown mustard (*B. juncea*) $2n = 36$ ($2 \times [8 + 10]$) has one genome ($x = 8$) of the black mustard and another genome ($x = 10$) from *B. campestris* ($2n = 20$). The 38 ($2 \times (9 + 10)$) chromosomes of the rapes and swedes descended from *B. oleracea* ($2n = 18$) and *B. campestris* ($n = 20$). Sometimes *Arabidopsis* ($2n = 10$) is also called mustard since mustard also means crucifer. ▶*Brassica*

Mutatm Mouse: Commercially available transgenic strain with the *LacZ* insertion useful for testing mutagens/carcinogens. The transgene is extracted from mice and introduced into λ phage and subsequently into *E. coli* bacteria. In the presence of Xgal substrate, the mutant bacterial colonies appear colorless on a blue background because of the inactive galactosidase. Actually, mutations inside the mouse are ascertained outside the animals for convenience of detectability. ▶Big Blue, ▶Lac operon, ▶ β -galactosidase, ▶Xgal; Nohmi T et al 2000 Mutation Res 455:191.

Mutability: Mutability indicates how prone is a gene to mutate; it indicates a genetic instability. This may be an intrinsic property of the gene or due to the presence of transposable elements or it may depend on the functionality of the genetic repair systems.

Mutable Gene: A mutable gene has higher than usual rate of mutation. ▶mutator genes, ▶transposable elements, ▶mismatch repair, ▶DNA repair, ▶mutator

Mutagen: Physical, chemical, or biological agent capable of inducing mutation. ▶distal mutagen, ▶promutagen, ▶proximal mutagen, ▶ultimate mutagen, ▶activation of mutagen, ▶physical mutagens, ▶chemical mutagens, ▶biological mutagens, ▶effective mutagen, ▶efficient mutagen, ▶super-mutagen, ▶triple helix formation, ▶mutagen direct, ▶mutagen indirect, ▶environmental mutagens

Mutagen Assays: ▶bioassays in genetic toxicology, ▶Ames test, ▶C/B, ▶autosomal dominant assays, ▶autosomal recessive assays, ▶Basc

Mutagen Direct: A direct mutagen acts by modifying DNA (or RNA bases) by, e.g., alkylation or deamination, cross-linking DNA strands, and breaking the nucleic acid backbone.

Mutagen Indirect: An indirect mutagen damages DNA by its metabolic products (activation of promutagens), increase of reactive free radicals (ROS), affects (reduce) apoptosis, increases recombination, mutates oncogenic suppressors, etc.

Mutagen Information Center: ►databases

Mutagen Sensitivity: Mutagen sensitivity is determined by DNA repair and the metabolic enzymes degrading or activating mutagens/promutagens. ►DNA repair, ►promutagen; Tuimula J et al 2002 Carcinogenesis 23:1003.

Mutagenesis: Induction and procuring of mutations either by mutagenic agents in vivo or by the use of reversed genetics. Mutagenic agents usually inflict damage to the genetic material. The cell attempts to repair the lesions and uses transcription factors to meet this goal. By binding 30 damage-related transcription factors to the DNA, the DNA damage response pathway can be mapped (Workman CT et al 2006 Science 312:1054). ►mutation induction, ►cassette mutagenesis, ►transposable elements, ►insertion elements, ►insertional mutation, ►REMI, ►localized mutagenesis, ►directed mutation, ►oligonucleotide-directed mutagenesis, ►sequence saturation mutagenesis, ►RID, ►reversed genetics, ►genome-wide functional analysis, ►synthetic lethals, ►DNA repair; Jackson IJ 2001 Nature Genet 28:198.

Mutagenesis, Genome-Wide: ►insertional mutation; Spradling AC et al 1995 Proc Natl Acad Sci USA 92:10824; Szabados L et al 2002 Plant J 32:233.

Mutagenesis, Site-Selected: ►localized mutagenesis, ►directed mutation

Mutagenesis, Site-Specific: ►localized mutagenesis, ►directed mutation, ►targeting genes, ►site-specific mutation, ►RID, ►mutation locus-specific in humans

Mutagenic Potency: Mutagenic potency is difficult to determine for many agents that have low mutagenicity (see Table M8). Therefore, the genetic and carcinogenic hazard of many compounds is unknown, and possibly harmless agents may have been found mutagenic in some studies while other studies do not verify their harmful effect. There are other agents that may be definitely mutagenic and/or carcinogenic but may have escaped attention. Also, there is no perfect way to quantitate mutagenic effectiveness, particularly for human hazards because of the different quantities humans may be exposed to. As an example, the mutagenicity in the Ames *Salmonella* assay of a few compounds is listed in the table. It is interesting to note that ethylmethane sulfonate, the probably most widely used mutagen, is only the ninth on this list and nitrofurantoin, an erstwhile food preservative, exceeds its effectiveness as a mutagen on molar basis more than three thousand fold. ►environmental mutagens, ►Ames test, ►mutagen assays, ►bioassays in genetic toxicology

Mutagenic Specificity: As per mutagen specificity, base analogs (5-bromouracil, 2-aminopurine) affect primarily the corresponding natural bases. The target of hydroxylamine is cytosine. Alkylating agents preferentially affect guanine. There are no simple chemicals, however, that would selectively recognize a particular gene or genes, yet the frequency of mutation may vary according to the gene locus and the mutagen used. With the techniques of molecular biology, specifically altered genes can be produced by synthesis and introduced into the genetic material by transformation. Gene replacement by double crossing-over can substitute one allele for another (see Table M9).

Table M8. Mutagenic potency

| Compound | Mutations/nmole | Compound | Mutations/nmole |
|------------------------|-----------------|-----------------------|-----------------|
| Caffeine | 0.002 | Ethidium bromide | 80 |
| EDTA | 0.002 | Sodium azide | 150 |

Mutagenicity and Active Genes: Experimental data indicate that replicating or actively transcribed genes are preferred targets of mutagens, probably because of the decondensation of the genetic material. Spontaneous deleterious mutation does occur during the stationary phase of *E. coli* when replication is very low (Loewe L et al 2003 Science 302:1558).

Mutagenicity of Electric and Magnetic Fields: A large body of the published positive results lack rigorous experimental verification and reproducibility. Some newer data do not apparently suffer from these shortcomings. An electric field has electric charges at specific points and in the magnetic field magnetic force prevails. (See McCann J et al 1998 Mutation Res 411:45), ►mutagenicity of active genes

Mutagens-Carcinogens: A very large fraction of mutagens (genotoxic agents) are also carcinogens but not all carcinogens are mutagenic. The difference is based on the biology of the two events. Mutation is a single step alteration in the DNA/RNA and carcinogenesis is a multistep process. ►bioassays in genetic toxicology, ►environmental mutagens and carcinogens; Zeiger E 2001 Mutation Res 492:29; <http://potency.berkeley.edu/cpdb.html>.

Mutant: An individual with mutation.

Mutant Enrichment: ►screening, ►mutation detection, ►filtration enrichment

Mutant Frequency: The frequency of mutant individuals in a population, disregarding the time or event that produced the mutation. It is thus a concept different from mutation frequency. ►mutation rate, ►jackpot mutation

Mutant Hunt: Inducing/collecting/isolating particular mutants for a purpose.

Mutant Isolation: See Figs. M135 and M136 for the isolation of mutations. Basically similar procedures can be used in various microorganisms. The isolation of mutations is greatly facilitated if selective techniques are available.

Figure M135. Allyl alcohol selection of alcohol dehydrogenase mutant maize pollen. The black is dead the germinating white pollen is resistant. (Courtesy of M. Freeling, photo by D.S.K. Cheng, see also Nature [Lond] 267:154)

Revertants of auxotrophs can grow on minimal media whereas the resistants (to antibiotics, heavy metals, metabolite analogs, etc.) can be selectively isolated in the presence of the compound to what resistance is sought. Herbicide-resistant plants can be

Salmonella revertants
(G.P. Rédei, unpublished photos)

Kanamycin resistant *Arabidopsis* seedlings

Thiamine-revertant *Arabidopsis*

Figure M136. Selective isolation of mutants of bacteria and plants

selected in the presence of the herbicide. (►[mutation detection](#))

Auxotrophic animal cells could be isolated in the presence of 5-bromodeoxyuridine because the wild type cells that incorporated the nucleoside analog after exposure to visible light—because of breakage of the analog-containing DNA—are inactivated. The non-growing mutant cells fail to incorporate the analogs and thus stay alive and after transferring them to supplemented media they may resume growth. Feeding the cells allyl alcohol can isolate alcohol dehydrogenase mutations. The wild type cells convert this substance to the very toxic acrylaldehyde and are killed, whereas the alcohol dehydrogenase inactive mutants (microorganisms, plants) cannot metabolize allyl alcohol and selectively survive. ►[replica plating](#), ►[fluctuation test](#), ►[filtration enrichment](#), ►[penicillin screen](#), ►[selective medium](#), ►[Ames test](#), ►[reverse mutation](#), see Fig. [M137](#).

Mutarotation: A change in optical rotation of anomers (isomeric forms) until equilibrium is reached between the α and β forms.

Mutase: An enzyme mediating the transposition of functional groups.

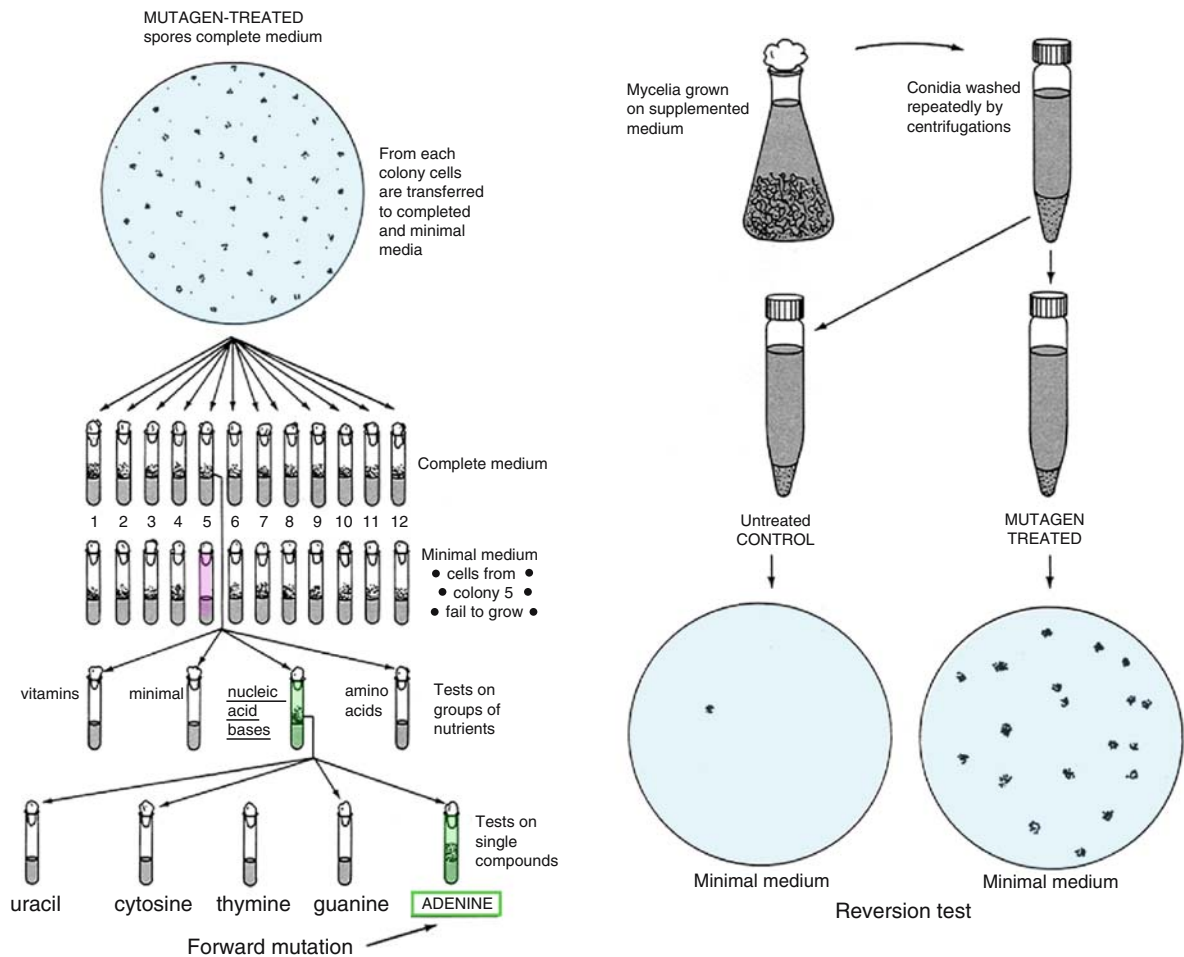

Mutosome: The enzyme complex (Rec A, UmuC-UmuD', pol III/pol V) involved in the error-prone DNA replication in translesion. In *E. coli*, the repair polymerase V and to some extent RecA are required. ►[DNA repair](#), ►[DNA polymerases](#), ►[RecA](#), ►[translesion pathway](#); Schlacher K et al 2005 Mol Cell 17:561.

Mutasynthesis: In mutasynthesis, a biochemically altered mutant of an microorganism may produce modified metabolites either directly or from a precursor analog; the new product (e.g., antibiotic) may be more useful as a drug.

Mutation: Heritable change in the genetic material; the process of genetic alteration (see Figs. [M138](#) and [M139](#)). ►[mutagen](#), ►[spontaneous mutation](#), ►[mutagenic potency](#), ►[mutagenic specificity](#), ►[mutagenicity in active genes](#), ►[mutant isolation](#), ►[mutagen assays](#), ►[mutation detection](#), ►[mutant frequency](#), ►[mutation rate](#), ►[mutation in multicellular germline](#), ►[somatic mutation](#), ►[mutation in cellular organelles](#), ►[mutator genes](#), ►[mutation chromosomal](#), ►[transposable elements](#), ►[mutation beneficial](#), ►[mutation neutral](#), ►[mutation pressure](#), ►[equilibrium mutations](#), ►[mutation useful](#), ►[mutation in human populations](#), ►[genetic load](#), ►[somatic hypermutation](#), ►[auxotrophy](#), ►[forward mutation](#), ►[reverse mutation](#), ►[polymorphism](#)

Mutation, Adaptive: ►[mutation beneficial](#)

Mutation, Age of: The age of a mutation may be inferred on the basis of breaking up the linkage disequilibrium of the ancestral haplotype by additional mutations and recombination. The task links the present haplotype to the haplotype of the coalescence. The identification of the ancestral haplotype is, however, problematic generally. There is no way to determine with certainty the constitution of the original haplotype. One approximation is the study of closely linked markers. The probability that the haplotype stays ancestral during the period elapsed since the mutation occurred can be statistically inferred. If we consider that p is the probability of the ancestral haplotype in a very large population in which all lineages are basically independent, then $G \sim -\ln(p)/r$ where G is the generations, and r is the frequency of mutations and recombination. ►[haplotype](#), ►[coalescent](#), ►[linkage disequilibrium](#), ►[genealogy](#); Reich DE, Goldstein DB p. 129 in Microsatellites, Goldstein DB, Schlötterer C (Eds.) 1999 Oxford University Press, Oxford, UK; Slatkin M, Rannala B 2000 Annu Rev Genomics Hum Genet 1:225.

M

Figure M137. General procedures for the isolation of forward and reverse mutants in fungi or other haploid organisms. The chart (left) illustrates nonselective screening of forward mutants. Mutagen-treated haploid cells are propagated on a complete medium (containing vitamins, aminoacids, nucleic acid bases, etc.). Each colony on the Petri plate is the progeny of a single cell. Inocula are transferred both to minimal (without organic supplements) and to complete media to test the nutritional requirements of the colonies. Wild-type cells are expected to grow on both minimal and complete media. Auxotrophic mutants will grow on the complete medium (as shown in test tube 5) but not on the minimal. Then cells from the complete medium culture 5 are tested further for growth on groups of nutrients (vitamins, nucleic acid bases, amino acids, etc.). The mutant will grow only on the medium which contains the compound that cannot be synthesized because of the genetic defect. Then the response of the mutant is tested on media containing single compounds. An adenine mutant will grow only on adenine. For reverse mutant isolation (right chart), cells from an auxotroph are washed repeatedly to remove the needed compound. Then the cells are exposed to a mutagen or only to the solvent of the mutagen (control), and after washing they are spread onto minimal media. Only the revertants are expected to grow. The control plate provides information on spontaneous rate of reversion. The treated cells show the effect of the potential mutagen.

Mutation and Allelic Frequencies: ►equilibrium mutations

Mutation and DNA Replication: Most commonly, mutation is caused by base substitution as replicational error. In multicellular eukaryotes, the detection of the time of mutations is technically difficult or impossible although dormant seeds exposed to ionizing radiation regularly display mutations in

the progeny. These mutations are due, however, to chromosomal breakage or to the production of reactive chemicals that may act during subsequent cell divisions. In prokaryotes, tests can be devised for the detection of mutations occurring during the stationary phase. Using a conditional lethal system for selection, the cells may survive under both restrictive and permissive conditions. Mutations arising under restrictive growth conditions are not

Figure M138. The thiazole-requiring mutants of *Arabidopsis* fail to grow on basal or pyrimidine media but display normal growth on thiazole or thiamine. (From left to right: Basal, Thiazole, Pyrimidine, Thiamine media)

Figure M139. The Thiamine biosynthetic pathway is controlled by single genes

expected to survive but may live under permissive conditions. Thus bacterial cultures in stationary phase are expected to lose all mutants, which occurred during the preceding exponential growth phase. Thus when the culture is shifted to permissive conditions, all the immediately detectable mutations must have their origin in mutations without replication.

►base substitution, ►mutagenicity in active genes, ►growth curve, ►conditional lethal, ►permissive condition; Freese E 1963 p 207. In: Molecular Genetics Pt. I. Taylor JH (Ed.) Acad. Press, New York.

Mutation Asymmetry: As per mutation asymmetry, the base substitution in the transcribed and non-transcribed strands is not equally frequent. It may be caused by transcription-coupled repair. ►DNA repair; Majewski J 2003 Am J Hum Genet 73:688.

Mutation Avoidance: Removal of potential mutations by DNA repair. ►DNA repair

Mutation, Beneficial: when a new mutant appears in the population with a reproductive success of 1.01 (selective advantage 0.01), the odds against its survival in the first generation, $e^{-1.01} \cong 0.364$. Its chances for elimination by the 127th generation will be reduced to 0.973 compared to the probability to a neutral mutation that has a 0.985 chance of extinction. Ultimately, at a selective advantage of 0.01, its chance of survival will be 0.0197. According to the mathematical argument, even mutations with twice as great fitness than the prevailing wild type, have a high (<13%) probability of being lost, $e^{-2} \cong 0.1353$, during

the first generation. Under normal conditions, the mutants' selective advantage (s) is generally very small and the probability of its ultimate survival is $(y) = 2s$. The chance of its extinction is $(l) = 1 - 2s$. In order that a mutant to have a better than random chance (0.5) for survival, the following conditions must prevail: $(1 - 2s)^n < 0.5$ or $(1 - 2s)^n > 2$, hence $-n \log_e (1 - 2s) > \log_e 2$ or approximately $-n(-2s) > \log_e 2$, and therefore $n > \log_e 2 / (2s)$, i.e., $0.6931 / (2s)$.

If $s = 0.01$ and $n =$ number of mutations, n must be larger than $0.6931 / (2 \times 0.01) = 34.655$.

In simple words, approximately 35 times must a mutation, with 0.01 selection coefficient, occur to be ultimately accepted and fixed. If the spontaneous rate of mutation at a locus is 1×10^{-6} , a population of 35 million is required for providing an adequate chance for the survival of a mutant of that type. Since the proportion of advantageous mutations is probably no more than 1 per 10,000 mutations, very few new mutations have a real chance of survival. The cause of this may be attributed to the fact that during the long history of evolution of the organisms, the majority of the possible mutations have been tried and the good ones were adopted by the species. The chances of new mutations is favored, however, when environmental conditions, such as agricultural practice, change in pests, pathogens, and predators, etc. take place for which historical adaptation does not exist.

A new study suggests that 1 in 150 newly arising mutations in bacteria is beneficial and that 1 in 10 fitness-affecting mutations increases the fitness of the individual carrying it. This high beneficial mutation rate is contingent of the relatively small size of the bacterial population ($\sim 10^4$) where clonal interference/competition among mutations would not eliminate many beneficial mutations. Hence, an enterobacterium has an enormous potential for adaptation and may help explain how antibiotic resistance and virulence evolve so quickly (Perfeito L et al 2007 Science 317:873).

►mutation neutral, ►fitness, ►selective advantage, ►selective sweep, ►mutation rate, ►adaptive evolution, ►genetic load, ►deleterious mutation

Mutation Bias: As per mutation bias, microsatellite sequences undergo frequent unequal recombination or replicational errors but the changes increase when the size of the tracts is short and decrease when it is longer than a particular size (~ 200) because the longer tracts are likely to include imperfections. This bias may be maintained in the population by selective forces. In various organisms, one type of base pair substitutions are more frequent than the others, presumable caused by differences of genetic repair. ►microsatellite, ►unequal crossing over; Udupa SM, Baum M 2001 Mol Genet Genomics 265:1097; Green P et al 2003 Nature Genet 33:514.

Mutation, Chromosomal: Partial chromosomal losses (deletion, deficiency), duplications, and rearrangements of the genetic material (inversion, translocation, transposition) are considered chromosomal mutations. The various types of aneuploids (nullisomy, monosomy, trisomy, polysomy, etc.) or increase in the number of genomic sets (polyploidy) can also be classified as chromosomal mutations. (See the specific entries for more details).

Mutation Clearance: The removal of disadvantageous mutations from a population. The emergence of sex and recombination facilitate the process.

Mutation, Compensatory: Compensatory mutation restores stability and/or functionality of another mutation.

Mutation, Cost of Production: The cost of production of mutations varies a great deal from organism to organism and also depends on the developmental stage when the mutagen is applied. Mutation induction at the gametic stage may be less expensive than at the multicellular (diploid) germline stage. In higher plants such as *Arabidopsis*, mutagens are generally applied to the mature seed and thus two generations are required for the isolation of mutants to be used for further experimental studies. The cost of raising these two generations may not be equal and both contribute to the final cost. Although in large M_2 families there is an increased probability for recovering the mutations induced, from the viewpoint of cost effectiveness large number of families with minimal size each are desirable. In case of recessive mutations, depending on the (n) number of individuals in M_2 families, the probability of recovery (P) of a mutant is at $n = 1$ ($P = 0.25$), $n = 2$ ($P = 0.437$), $n = 4$ ($P = 0.683$), $n = 8$ ($P = 0.899$), $n = 16$ ($P = 0.989$),

and $n = 24$ ($P = 0.998$) in case of heterozygosity of the M_1 generation, derived from a single cell. It is thus obvious that increasing the M_2 size from 1 to 24 involves the increase of probability of recovery only from 0.25 to 0.998. In the final cost, the cost of both generations must be included along with the effectiveness of recovery of the mutations induced. Table M10 indicates that M_2 family sizes larger than four individuals generally increase the labor and the cost. The recovery of mutations is most effective if selective techniques are applicable. Unfortunately, in some cases (morphological mutants) this may not be possible. (See Rédei GP et al 1984 In: Mutation, Cancer and Malformation, Chu EHY, Generoso WM (Eds.) Plenum, New York, pp 295).

Mutation, Dating of Origin: G (number of generations since the emergence of the mutation) can be determined in a population using the information of linkage disequilibrium (δ) concerning closely linked genetic or molecular markers and their known recombination frequencies (θ):

$$G = \frac{\log[1 - Q/(1 - pN)]}{\log(1 - \theta)} \times \frac{\log \delta}{\log(1 - \theta)}$$

where $\delta = (pD - pN)/(1 - pN)$ and pD and pN represent the two different linkage phases of the homologous chromosomes. Q (probability) = $(1 - [1 - \theta]^G)(1 - pN)$. (See Guo SW, Xiong M 1997 Hum Hered 47(6):315; Colombo R 2000 Genomics 69:131).

Mutation Detection: Detection of mutation depends on the general nature of the organisms. In haploid organisms (bacteria, algae, some fungi), in haploid cells (microspores, pollen, sperm), in hemizygous cells (e.g., Chinese hamster ovary cell cultures), or in heterozygotes for easily visible somatic markers, the mutations are readily detectable. In diploid or polyploid cells, only the dominant mutations can immediately be

M

observed and for the detection of recessive mutations a more elaborate procedure is required (►mutation in the multicellular germline). The most effective methods involve selective screening. In diploid cell cultures, recessive mutation can be detected if mitotic recombination generates homozygosity at the mutant locus (Guo G et al 2004 Nature [Lond] 429:891; Yusa K et al ibid pp 896) or if the dominant wild type allele is deleted. Molecular methods are also available but these are generally not suitable for large-scale screening. When single-stranded DNA is subjected to electrophoresis in non-denaturing gel, changed pattern is detectable by SSCP. Heteroduplexes can be resolved by instability in non-denaturing gradient gels (DGGE). Also, heteroduplexes move differently in non-denaturing gels. Cleavage of heteroduplexes by chemicals or enzymes may detect mutant sites. Polymorphism at a single locus can be detected by automated analysis using PCR and fluorescent dyes coupled with a quencher (see more under ►polymorphism). Mutation may be detected by chemical modification of the mismatches. Carbodiimide generates electrophoretically slow moving DNA containing mismatched deoxyguanylate or deoxythymidylates. Hydroxylamine modifies deoxycytidylate and osmium tetroxide modifies deoxycytidylate and deoxythymidylate in such a way that the DNA at these residues becomes liable to cleavage by strong bases. Ribonuclease A cleaves at mismatches (depending on the context) in RNA-DNA hybrids. The Mut Y glycosylase of *E. coli* excises adenine from A-G and, with somewhat less efficiency, from A-C mispairs. In *E. coli*, methyl-directed mismatch system is working primarily up to 3-nucleotide insertions or deletions but longer sequences barely respond, if corrected at all, and C-C pairs are ignored. The MutH/L/S multi-enzyme complex misses only 1% of the G-T mispair-induced cuts at nearby GATC sequences. The repair is identified by PCR, which also may be a source of replicational error. The latter errors can be estimated as $f = 2/na$, where f is the estimated fraction of mutations within the sequence, l = the length of the amplified sequence, n = the PCR cycles, and a = the polymerase-specific error rate/nucleotides; (a for Taq polymerase is within the range of 10^{-6} to 10^{-7}). Direct sequencing may provide the most precise information at the highest investment of labor. ►selective screening, ►replica plating, ►sex-linked lethal tests, ►specific-locus tests, ►mutation in human populations, ►Ames test, ►host-mediated assays, ►EMC, ►SSCP, ►DGGE, ►DNA sequencing, ►gel electrophoresis, ►polymorphism, ►PCR, ►footprinting genetic, ►mutant isolation, ►bioassays in genetic toxicology, ►substitution mutation, ►padlock probe, ►SNIPS, ►Comet assay, ►heteroduplex analysis, ►allele-specific probe for mutation, ►ARMS, ►alanine-scanning mutagenesis, ►hemiclinal, ►cancer [INTER-SS PCR]

Mutation Equilibrium: ►equilibrium mutations

Mutation Frequency: The same as mutation rate; see also ►mutant frequency (that is different from mutation frequency).

Mutation, Implicit: A replication error rather than base substitution, insertion, deletion, or recombination. This term is used in genetic algorithms. ►algorithm genetic

Mutation in Cancer Cells: ►cancer, ►Knudson's two-mutation theory

Mutation in Cellular Organelles: Cellular organelles mitochondria and plastids are generally present in multiple copies per cell, and within individual organelles generally several copies of DNA molecules exist. Therefore, it generally is not expected that the mutations would be immediately revealed. For their visible manifestation they have to "sort out", i.e., the mutations may not be visible until single organelles become "homogeneous" regarding the mutation, and single cells would be "homoplasmonic" regarding that particular organelle. Although this process is frequently claimed to be stochastic, the direct observation does not seem to support the assumption. Organelles divide by fission, and the daughter organelles are expected to stay in the vicinity of the parental organelle within the viscous cytosol. Thus it is not mere chance where they are located, and the progeny organelles tend to remain clustered unless the plane of the cell division separates them. Therefore, sorting out may be a relatively fast process. Mutations in chloroplast gene generally do not affect the morphology of the plants, however, inactivation of the *clpP1* (caseinolytic protease P1) gene interferes with shoot development in tobacco (Kuroda H, Maliga P 2003 Nature [Lond] 425:86). Mutation in tRNA^{Leu} (MTTL1) in lung carcinoma cybrid cells may be higher than 95% and suppressor mutations in mitochondrial DNA have been identified in only about 10% of the total mtDNA. ►mitochondrial genetics, ►chloroplast genetics, ►mtDNA, ►chloroplasts, ►mitochondrial diseases in humans, ►suppressor gene, ►suppressor tRNA, ►sorting out

Mutation in Human Populations: Mutation in human populations is difficult to study directly because the random or assorted mating systems do not favor the identification of recessive mutations. Therefore, human geneticists generally rely on the relative increase of "sentinel phenotypes" such as new dominant mutations, hemophilia, muscular dystrophy, and cancer that may be used as "epidemiological indicators" for an increase of mutation. Also, sister chromatid exchange, chromosomal aberrations, and sperm motility assays may reveal mutations.

Molecular methods, such as RFLP, RAPD, and PCR have become more available recently and have changed the previously held view that was based on the fact that no transmitted genetic effects of radiation had been clearly detected by the traditional methods in human populations. Mutational hazard for humans is generally inferred from mouse data, which include induced mutations. The immature mouse oocytes are insensitive to radiation-induced mutation but quite likely to be killed by 60 rads of neutrons and 400 R of X-rays or γ rays. Maturing or mature mouse oocytes on the other hand are very susceptible to mutation by acute radiation, although the sensitivity to low-dose rate irradiation is 1/20 or less. In contrast, the immature human oocytes are not susceptible to killing but their susceptibility to mutation is not amenable to testing. The estimated mutational hazard of mouse oocytes at various stages ranged from 0.17 to 0.44 times that in spermatogonia, indicating lower hazard to females than to males. In industrialized societies, chemical mutagens constitute the major hazard, and because of their variety and potency, their effects are difficult to assess, especially at low levels of exposure. Mutation rates can be estimated also on the basis of base substitutions in synonymous and non-synonymous codons. It may be assumed that the majority of non-synonymous substitutions are more or less deleterious, whereas the synonymous substitutions are neutral. It has been estimated that a total of 100 new mutations occur in the genome of each human individual and that the rate of deleterious mutations per generation per diploid human genome is ~ 1.6 . (See more under individual entries, ►mutation rate [undetected mutation], ►doubling dose, ►bioassays in genetic toxicology, ►specific locus mutations test, ►RBE, ►atomic radiations, ►base substitution mutation, ►synonymous codon, ►mutation neutral, ►genetic load, ►diversity, ►human mutation assays, ►mutation locus-specific in humans; <http://mutview.dmb.med.keio.ac.jp>; <http://archive.uwcm.ac.uk/uwcm/mg/hgmd0.html>; <http://www.hgmd.cf.ac.uk/ac/index.php>; human gene mutation database: <http://www.hgmd.org/>).

Mutation in Multicellular Germline: Mutation in the multicellular germline reveals the numbers of cells in that germline at the time the mutation occurred (see Fig. M140). E.g., if a plant apical meristem is treated with a mutagen at the genetically effective 2-cell stage, in the second generation of this chimeric individual the segregation for a recessive allele will not be 3:1 but 7:1. This is so because one of the cells will produce four homozygous wild type individuals, the other cell will yield one homozygous wild type + 2 heterozygotes (=3 dominant phenotypes) and one homozygous recessive mutant ([4 + 3]:1). In case the

germline contains four cells, the segregation ratio is expected to be 15:1 (1/16). In case it consists of eight cells, the proportions are 31:1. ►mutation rate, ►GECN; Rédei GP et al 1984 In: Mutation, Cancer and Malformation, Chu EHY, Generoso WM (Eds.) Plenum, New York, pp 295.

Mutation Load: ►genetic load

Mutation, Locus-Specific in Humans: Database of mutations specific for human genes: http://archive.uwcm.ac.uk/uwcm/mg/docs/oth_mut.html.

Mutation, Neutral: A neutral mutation is neither advantageous nor deleterious to the individual homo- or heterozygous for it. Its chance of immediate loss is determined by the first term of the Poisson series, $e^{-1} \cong 0.368$. (►evolution non-Darwinian). Consequently, its chance for survival is $1 - 0.362$. The chance for its extinction during the second generation is $e^{-0.632} \cong 0.532$, and by the third generation it is $e^{-(1 - 0.532)} \cong 0.626$ ($e = 2.71828$). In general terms, the extinction of any neutral mutation is e^{x-1} where x is the probability of its loss in the preceding generation. According to R.A Fisher, by the 127th generation the odds against the survival of a neutral mutation is 0.985 and may eventually reach 100%. Several evolutionists, notably M. Kimura, have argued statistically against the conclusion of Fisher (and the Darwinian theory of the necessity of selective advantage). Accordingly, if the rate of mutation for a locus is μ , the population size is N , and the organism is diploid, the number of new mutations occurring per generation per gene are $2N\mu$. The chance for random fixation is supposed to be $(1/2)N$ because the new allele is represented only

once among the total of $2N$. The probability of fixation, accordingly, is expected to be $(2N\mu) \times [(1/2)N] = \mu$, indicating that the rate of incorporation of a new neutral mutation into the population is equal to the mutation rate. The average number of generations required for fixation of a neutral mutation (according to Kimura and Ohta) is expected to be $4N_e$ where N_e = the effective population size. Thus, if the effective population size = 1,000 individuals, it takes 4,000 generations for a neutral mutation to be fixed in the population.

Sequencing 419 genes from 24 lines of *Drosophila melanogaster* and some related species, nearly 30% of the amino acid substitutions appeared to be adaptive (Shapiro JA et al 2007 Proc Natl Acad Sci USA 104:2271). In *Caenorhabditis elegans*, 65–80% of the mutations do not have a visible phenotype and thus do not seem to have much effect on fitness. In some human families, a 28-kb, apparently neutral, deletion was detected in chromosome 15q11-q13 area involved in imprinting (Buiting K et al 1999 Am J Hum Genet 65:1588). On the basis of nucleotide sequences, the neutrality can be statistically estimated by the HKA formula (Hudson RR et al 1987 Genetics 116:153) at the constant rate neutral model under specified conditions:

$$\chi^2 \sum_{i=1}^L (S_i^A - \hat{E}[S_i^A])^2 / \hat{Var}[S_i^A] + \sum_{i=1}^L (S_i^B - \hat{E}[S_i^B])^2 / \hat{Var}[S_i^B] + \sum_{i=1}^L (D_i - \hat{E}[D_i])^2 / \hat{Var}[D_i]$$

where L indicates the locus (loci, l) in species A and B sequenced. S_i^A and S_i^B stand for the number nucleotide sites that are polymorphic at locus i in the number of gametes of species A and B, respectively. D_i indicates the number of differences at locus i between a random sample of gametes of species A and B, respectively. \hat{E} and \hat{Var} stand for the estimates of expectation and variance, respectively. In the past, sequence variation in mitochondrial DNA has been considered as neutral but this assumption may not be generally valid. It is generally assumed the synonymous substitutions in the codons are neutral because these do not alter the amino acid sequence and composition of the proteins. This assumption may not be entirely valid because the codon usage is not stochastic and synonymous base substitutions may still affect RNA splicing and stability (Chamary JV et al 2006 Nature Rev Genet 7:98). The basic rate of neutral mutation can be detected in non-functional pseudogenes. ►effective population size, ►non-Darwinian evolution, ►adaptive evolution, ►neutral space, ►mutation beneficial, ►ultraconserved DNA elements, ►mutation rate, ►fitness, ►imprinting, ►radical amino acid substitution, ►McDonald-Kreitman hypothesis, ►Tajima's method,

►codon usage; Hudson RR et al 1987 Genetics 116:153; Kimura M, Ohta T 1977 J Mol Evol 9 (4):367; Gerber AS et al 2001 Annu Rev Genet 35:539; Clark AG et al 2003 Science 302:1960.

Mutation Pressure: Repeated occurrence of mutations in a population.

Mutation Pressure Opposed by Selection: Mutations are frequently prevented from fixation by chance alone (see mutation neutral, mutation beneficial, non-Darwinian evolution). An equilibrium of selection pressure and mutation pressure may be required for the new mutations to have a chance for survival. Mathematically, the frequency of homozygous mutants is $q^2 = \mu/s$ where μ is the mutation rate and s is the coefficient of selection. ►allelic fixation

Mutation-Preventive Concentration: A high concentration of a drug that does not permit the survival of even resistant mutant cells.

Mutation Rate: Frequency of mutation per locus (genome) per generation. This calculation is relatively simple if the cells population is haploid (prokaryotes, most of the fungi, or when the gametes are mutagenized). Mutation rate can be expressed also as alteration per nucleotide or as mutation per replicational cycle. If mutation takes place in the multicellular germline of higher eukaryotes, only indirect procedures can be used. First, the genetically effective cell number (GECN) in the germline must be determined (see genetically effective cell number). One must know also the level of ploidy. Thus mutation rate in these germline cells (R) is:

$$R = \frac{\text{number of independent mutational events}}{\text{survivors} \times \text{GECN} \times \text{ploidy}}$$

The standard error of mutation rates (s_m) can be computed as $\sqrt{\mu[1 - \mu]/n}$ where μ = the mutation rate observed, and n = the size of the population. The calculation of the mutation rate on the basis of survivors may pose problems if two different agents are compared. An example: if we use 10,000 haploid cells as a concurrent control and find 10 mutations, the spontaneous mutation rate would be $10/10,000 = 0.001$. If we expose another 10,000 cells to a mutagen that is lethal to 5,000 cells but again we obtain 10 mutations, the calculated apparent induced mutation rate is $10/5,000 = 0.002$, when actually the treatment may not have induced any mutation, it may have only reduced survival. In case the mutagen is very potent and in each genome or family multiple mutations occur, it may become very difficult to distinguish the multiple mutations from the single ones without further genetic analysis. Some information indicates that in bacteriophages, in case of high mutation rate (induced by mutator factors) more mutants contain more than a single (clustered) mutation as expected

by random distribution (Drake JW et al 2005 Proc Natl Acad Sci USA 102:12849). Since the distribution of mutations follows the Poisson distribution, in such a case the average mutation rate may be better determined on the basis of the size of the fraction of the population that shows no mutation at all. This is the zero class of the Poisson series, $e^{-\mu}$. If, e.g., the fraction of mutations of the population is 0.3, then zero class is $1 - 0.3 = 0.7 = e^{-\mu}$. Hence $-\mu = \ln 0.7 = -0.3566$ and $\cong 0.36$. In yeast for the determination of spontaneous backmutation rate, the formula of von Borstel may be used. Accordingly, $M = e^{(N_0/N)} - m_b/2C$, where N = the total number of compartments, N_0 = number of compartments without reversions, m_b = the average number of mutants in the inoculum, and C = the average number of cells in the compartment after the stoppage of growth. If no mutations are found at all in an experimental population, that does not necessarily mean that the mutation rate is zero. An approximation to the possible mutation frequency may be made. If we assume perfect penetrance and “normal distribution” of undetected mutations, we may further assume that in a population of n genomes the frequency of mutations is $(1 - q)$ at a probability of P . In order to obtain an estimate of q , we have to solve the equation: $(1 - q)^n = (1 - P)/2$, hence $\hat{q} = 1 - \sqrt[n]{[1 - P]/2}$. As an example, after arbitrary substitution of 10,000 for n and 0.99 for P , $\hat{q} \approx 1 - \sqrt[10000]{0.01/2} \approx 1 - 0.9995 \approx 5.3 \times 10^{-4}$. In simple words, this means that if we observed no mutations at all, there is a high probability that actually more than five may have occurred under these conditions but we have missed them by chance. It is also possible—of course—that the rate of mutation in this case is much below the 10^{-4} range or it may even be zero.

Mutation rate in human populations in case of dominance may be estimated:

$$\frac{\text{number of sporadic cases}}{2 \times \text{number of individuals}} = \mu.$$

The number of individuals stands for the number of total population studied and 2 is used to account for diploidy. Frequently, it may be necessary to use a correction factor for penetrance or viability. Recessive X-linked mutations can be estimated on the basis of the afflicted males and the formula becomes $\mu = (1/3)s(n/N)$, where n = the number of new mutations, N = the size of the population examined and s = the relative selective value and/or penetrance. (The 1/3 multiplier is used because the females have 2 and the males have 1 X chromosome). Estimation of the rate of recessive mutations is very difficult in human populations because the detection of homozygotes would require controlled mating (inbreeding). Mutation rate in mammals varies a great

deal (Ellegren H et al 2003 Curr Opin Genet Dev 13:562). The majority of the spontaneous mutations among humans occur in the males (achondroplasia, acrodyostosis, Marfan syndrome, oculodentaldigital syndrome, Pfeiffer syndrome) because more cell divisions take place in the male germline than in that of the female. Some analyses indicate four times higher mutation rates in males than in females and lower base substitutions in the human X-chromosomes than in the autosomes. Some other studies claim much smaller excess of mutations in the human males (Crow JF 2000 Trends Genet 16:525). On the basis of sequencing the human genome the male:female substitution rate $\alpha_m:\alpha_f = 2.1$. Mutability increases with paternal age. In some instances, the increased male mutation rate was attributed to a paradoxical selective advantage of the spermatogonia carrying the mutation (Goriely A et al 2003 Science 301:643). The number of indel mutations in the X and Y chromosomes is practically the same but in the Z chromosome of birds about twice as many indels were detected than in the W chromosome (Sundström H et al 2003 Genetics 164:259). In some human diseases, (e.g., Duchenne muscular dystrophy, neurofibromatosis) there is no large sex bias, however. Actually, deletions may be more frequent in females than in males (presumably because of the long dictyotene stage). In point mutation there is a reverse tendency. Human geneticists may also have great difficulty in identifying mutations that have symptoms overlapping several syndromes. For single cases, multivariate statistics may be used but for many this procedure may be arduous.

Precise calculation of mutation rate is almost intractable by classical techniques but may be solved by molecular methods. DNA sequencing indicates genetic variations in the range of about 1 per kb. Many of these are synonymous at the protein level or do not alter the visible phenotype. The rate of synonymous mutations is higher than that of the non-synonymous (Li WH et al 1985 Mol Biol Evol 2:150). Calculating mutation rate may not be accurate if the incidence of the mutation is considered at a particular age but potential loss of the mutations by abortus or neonate death is not considered. The mutation rate on the basis of single nucleotide polymorphism in a population for the Y chromosomes and autosomes has been estimated within the range 1.9×10^{-9} to 5.4×10^{-9} , and for mitochondria 3.5×10^{-8} per site per year. Other estimates for average nucleotide changes/human genome are higher (2.5×10^{-8} , ~ 175 /diploid genomes/generation). Single nucleotide replacements appear an order of magnitude higher than “length mutation”. Both transitions and transversions are most common at CpG sites. The average deleterious mutation rate (U) in humans appears 3 or less. In the HIV1 retrovirus,

mutation rate per nucleotide per generation was estimated to be as high as 1 per 10^{-5} to 10^{-4} .

Mutation rate in bacteria has been estimated by various means.

Rate = $\ln 2(M2 - M1)/(N2 - N1)$, alternatively $R = 2\ln 2(\frac{M2}{N2} - \frac{M1}{N1})/g$ where M1 and M2 are the number of mutant colonies at time 1 and 2, respectively; N1 and N2 are the corresponding bacterial counts, \ln = natural logarithm, g = number of generations. In order to obtain reliable estimates on the rates, the culture must be started by large inocula to avoid bias due to mutation at the early generations when the population is still small, and the experiments must be maintained over several generations under conditions of exponential growth. The majority of the *Caenorhabditis* genes do not mutate to visible, lethal, or sterile phenotypes. Some double mutants may display, however, mutant phenotype. In *Caenorhabditis*, by sequencing PCR-amplified genomes the spontaneous mutation rate per nucleotide per generation was found to be 2.1×10^{-8} , about an order higher than previous estimates for the organism (Denver DR et al 2004 Nature [Lond] 430:679) and for some of the figures given above for humans. More than half of the mutations were insertions or deletions. The rate of mitochondrial mutations was also higher (1.6×10^{-7}) than the neutral mutation rate in bacteria (Ochman H 2003 Mol Biol Evol 20:2091) or in human mitochondria as shown. The true mutation rate can be determined only by sequencing of the DNA. ▶mutation spontaneous, ▶fluctuation test, ▶multivariate analysis, ▶discriminant function, ▶F_{ST}, ▶polymorphism, ▶diversity, ▶chromosome replication, ▶synthetic lethal, ▶band-morph variants, ▶hemophilia, ▶SNIP, ▶substitution mutation, ▶base substitution, ▶error in replication, ▶DNA repair, ▶mitochondrial mutation, ▶indel, ▶mutator gene, ▶hot spot; Crow JF 2000 Nature Rev Genet 1:40; Nachman MW et al 2000 Genetics 156:297; Kumar S, Subramanian S 2002 Proc Natl Acad Sci USA 99:803.

Mutation Rate, Effective (w): The product of the mutation rate and the variance of mutational changes.

Mutation Rate, Evolution of: The evolution of the mutation rate is determined by the presence of mutator and antimutator factors. ▶mutator, ▶antimutator; Baer CF et al 2007 Nature Rev Genet 8:619.

Mutation Rate, Induced: Inducing N-ethyl-N-nitrosourea in mice at specific loci, 1.5×10^{-3} mutations per locus were observed. This rate may, however, be an overestimate for other eukaryotes, and the range appears to be about 10^{-4} or less. The induced mutation rate per cGy per locus in mouse was estimated to be 2.2×10^{-7} and in *Drosophila* $1.5\text{--}8 \times 10^{-8}$. It appeared also that in mouse the females had lower rates than the

males although the frequencies are much affected by the developmental stages. ▶mutation rate spontaneous, ▶supermutagens, ▶Gy, ▶MNU, ▶error in replication

Mutation Rate in Fitness: In *Drosophila*, about 0.3/ genome/generation was estimated as the frequency of deleterious mutations. In *E. coli*, the rate of deleterious mutations per cell was estimated to be 0.0002. This is larger than three orders of magnitude difference. The *Drosophila* genome is about 20 fold larger than that of *E. coli* and during a generation approximately 25 divisional cycles take place compared to one in the bacterium. If we take the liberty of making adjustments for these differences, $0.0002 \times 20 \times 25 = 0.1$, the deleterious mutation rate in the eukaryote and the prokaryote falls within close range. Mutation rate in fitness is very difficult to estimate and in *Caenorhabditis* it appears three order of magnitude lower than in *Drosophila*. (See Zeyl C et al 2001 Evolution Int J Org Evolution 55:909).

Mutation Scan: A system of mutation detection.

Mutation Screening: Selective isolation of mutation(s).

Mutation Shower: Chronocoordinate multiple mutations spanning multiple kilobases (Wang J et al 2007 Proc Natl Acad Sci USA 104:8403).

Mutation Spectrum: The mutation spectrum indicates the range of mutations observed in a population under natural conditions or after exposure to different types of mutagens (see Fig. M141). The theoretical expectations would be that the common genetic material would mutate at the same rate at identical nucleotides in different organisms or under different conditions. This expectation is not met because some mutagenic agents have specificities for certain bases. Others act by breaking the chromosomes, depending on their organization and the physical and biological factors present. Also, genes present in multiple copies per genome may suffer mutational alterations but this

Figure M141. Sample of the spectrum of morphological mutations in *Arabidopsis* expressed at the rosette stage grown under 9 hours daily illumination. Columbia wild type is at the top right corner

may not be observed by classical genetic analysis although molecular methods may detect them. In general, obligate auxotrophic mutations are very limited in higher plants when the screening uses selective culture media. A range of morphological mutants of *Arabidopsis* (Figure M141); Li SL et al

1967 Mol Gen Genet 100:77; Reich DE, Lander ES 2001 Trends Genet 17:502.

Mutation, Spontaneous: Spontaneous mutation occurs at low frequency and its specific cause is unknown (Figure M142). The rate of spontaneous mutation per

Figure M142. Mutations affecting the shape of the flower of snapdragon. The standard wild type is in the upper left corner. (Composed on the basis of H. Stubbe 1966 Genetik und Zytologie von *Antirrhinum* L. Sect. *Antirrhinum*. Fischer, Jena, Germany)

genome may vary. In bacteriophage DNA, it is 7×10^{-5} to 1×10^{-11} , in bacteria 2×10^{-6} to 4×10^{-10} , in fungi 2×10^{-4} to 3×10^{-9} , in plants 1×10^{-5} to 1×10^{-6} , in *Drosophila* 1×10^{-4} to 2×10^{-5} , in mice for seven standard loci is 6.6×10^{-6} per locus, in humans, 1×10^{-5} to 2×10^{-6} rates have been reported. The total number of detectable spontaneous mutations per live birth had been estimated as 10–3% but neither of these % estimates is very accurate because of the uncertainties of identifying very low levels of anomalies. In RNA viruses, the very high rates of 1×10^{-3} to 1×10^{-6} per base per replication have been estimated. The RNA viruses lack repair system. Amino acid substitutions in proteins may occur at the rate of 10^{-4} /residue. The error rate of the reverse transcriptase is extremely high because the enzyme does not have editing function. The induced rate of mutation may be three orders of magnitude higher but it varies a great deal depending on the locus, the nature of the mutagenic agent, the dose, etc. Mutation rates per mitochondrial D loop have been estimated to be 1/50 between mothers and offspring but other estimates used for evolutionary calculations are 1/300 per generation. Mutation rate in mitochondria on the basis of phylogenetic studies was estimated $\sim 0.17 \pm 0.15$ – 2.2 /site/Myr to 1.35 ± 0.72 – 1.98 /site/Myr at the 95% confidence level. Mutation rate per base in the human mitochondria has been estimated as 5×10^{-7} . ▶mutation rate induced, ▶mutation rate, ▶confidence interval, ▶Myr; for human diseases see Sankaranarayanan K 1998 Mutation Res 411:129; Maki H 2002 Annu Rev Genet 36:279.

Mutation, Useful: Although the majority of the new mutations have reduced fitness and are rarely useful for agricultural or industrial applications, some have obvious economic value.

Spontaneous and induced mutations have been incorporated into commercially grown crop varieties by improving disease and stress resistance, correcting amino acid composition of proteins, and eliminating deleterious chemical components (erucic acid, alkaloids, etc.).

Most of the natural variation in the species arose by mutation during their evolutionary history, and many have been added to the gene pool of animal herds and cultivated plants. Many of the floricultural novelties are induced mutants. Some of the animal stocks have accumulated single mutations, others such as the platinum fox are based on a single dominant mutation of rather recent occurrence (see Fig. M143).

Genetic alterations in industrial microorganisms have contributed very significantly to the production of antibiotics. (See Demain AL 1971 Adv Biochem Eng 1:113; Sakaguchi K, Okanishi M (Eds.) 1980 Molecular Breeding and Genetics of

Figure M143. Dark platinum fox mutant (From Mohr O, Tuff P 1939 J Heredity 30:227)

Applied Microorganisms, Academic Press, New York; Quesada V et al 2000 Genetics 154:421).

Mutational Bias: Microsatellites tend to change to longer repeats sequences, thus the bias is in favor of longer repeat tracts although long repeats may not recombine if mismatches are included that impede chromosome pairing. ▶microsatellite

Mutational Decay: Losing DNA sequences during evolution when their presence is no longer indispensable.

Mutational Delay: As per mutational delay, there is a time lag between the actual mutational event and the phenotypic expression because recessive mutations may show up only when they become homozygous. In organelles, the mutations must sort out before becoming visible, etc. ▶sorting out, ▶pre-mutation

Mutational Dissection: Analysis of a biochemical, physiological, or developmental process with the aid of mutations in the system.

Mutational Distance: The number of amino acid or nucleotide substitutions between (among) macromolecules that may indicate their time of divergence on the basis of a molecular clock. ▶evolutionary distance, ▶evolutionary clock

Mutational Envelope Scanning: As per mutational envelope scanning, functional similarities between proteins may be hidden because only a limited number of residues are critical for function, e.g., for ligand binding. Systematic mutations induced (e.g., by alanine scanning mutagenesis) at the critical side chains may reveal the hidden functional similarities. These hidden features may not be revealed by common biochemical, crystallographic, or nuclear magnetic resonance studies. ▶homologue-scanning mutagenesis; Christ D, Winter G 2003 Proc Natl Acad Sci USA 100:13202.

Mutational Load: ▶genetic load

Mutational Spectrum: The array and frequency of the different mutations that have been observed under certain conditions or in specific populations. The spectrum of auxotrophic mutations is much lower in most eukaryotes (except yeast and other fungi) than in lower and higher photoautotrophic organisms.

► [mutation spectrum](#)

Mutations Undetected: ► [mutations rate](#)

Mutator Genes: Mutator genes may be functioning on the basis of abnormal level of errors in DNA synthesis (error-prone DNA polymerase III) or abnormally low level of genetic repair due to defect of proofreading exonuclease in bacteria. The actual repair DNA polymerase in bacteria is pol I that also has 5'→3' polymerase and double and single-strand 3'→5' exonuclease capability. MutS protein recognizes DNA mismatches while MutL protein scans for nicks in the DNA and then through exonuclease action slices back the defective strand beyond the mismatch site and facilitates the replacement of the erroneous sequences with new and correct sequences. In bacteria, MutH protein recognizes mismatches not by the proofreading system of the exonucleases but by the distortion of the DNA molecules newly made. The recognition of the new strands depends on the not yet methylated A or C sites within GATC sequences in the new strands. Once the distortion is found, the mismatched base can be selectively excised. If either of these repairs fail, mutator action is observed.

Any defects in the bacterial gene *dam* (DNA methylase) may also result in high mutation rates because the correct base may be excised and replaced erroneously (see Fig. M144).

The active sites of DNA polymerases are highly mutable and the mutant enzymes may act as mutators of other genes (Patel PH, Loeb LA 2000 Proc Natl Acad Sci USA 97:5095).

Introducing point mutations in three structural domains of bacterial Pol I DNA polymerase resulted in $\sim 8 \times 10^4$ increase of transition mutations at random sites but with preference for plasmids DNA. The desired mutations can be selectively isolated and used for synthetic chemistry, gene therapy, and molecular biology (Camps M et al 2003 Proc Natl Acad Sci USA 100:9727).

Some of the so called mutator genes of the past were actually insertion elements that moved around in the genome and caused mutation by inactivation of genes through disrupting the coding or promoter sequences or altering specific bases in the gene(s). The mutator genes *mutA* and *mutC* of *E. coli* cause the A • T → T • A and G • C → T • A transversions in the anticodon of two different copies of tRNA genes, which normally recognize the GGU and GGC codons. As a consequence, Asp replaces Gly at a rate of 1 to 2%. Defective methyl-directed mismatch repair (gene MutS) occurs in 1–3% of *E. coli* and *Salmonella* raising the mutation rate to antibiotic resistance (Rif [rifampicin], Spc [spectinomycin] and Nal [nalidixic acid]) up to hundreds of fold, depending on the strain

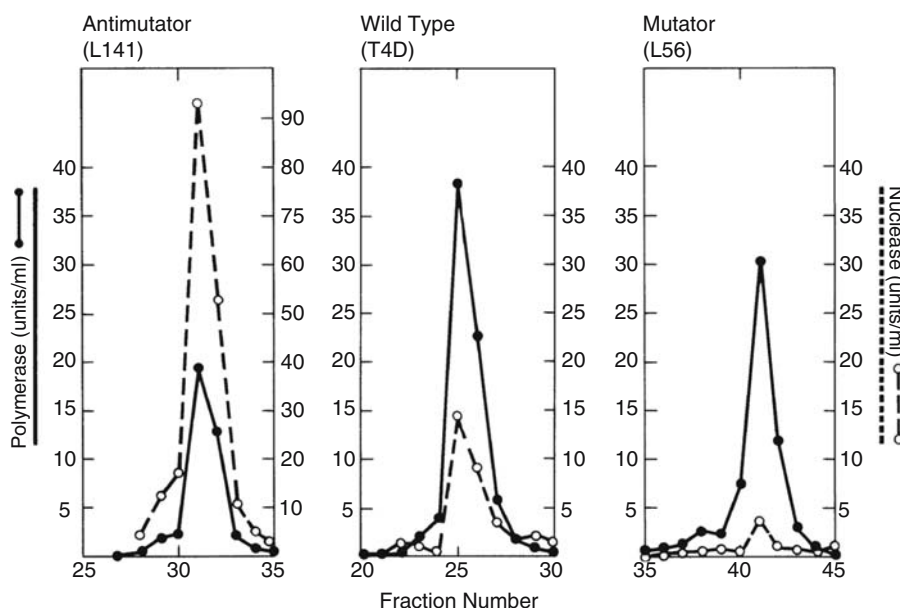

Figure M144. Mutator and antimutator activity may depend on the balance between DNA polymerase and nuclease functions. (From Muzyczka N et al. 1972 J. Biol. Chem, 247:7116)

of bacteria. Besides polymerase and repair defects, increase in mutation rate may be caused by anomalies of the replication accessory proteins such as RPA/RAF, PCNA, and RAD27/Rthp/Fen-1. Single-nucleotide substitutions in normal and neoplastic human tissues is two-hundred-fold different. In normal tissues, the frequency of spontaneous random mutation was exceedingly low, less than 1×10^{-8} per base pair. In contrast, tumors from the same individuals exhibited an average frequency of 210×10^{-8} per base (Bielas JH et al 2006 Proc Natl Acad Sci USA 103:18238).

High mutator activity may increase evolutionary adaptation in bacteria. Once the particular strain is well established, the high mutator activity is expected to decrease in that habitat. High mutator activity of a nuclear gene of *Arabidopsis*, *chm*, has been traced to mutation in mutS-like mismatch repair gene. The protein localized to the mitochondria and the mutations are manifested most obviously in the plastids (Abdelnoor RV et al 2003 Proc Natl Acad Sci USA 100:5968). The defect in *chm* apparently fails to correct the defects in substoichiometric shifting in the mtDNA. ▶insertional mutation, ▶transposable elements, ▶DNA replication prokaryotes, ▶DNA repair, ▶anti-mutators, ▶mutations in cellular organelles, ▶mismatch repair, ▶mutation detection, ▶RAD, ▶DNA polymerases, ▶anticodon, ▶tRNA, ▶substoichiometric shift, ▶transversion, ▶amino acids, ▶RPA, ▶PCNA, ▶RAD27, ▶Mu, ▶proofreading, ▶cancer, ▶mutation rate, ▶hot spot; Giraud A et al 2001 Science 291:2606; Shah AM et al 2001 J Biol Chem 276:10824; Shinkai A, Loeb LA 2001 J Biol Chem 276:46759; Shaver AC et al 2002 Genetics 162:557; Rédei GP 1973 Mutation Res 18:149.

Mutator Phage: The best characterized mutator phage is the Mu bacteriophage. The Mu particle includes a 60 nm isosahedral head and a 100 nm tail (in the extended form) containing also base plates, spikes, and fibers. The phage may infect Enterobacteria (*E. coli*, *Citrobacterium freundii*, *Erwinia*, *Salmonella typhimurium*). Its DNA genetic material consists of a 33-kb (α) and a 1.7-kb (β) double-stranded sequences separated by a 3-kb, essentially single-stranded, G-loop (specifies host range). It also has variable length (1.7-kb) single-strand “split ends” (SE). Besides the coat protein genes, the *c* gene is its repressor (prevents lysis). The other genes are *ner* (negative regulator of transcription), *A* (transposase), *B* (replicator), *cim* (controls superinfection [immunity]), *kil* (killer of host in the absence of replication), *gam* (protein protects its DNA from exonuclease V), *sot* (stimulates transfection), *arm* (amplifies replication), *lig* (ligase), *C* (positive regulator of the morphogenetic genes) and *lys* (lysis). Upon lysis,

50 to 100 page particles are liberated. The Mu chromosome may exist in linear and circular forms. Mu can integrate at about 60 locations in the host chromosome with some preference. At the position of integration, 5-bp target site duplications take place. The integration events cause insertional mutation in the host. Mu causes host chromosome deletions, duplications, inversions, and transpositions. These functions require gene *A*, the intact termini of the phage and replication of the phage DNA. A related other phage, D108, has several DNA regions that are non-homologous. Its host range is the same as that of Mu. ▶bacteriophages, ▶temperate phage, ▶Mu bacteriophage, ▶insertion elements; Nakai H et al 2001 Proc Natl Acad Sci USA 98:8247.

Mutein: Mutant protein.

Muton: An outdated term meaning the smallest unit of mutation. For three decades it is known that single nucleotides or nucleotide pairs are basic units of mutation. Benzer S 1957 In: The Chemical Basis of Heredity. McElroy WD, Glas B (Eds.) Johns Hopkins University Press, Baltimore, MD, pp 70).

MutS: ▶mismatch repair

Mutual-Best Blast Matches: Mutual-best BLAST matches use BLAST computer program for determining orthologous sequences in different species. ▶BLAST, ▶orthologous loci

Mutual Exclusiveness: An example of mutual exclusiveness is that alternative alleles at particular genetic sites in a haploid cannot exist simultaneously.

Mutualism: A mutually beneficial or alternatively a selective situation for increased exploitative association of organisms. ▶symbionts, ▶commensalism, ▶sociogenomics; Curie CR 2001 Annu Rev Microbiol 55:357.

MVR (minisatellite variant repeat): Within different-length minisatellite allele pairs of the same size different alterations may occur at different sites and generate isoalleles (see Fig. M145).

Figure M145. Minisatellite alleles

The hypervariable alterations (represented by the triangles) may be identified with aid of restriction enzyme digestion and electrophoresis and can yield profile of an individual. The majority of the mutations

show polarity, i.e., the alterations are most common at the end of the minisatellite site. Many of the mutations generate alleles of different lengths as a result of recombination of the parental alleles. Mutation rate is variable depending on alleles but apparently it is independent from the length of the repeat as long as homologies are not much violated. ▶[minisatellite](#), ▶[DNA fingerprinting](#); Junge A 2001 *Forensic Sci Int* 119:11.

Mx Proteins: 70–80-kDa interferon-inducible GTPases of the dynamin family that interfere with the replication and transcription of negative-strand RNA viruses. Mx1: myxovirus (influenza) resistance; it is located at human chromosome 21q22.3. ▶[dynamin](#), ▶[replicase](#); Regad T et al 2001 *EMBO J* 20:3495.

Mxi1: A tumor suppressor gene at human chromosome 10q24–26. ▶[prostate cancer](#), ▶[MYC](#); Wang DY et al 2000 *Pathol Int* 50(5):373.

Mxi/Max: Heterodimeric specific transcriptional repressors. ▶[Max](#), ▶[Mad/Max](#), ▶[E box](#); Billin AN et al 2000 *Mol Cell Biol* 20:9945.

My: A million years during the course of evolution; MYA means million years ago. ▶[KYA](#)

Myasis (myiasis): The infestation of a live body with fly larvae (maggots) such as occurs as a consequence of screw worm, a common pest of southern livestock (see Fig. M146). ▶[genetic sterilization](#)

Figure M146. Adult screwworm fly. It has an average life span of three weeks and during the period of time it may travel 100 to 200 kilometers but it can survive only during the warm winters such as exist in Mexico or in the southern USA. (From Stefferud A (Ed.) 1952 *Insects. Yearbook of Agriculture*, USDA, Washington, DC)

Myasthenia (gravis, MG, 17p13): Generally involves muscular (eye, face, tongue, throat, neck) weakness, shortness of breath, fatigue, and the development of antibodies against the acetylcholine receptors. The genetic determination is ambiguous, generally it appears autosomal recessive. The infantile form lacks the autoimmune feature, although it also includes a defect in the acetylcholine receptor. Anticholinesterase therapy and immunosuppressive drugs may

be helpful. Newborns of afflicted mothers may be temporarily affected through placental transfer. In persons with “limb girdle,” pattern of muscle weakness may have small neuromuscular junction but normal acetylcholine receptor and acetylcholinesterase action (Beeson D et al 2006 *Science* 313:1975). ▶[neuromuscular diseases](#), ▶[epistaxis indirect](#), ▶[IVIG](#), ▶[rapsyn](#), ▶[acetylcholine](#)

Myb Oncogene: An avian myeloid leukemia (myeloblastosis) oncogene; its human homolog was assigned to chromosome 6q21–q23. Its product is a transcription factor. The same gene is also called AMV (*v-amv*). The MYB gene product is translated into ~75-kDa protein in immature myeloid cells and its activity is substantially reduced as differentiation proceeds.

The Myb protein (see Fig. M147), with a nuclear protein-binding leucine zipper in the regulatory domain, recognizes the 5'-PyAAC(G/Py)G-3' core sequence and in case the C- or N- terminus or both are deficient it becomes a potent activator of leukemia, although overexpression of the entire Myb may also be oncogenic. The Myb oncogene regulates hematopoiesis. The Myb A protein is required for normal spermatogenesis and mammary gland development. Using antisense oligodeoxynucleotides for codons 2–7 may reduce its transcription. The same treatment may be effective against chronic myelogenous leukemia. Recent data indicates that the Myc/Max/Mad proteins may regulate ~15% of all the genes (Orian A et al 2003 *Genes Dev* 17:1101). Myb homology domains occur in multiple copies in both monocotyledonous and dicotyledonous plants and are involved in various regulatory functions, such as in transcription factors. ▶[E box](#), ▶[oncogenes](#), ▶[leukemias](#), ▶[AMV](#), ▶[hematopoiesis](#), ▶[antisense technologies](#), ▶[incompatibility alleles](#)

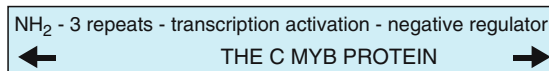

Figure M147. The C MYB protein

MYC (8q24.12–q24.13): An oncogene named after the myelocytomatosis retrovirus of birds from which its protein product was first isolated. It is a widely present DNA-binding nuclear helix-loop-helix phosphoprotein in eukaryotes. c-MYC is expressed only in dividing cells and it is an inhibitor of terminal differentiation. C-MYC induces the expression of the cell cycle activating kinase, CDK4. The MH-2 virus carries, besides the *v-myc* gene, also the *v-mil* gene, which encodes serine/threonine kinase activity and invariably causes monocytic leukemia. Most retroviruses in this group cause only the formation of non-immortalized macrophages requiring growth factors

for proliferation. The cellular forms of the oncogenes are specially named after the type of cells in which, they are found. NMYC occurs in neuroblastomas (and retinoblastomas). Homologues of this gene were assigned to human chromosome 2p24 and to mouse chromosomes 12 and 5. The LMYC genes are involved in human lung cancer where one was located to chromosome 1p32 and two to the mouse chromosomes 4 and 12. Alternative splicing and polyadenylation produce several distinct mRNAs from a single gene. Metastasis is favored by the presence of a 6-kb restriction fragment of the DNA. In human chromosome 7, another form, the MYC-like one gene was detected with a 28-bp near perfect homology to the avian virus. In both man and mouse, translocation sequences were identified between the Myc gene (human chromosome 8) and several immunoglobulin genes encoding the heavy, κ and λ chains. cMyc overexpression causes telomeric association of interphase chromosomes, which may result in breakage-bridge-fusion cycles and various types of chromosomal rearrangements (Louis SF et al 2005 Proc Natl Acad Sci USA 102:9613).

(PVT1) has an activation role in Burkitt's lymphomas (caused by the Epstein-Barr virus) and plasmacytomas (neoplasia). Myc/MAX heterodimer binds to the CDC25 gene and activates transcription after binding to the DNA sequence CACGTG. This binding site is recognized by a number of MYC-regulated genes. Frequent targets of activated Myc are the cycline genes as well as ornithine decarboxylase, lactate dehydrogenase and thymosine β 4. When cellular growth factors are depleted, Myc can induce apoptosis with the cooperation of CDC25. MYC in cooperation with RAS mediate also the progression of the cell cycle from G1 to the S phase through induction of the accumulation of active cyclin-dependent kinase and transcription factor E2F. MAD (Mxi1; 10q24–26) protein holds MYC in check. MAD forms a heterodimer with MAX (MAD-MAX), and this successfully competes with MYC-MAX heterodimers for transcription and thus can control malignancy. Down-regulation of the human ferritin gene by MYC leads to cellular proliferation. Myc expression may mediate Fas-FasL (Fas-ligand) interaction and an apoptosis pathway through FADD. The BIN1 protein interacts with MYC and serves as a tumor suppressor. Myc apparently affects the expression of thousands of genes and its effect can be detected by microarray hybridization and correlation analysis (Remondini D et al 2005 Proc Natl Acad Sci USA 102:6902). ▶oncogenes, ▶hepatoma, ▶cancer, ▶Burkitt's lymphoma, ▶Gardner syndrome, ▶PVT, ▶CDC25, ▶MAD, ▶BIN1, ▶apoptosis, ▶Fas, ▶FADD, ▶RAS, ▶CDK, ▶E2F, ▶CDF, ▶MAX, ▶ferritin, ▶immunoglobulins,

Mycelium: a mass of fungal hyphae. ▶hypha

Mycobacteria: are Gram-positive bacteria and cause tuberculosis (killing 3 million people annually) and responsible for leprosy (*Mycobacterium leprae*, 3.27 Mb, 1604 genes), respectively. *M. leprae* is somewhat difficult to study because it does not grow in axenic cultures. The bacteria can be propagated to sufficient quantities for analysis in the nine-banded armadillo (*Dasypus novemcinctus*). About half of its genome is inactivated as pseudogenes. The populations have much lower variability than other bacteria. The bacterium probably originated in Eastern Africa and then spread to other parts of the world, primarily to India and Brazil and Western Africa (Monot M et al 2005 Science 308:1040). Their cell wall has low permeability and therefore they are rather resistant to therapeutic agents.

Mycobacterium tuberculosis (see Fig. M148) H37Rv genome is 4,411,529-bp and includes about 4,000 genes. (See Nature [Lond] 393:537 1998, see also corrections in Nature 396:190 1998). Through *mycobacterial protein fragment complementation* (in analogy to the yeast two-hybrid system) protein interaction network could be revealed that sheds light on virulence pathway of the tuberculosis bacterium (Singh A et al 2006 Proc Natl Acad Sci USA 103:11346). Envelope metalloprotease enzymes regulate the composition and virulence of the tuberculosis bacteria (Makinoshima H, Glickman MS 2005 Nature [Lond] 436:406). Worldwide about 2 billion people could be infected and 9 million have the active disease. The tuberculosis bacteria reside in the macrophages during latent infection and kept in check there by nitric oxide and other nitrogen intermediates (see Fig. M149). When the mycobacterial proteasome cleaves the inducible nitric oxide synthase, susceptibility to the disease increases

Figure M148. *M. tuberculosis*

Figure M149. Cyproflaxacin (a fluoroquinolone)

(Darwin KH et al 2003 Science 302:1963). Mouse chromosome 1 harbors a gene (*sst*) for super susceptibility to tuberculosis and within the same locus there is a gene, *Intracellular pathogen resistance* (*Ipr1*). The closest human homolog to *Ipr1* is SP110 and there are three variants of it in West Africa (Gambia, Guinea-Bissau and Guinea) that convey resistance to tuberculosis. These variants lie within a 31-kb block and are in strong linkage disequilibrium (Tosh K et al 2006 Proc Natl Acad Sci USA 103:10364). The same gene conveys resistance also *Listeria monocytogenes* (Pan H et al 2005 Nature [Lond] 434:767). Infection by human immunodeficiency virus (AIDS) greatly increases the susceptibility to tuberculosis and antiretroviral drugs may provide protection thus against both diseases (Williams BG, Dye C 2003 Science 301:1535). Tuberculosis of cattle is caused by *M. bovis* and it can be transmitted also to humans and other animals. The transmission to humans is usually by not or improperly Pasteurized milk. *Mycobacterium avium* K-10 (paratuberculosis) genome has 4,829,781 bp and 4,350 open reading frames and more than 3,000 genes are homologous with the human tuberculosis bacterium but 161 sequences are unique to the bird bacterium (Li L et al 2005 Proc Natl Acad Sci USA 102:12344).

Tuberculosis is most commonly treated by isoniazid (INH) and as a result saturated hexacosanoic acid (C26:0) accumulates on a 12-kDa acyl protein carrier (see Fig. M150). This complex associates also with β -ketoacyl carrier protein synthase (KasA). Apparently INH acts by inhibiting KasA. When mutations occur in the latter, INH resistance develops. Apparently INH acts by inhibiting KasA. Nitroimidazopyran drugs are also promising against tuberculosis. The cure of tuberculosis generally requires strict multidrug therapy to avoid the emergence of drug-resistance, which is a very serious threat nowadays.

Figure M150. Isoniazid

Diarylquinoline (see Fig. M151), which apparently active on the proton pump of ATP synthase, at 0.06 $\mu\text{g/mL}$ in vitro, exceeded significantly the efficacy of isoniazid and rifampin and does not appear to have serious side effects (Andries K et al 2005 Science 307:223).

Fluoroquinolones (e.g., moxifloxacin and gatifloxacin) interact with DNA gyrase and DNA

Figure M151. Diarylquinoline

topoisomerase are effective antibacterial agents yet the MfpA bacterial plasmid-encoded protein, which contains as every fifth amino acid either leucine or phenylalanine can convey resistance even against these newer fluoroquinolones. The MfpA protein forms a right-handed quadrilateral β helix (a DNA mimic), binds to DNA gyrase and inhibits its activity and conveys resistance to fluoroquinolone in vivo (Hegde SS et al 2005 Science 308:1480).

The mouse strain DBA/2 is very susceptible to tuberculosis whereas C57BL/5 is more resistant. The resistance is controlled by a QTL in chromosome 19 and 1. In humans natural resistance factors (controlling bacterial proliferation) have been found in chromosomes 2q, 15q and Xq (Mitsos L-M et al 2003 Proc Natl Acad Sci USA 100:6610). *Mycobacterium vaccae* and *Bacillus Calmette-Guérin* (BCG, also a mycobacterium) produce cross-reactive material against *M.l.*, and *M.v.* is suited for vaccine production against leprosis. *M.l.* cannot efficiently be propagated in vitro for vaccine production and only the nine-banded armadillo would be a suitable animal host. The virulence of mycobacteria seems to be controlled by the *erp* (exported repetitive protein) gene. Some major (2q32-q35, 15q11-q13) and apparently several minor genetic factors determine the susceptibility to tuberculosis and other diseases. Gene UBE3A, a ubiquitin ligase is located in the imprinted region of chromosome 15. Mycobacterial infection susceptibility genes encode the interferon- γ receptor (INFR-1, 6q23-q24; INFR-2, 6q23-q24), interleukin-12 β -1 chain receptor (9p13) and STAT1 (2q32). Some INFR-2 mutations gained new N-glycosylation sites (Vogt G et al 2005 Nature Genet 37:692).

The use of the BCG (bacillus Calmette-Guérin) vaccine is substantially effective for childhood treatment but much less efficient for adult infections. BCG primes T_H1 (helper T cells) and promotes the release of interferon (IFN- γ) by the macrophages. Newer vaccines incorporating antigen 85A of the bacterium with some adjuvants appear promising (Young D, Dye C 2006 Cell 124:683). ▶vaccine, ▶*Bacillus Calmette-Guérin*, ▶leprosy, ▶AIDS, ▶glycosylation, ▶PGRS, ▶interferon, ▶ T_H1 ;

Mycology: the discipline of studying the entire range of mushrooms (fungi).

Mycophenolic Acid (MPA): ►IMPDH

Mycoplasma: Parasitic and/or pathogenic bacteria. They may also contaminate animal cell cultures. *Mycoplasma genitalium* was the first free-living organism to be completely sequenced by 1995, containing 580,070-bp DNA, 480 open reading frames, and 37 RNA transcribing genes; 31.8% of its known genes (127) is involved in translation.

The intact genomic DNA from *Mycoplasma mycoides* large colony (LC), virtually free of protein, was transplanted into *Mycoplasma capricolum* cells by polyethylene glycol-mediated transformation. Cells were selected for the tetracycline resistance marker of the donor, and proved that they contained the complete donor genome and were free of detectable recipient genomic sequences (Lartigue C et al 2007 *Science* 317:632).

Mycoplasma pneumoniae has $\sim 0.82 \times 10^6$ bp DNA genome and 679 genes. *Mycoplasma penetrans* sequenced circular genome is 2,358,633 bp and includes 1038 predicted coding sequences, one set of rRNA genes, and 30 tRNA genes (Sasaki Y et al 2002 *Nucleic Acids Res* 30:5293). ►phytoplasmas, ►gene number; Glass JI et al 2000 *Nature [Lond]* 407:757; Flynn JL, Chan J 2001 *Annu Rev Immunol* 19:93; <http://genolist.pasteur.fr/>.

Mycorrhiza: A symbiotic association between plant roots and certain fungi. Some of the mycorrhizal fungi are genetically quite peculiar in as much they are haploid but heterokaryotic with multiple nuclei and substantial differences among the nuclei (Hijri M, Sanders IR 2005 *Nature [Lond]* 433:160). ►nitrogen fixation, ►symbionts; Smith KP, Goodman RM 1999 *Annu Rev Phytopath* 37:473, nitrogen path: Govindarajulu M et al 2005 *Nature [Lond]* 435:819; arbuscular mycorrhiza: <http://www.ffp.csiro.au/research/mycorrhiza/intro.html>.

Mycosis: Infection or disease by fungi. The infection may be superficial, subcutaneous, and systemic by inhalation of the spores. Most commonly, fungi cause

skin diseases. Immune-compromised individuals are particularly susceptible to mycoses.

Mycotoxins: Fungal metabolites that damage DNA. The best known are: aflatoxins, sterigmatocystin, ochratoxin, zearalenone, and some penicillin toxins. ►aflatoxin

MyD88: (myeloid [bone marrow like] differentiation primary response factor, encoded in human chromosome 3p22-p21.3): An adaptor protein in the Toll — NF- κ B signaling pathway. ►NF- κ B, ►Toll/TRAF6, ►TIRAP

Myedema (hyperthyroidism): Myedema is also attributed to hypothyroidism caused by autosomal recessive/dominant conditions. It involves dry skin with wax-like deposits. Some HLA genes and autoimmune causes have been implicated. ►Graves disease

Myelencephalon: The part of the brain of the embryo that develops into the medulla oblongata (the connective part between the pons [brain stem]) and the spinal cord. ►brain

Myelin: A lipoprotein forming an insulating sheath around nerve tissues. ►Pelizaeus-Merzbacher disease, ►Marie-Charcot-Tooth disease, ►multiple sclerosis; Greer JM, Lees MB 2002 *Int J Biochem & Cell Biol* 34:211.

Myeloblast: A precursor (formed primarily in the bone marrow) of a promyelocyte and eventually a granular leukocyte. It contains usually multiple nucleoli. ►leukocyte, ►Wegener granulomatosis

Myeloblastin: A serine protease, specific for myeloblasts controlling growth and differentiation and myelogenous leukemia. ►leukemia

Myelocyte: A precursor of the granulocytes, neutrophils, basophils and eosinophils.

Myelocytoma: ►myeloma

Myelodysplasia (MDS): A recessive form of leukemia, generally associated with monosomy of human chromosome 7q. The critical deletion apparently involves chromosomal segment 7q22-q34. Peptide mass fingerprinting and quadrupole TOF MS identified two differential proteins: CXC chemokine ligands 4 (CXCL4) and 7 (CXCL7), both of which had significantly decreased serum levels in MDS, as confirmed with independent antibody assays (Aivado M et al 2007 *Proc Natl Acad Sci USA* 104:1307). ►leukemia, ►nucleophosmin, ►chemokine, ►CXCR, ►mass spectrum, ►proteomics, ►MALDI, ►quadrupole, ►TOFMS

Myeloma: Bone marrow cancer. CREB seems to promote myeloid transformation (Shankar DB et al 2005 Cancer Cell 7:351). Myeloma cells are used to produce hybridomas. ▶Bence Jones proteins, ▶monoclonal, ▶antibody, ▶hybridoma, ▶CREB

Myelomeningocele: ▶spina bifida

Myelopathy: Diseases involving the spinal cord and myelination of the nervous system. About 15 different human anomalies are involved. ▶Dejerine-Sottas neuropathy, ▶Charcot-Marie-Tooth disease

Myelopoiesis: The formation of granulocytic and monocytic cell lineages. ▶granulocyte, ▶monocyte

Myelosuppression: Myelosuppression interferes with bone marrow function and blood cell formation. It is the most common target of cancer chemotherapy drugs. These drugs are aimed at highly proliferative cells and the bone marrow produces 4×10^{11} cells daily for long periods of time.

MYF-3 (myogenic factor): MYF-3 was located to human chromosome 11-p14 and its mouse homolog, *MyoD* is in chromosome 7. MYF-3 controls muscle development, may be subject to imprinting, and may possibly be involved in the formation of embryonic tumors. The protein is a helix-loop-helix transcription factor (MASH2) and it is a mammalian member of the *achaete-scute* complex of *Drosophila*. ▶imprinting, ▶Mash-2, ▶morphogenesis in *Drosophila*.

Myhre Syndrome: ▶dwarfism

Myleran (1,4-di[methanesulphonoxy] butane): A clastogenic (causing chromosome breakage) alkylating mutagen. Also called busulfan.

Mylotarg: Monoclonal antibody used for targeting acute myeloid leukemia with the toxin calicheamycin. ▶leukemia, ▶monoclonal antibody, ▶magic bullet

Myoadenylate Deaminase: ▶adenosine monophosphate deaminase

Myoblast: Muscle cell precursor. Myoblasts can be well cultured in vitro and reintroduced into animals where they fuse into myofibers. They can be used also as gene or drug delivery vehicles. The paired-box proteins, Pax3 and Pax7, are essential for the formation of skeletal muscles (Relaix F et al 2005 Nature [Lond] 435:948). ▶vectors, ▶dermomyotome

Myocardial Infarction: Obstruction of blood circulation to the heart; it may be accompanied by tissue damage. Infarcted (dead/decaying) heart muscle cells may be replaced by transplantation of regenerating bone marrow cells. Arachidonat 5-lipoxygenase activating protein (encoded at 13q12-q13) confers

increased risk of myocardial infarction and stroke. This gene overlaps the ALOX5AP lipoxygenase activating-protein (FLAP) coding region and increases the risk for stroke almost two-fold in Icelandic populations. The effect is due to the over production of leukotrienes B and inflammation of the arterial walls (Helgadóttir A et al 2004 Nature Genet 36:233). Human haplotype HapK, spanning this region, confers an about three-fold greater risk of heart disease to Afro-Americans than to European-Americans (Helgadóttir A et al 2006 Nature Genet 38:68). Presence of variants of the proprotein convertase subtilisin/kexin type 9 serine protease gene (PCSK9) involved substantial reduction cholesterol. The low density lipoprotein cholesterol and myocardial infarction decreased by 88% among US blacks. In whites 15% reduction in cholesterol and 47% reduction in the heart disease risks were observed among several thousands of individuals examined during a period of 15 years (Cohen JC et al 2006 N Engl J Med 354:1264). Complement-reactive protein (CRP) increases myocardial and cerebral infarct size. 1,6-bis(phosphocholine)-hexane can abrogate the infarct size and protects from cardiac dysfunction by blocking CRP action (Pepys MB et al 2006 Nature [Lond] 440:1217). Delivery to the myocardium myocytes and biotinylated insulin-like growth factor, a cardiomyocyte growth and differentiation factor in biotinylated nanofibers, improved systolic function significantly. The delivery activated Akt, decreased caspase-3 activation, and improved the expression of troponin I (Davis ME et al 2006 Proc Natl Acad Sci USA 103:8155). ▶coronary heart disease, ▶heart disease, ▶MEF, ▶lipoxygenase, ▶leukotriene, ▶ethnicity, ▶haplotype, ▶LDL, ▶cholesterol coronary heart disease atherosclerosis, ▶insulin-like growth factor, ▶caspases, ▶troponin, ▶systole

Myocardium: The heavy muscles of the heart. ▶heart disease; Buckingham M et al 2005 Nature Rev Genet 6:826.

Myoclonic Epilepsy: Myoclonic epilepsy occurs in different forms. The recessive juvenile EJM gene is situated within the boundary of the HLA gene complex in the short arm of chromosome 6p21 (Janz syndrome). It is characterized by generalized epilepsy with onset in early adolescence. Mutations in a sub-unit of the sodium channel SCN1A gene (2q24) cause slow growth from the second year of life and often become ataxic and later suffer from speech problems. Myoclonous epilepsy associated with ragged-red fibers is characterized also by epileptic convulsions, ataxia, and myopathy (enlarged mitochondria with defects in respiration). The defect was attributed to an adenine → guanine transition mutation at position

8344 in the human mitochondrial DNA involving the tRNA^{Lys} gene. The recessive (EPM2A, 6q24; EPM2B, 6p22.3) myoclonous epilepsy (LaFora disease) shows up at about age 15 and results in death within ten years that after. The EPM2A disease involves defects in a protein tyrosine phosphatase (laforin protein). The EPM2B/NHLRC1 disease is due to deletions or various types of mutations in the 395 amino acid protein malin, which appears to be a single-subunit E3 ubiquitin ligase. Normally, malin ubiquitinates laforin but mutation in the gene leads to LaFora disease (Gentry MS et al 2005 Proc Natl Acad Sci USA 102:8501). Both of these proteins are associated with the endoplasmic reticulum and are normally involved in clearance of polyglucosans in dendrites and the defect disturbs neuronal synapsis (Chan EM et al 2003 Nature Genet 35:125).

The myoclonus epilepsy Unverricht and Lundborg (EPM1) is a 21q22.3 chromosome recessive with onset between ages six to 13, beginning with convulsions turning within a few years into shock-like seizures (myoclonus). The latter disease is caused by mutation in the cystatin B (cysteine protease inhibitor) gene. The EPM1 disease involves a large insertion (600–900 bp) consisting of 12-bp repeats (CCCCGCCCGCG). The cases appeared to be initiated by pre-mutational changes of 12–13 repeats and usually by maternal transmission the “alleles” appeared stable. In the majority of cases of paternal transmission, the repeats increased. In some cases, a 18mer repeat was observed at the 5′ region of the promoter and a 15mer repeat at the 3′ region. The 18 and 15mer repeats included also six and four T and A bases, respectively. Benign familial adult epilepsy maps to 8q23.3-q24.1. Some human myoclonus diseases are apparently under dominant control. A *myoclonus* disease in cattle has an apparent defect in glycine-strychnine receptors. In mouse, the spastic mutation in chromosome 3 affects the α -1 glycine receptors, whereas the α -2 receptor defect is X-linked. The incidence of epilepsy, especially in some breeds, is more common in dogs than in humans (Lohl H et al 2005 Science 307:81). ▶[epilepsy](#), ▶[trinucleotide repeats](#), ▶[mitochondrial disease in humans](#), ▶[pre-mutation](#), ▶[ion channels](#)

Myoclonus: Sudden, involuntary contractions of the muscle(s) like in seizures of epilepsy or sometimes as a normal event during sleep. Myoclonus-dystonia, a dominant disease, is located to 7q21 and the gene encodes ϵ -sarcoglycan (Müller B et al 2002 Am J Hum Genet 71:1303). ▶[myoclonic epilepsy](#), ▶[dystonia](#), ▶[sarcoglycan](#)

MyoD: Muscle-specific basic helix-loop-helix protein that regulates muscle differentiation and the cessation

of the cell cycle. Its DNA binding consensus is CANNTG in the promoter or enhancer of the genes controlled. MyoD may activate p21, and p16 and promotes muscle-specific gene expression. When MyoD is phosphorylated by cyclinD1 kinase (Cdk), it may fail to transactivate muscle-specific genes. ▶[p21](#), ▶[p16](#), ▶[cell cycle](#), ▶[helix-loop-helix](#), ▶[Myf3](#), ▶[cyclin](#), ▶[Cdk](#), ▶[myogenin](#), ▶[MEF](#), ▶[enhancer](#); Tedesco D, Vesco C 2001 Exp Cell Res 269:301.

Myofibril: Muscle fiber made of actin, myosin and other proteins (bundle of myofilaments). ▶[satellite cells](#)

Myofibromatosis, Juvenile: Multiple fibroblastic tumors on the skin, muscles bones, and viscera in young infants due to autosomal recessive or dominant mutation. Prognosis for survival in severe cases is low.

Myogenesis: Muscle development.

Myogenin: A protein involved in muscle development. MyoD activates myogenin and overcomes the inhibitor of DNA-binding (helix-loop-helix) gene *Id*, and other muscle gene transcription and differentiation is set on course. ▶[MyoD](#), ▶[MYF5](#), ▶[MRF](#), ▶[MEF](#); Sumariwalla VM, Klein VH 2001 Genesis 30(4):239.

Myoglobin: A single polypeptide chain of 153 amino acids, attached to a heme group and functions in the muscle cells to transport oxygen for oxidation in the mitochondria. Recurrent myoglobinuria may result by a microdeletion in the mitochondrially-encoded cytochrome C oxidase (COX) subunit III. Some Antarctic fishes do not have myoglobin, and homozygous myoglobin knockout mice function in a practically normal manner. ▶[hemoglobin](#), ▶[mitochondrial disease in humans](#)

Myo-Inositol: An active form of inositols. They are widely used as phospholipid head-groups (see Fig. M152). They are essential for signaling, membrane trafficking, etc. ▶[inositol](#), ▶[phosphoinositides](#), ▶[embryogenesis somatic](#), ▶[phytic acid](#)

Myokymia: Hereditary spasmodic disorder of the muscles, caused by potassium channel defects. ► [ion channels](#)

Myoneurogastrointestinal Encephalopathy (mitochondrial myoneurogastrointestinal encephalopathy, MNGIE, 22q13.32-qter): A recessive defect in a nuclear gene, however, mitochondrial DNA aberrations may also accompany it. The onset usually sets in after the second decade of life and the clinical symptoms involve atrophy of the muscles (ophthalmoplegia), multiple neural disorders, lactic acidosis, etc. ► [ophthalmoplegia](#), ► [mitochondrial diseases in humans](#)

Myopathy: A collection of diseases affecting muscle function, controlled by autosomal dominant, autosomal recessive, X-linked, and mitochondrial DNA. Besides the weak skeletal muscles, ophthalmoplegia (paralysis of the eye muscles) usually accompanies it. The recessive homozygotes for myotonic myopathy are also dwarf and have cartilage defects and myopia. Two types are known with carnitine palmitoyl transferase deficiency (CPT1; mutation at 1pter-q12 (CPT2) involves myoglobinuria, especially after exercise or fasting. Another recessive myopathy is based on succinate dehydrogenase and aconitase. Phosphoglycerate mutase deficiencies (human chromosome 10q25 and 7p13-p12) also involve myoglobinuria. X-linked forms display autophagy (cytoplasmic material is sequestered into lysosome associated vacuoles) or slow maturing of the muscle fibers, or swelling and hypertrophy in the quadriceps muscles, respectively. Either insertion, deletion, or frameshift mutations in the ITGA7 integrin gene cause congenital myopathy (human chromosome 12q13). The Xq28-linked tubular myopathy is caused by defects in the myotubularin tyrosine phosphatase. The centronuclear myopathy is due to missense mutation in dynamin 2 and causes defect in centrosome function (19p13.2; Bitoun M et al 2006 Nature Genet 37:1207) and another similar myopathy due to anomalies of the myogenic factors (MYF5, MYF6) is encoded at 12q21 (Cupelli L et al 1996 Cytogenet Cell Genet 72:250). Dominant and recessive base substitution mutations in the skeletal muscle actin, ACTA1 gene (1q42), involve thin muscle fibers and severe, hypotonia, muscle weakness, feeding, and breathing difficulties and most commonly death during the first few months after birth. Occasionally, some afflicted individuals may survive to adulthood. ► [mitochondrial diseases in humans](#), ► [cartilage](#), ► [myopia](#), ► [carnitine](#), ► [Batten-Turner syndrome](#), ► [actin](#), ► [desmin](#), ► [integrin](#), ► [dynamin](#), ► [Sbfl](#), ► [troponin](#), ► [inclusion body myopathy](#), ► [myositis](#), ► [muscular](#)

[dystrophy](#), ► [cardiomyopathies](#), ► [adenosine monophosphate deaminase](#)

Myopia (nearsightedness): Myopia is caused by the increased length of the eye lens in the front-to-back dimension, and focusses the refracted light in front of the retina (nearsightedness). Most forms are under polygenic control with rather high heritability (around 0.6). Autosomal dominant, autosomal recessive (infantile), and X-linked forms have also been suggested. Some studies indicate significant positive correlation between myopia and intelligence. Myopia may be concomitant with various syndromes. ► [eye diseases](#), ► [farsighted](#), ► [human intelligence](#)

Myosins: Contractile proteins that form thick filaments in the cells, hydrolyze ATP, bind to actin, and account for the mechanics of muscle function, organelle movement, phagocytosis, pinocytosis, cell movement, RNA transport, phototransduction, signal transduction, etc. Myosins are activated by kinases (MLCK) and deactivated by phosphatases. MLCK is inhibited by PAK. Members of the 11 families of myosin are represented in amoebas, insects, mammals, and plants. The majority of myosin motors move in one direction toward the plus (+) end of actins. A conformational change at the actin-binding site (converter) of myosin class VI may facilitate movement of the lever in the minus (−) direction. This class of myosin has a 50-amino acid insertion at the converter region. The three-dimensional structure of myosin 5 has been determined (Liu J et al 2006 Nature [Lond] 442:209; Thirumurugan K et al 2006 Nature [Lond] 442:212). ► [filament](#), ► [microfilament](#), ► [myofibril](#), ► [phagocytosis](#), ► [pinocytosis](#), ► [Usher syndrome](#), ► [PAK](#), ► [RAC](#), ► [motor proteins](#), ► [kinesin](#), ► [deafness](#), ► [spindle](#); Homma K et al 2001 Nature [Lond] 412:831; crystal structure of myosin VI motor: Ménétrey J et al 2005 Nature [Lond] 435:779; <http://www.mrc-lmb.cam.ac.uk/myosin/myosin.html>.

Myositis: The name of some myopathies. ► [myopathy](#)

Myostatin Gene (human chromosome 2q32.1 recessive, GDF8): The inactivation (partial deletion) of the myostatin gene substantially increases muscle development in mammals. This mutation is found in the Belgian Blue and Piedmontese cattle breeds. Transforming growth factor- β is involved. The condition is also named 'double muscling' and 'growth/differentiation factor 8'. Inhibition of myostatin leads to robust muscle regeneration and this fact may mean therapeutic value for muscular dystrophy (Wagner KR et al 2005 Proc Natl Acad Sci USA 102: 2519). ► [insulin-like growth factors](#); Lee SJ, McPherron AC

2001 Proc Natl Acad Sci USA 98:93067; Schuelke M et al 2004 N Engl J Med 2004 350:2682.

Myotome: The area of the somites that forms involuntary muscles. ► [somites](#); Gros J et al 2004 Dev Cell 6:875.

Myotonia: The recessive myotonia congenita (chloride channel, CLCN1) is apparently in human chromosome 7q35 (Becker disease) and there is also a dominant form (Thomsen disease, 7q35). Both involve difficulties in relaxing the muscles. The various forms (M. fluctuans, M. permanens, paramyotonia congenita, K⁺-activated myotonia) may involve Na⁺ ion channel malfunctions. ► [periodic paralysis](#), ► [ion channels](#)

Myotonic Dystrophy (DM): A human disorder expressed as wasting of head and neck muscles, eye lens defects, testicular dystrophy, speech defects, frontal balding, frequently heart problems, and behavioral effects. It is controlled by a dominant gene (DMPK) at the centromere of human chromosome 19q13.2-q13.3 and it is caused by (CTG)_n expansion at the 3' untranslated region (Steinert disease). DM2 is a (CTG)_n expansion at 3q21 (Bachinski LL et al 2003 Am J Hum Genet 73:835). The DMPK related kinase, DK serine/threonine kinase, is at 1q41-q42. The prevalence is highly variable. It seems that DM may be a contiguous gene syndrome. In some isolated populations, it may occur in 1/500 to 1/600 proportion while in other populations the occurrence is about 1/25,000. The manifestation of the symptoms is enhanced in subsequent generations, and more are found in children of affected mothers than those of affected fathers. This observation may be due, however, to anticipation. The condition is dominant and it is quite polymorphic. Molecular evidence indicates that the DNA sequences concerned are unstable in the 3'-untranslated tracts downstream of the last exon of the protein kinase gene. The difficulties involving nucleosome assembly in DNA containing CTG triplet repeats in the 3'-untranslated region of a serine/threonine kinase gene seem to be concerned. It appears that the CUG repeats of the RNA transcript bind proteins (CUG-BP), which interfere with the proper splicing of the transcript. This toxic RNA can be silenced and DM can be normalized (Mahadevan MS et al 2006 Nature Genet 38:1066). The crystal structure of CUG repeats is known (Mooers BHM et al 2005 Proc Natl Acad Sci USA 102:16626). A troponin protein has been implicated with the binding. On the basis of linkage with chromosome 19 centromeric genes, prenatal

tests are feasible. Mutation frequency was estimated within the $1.1-0.8 \times 10^{-5}$ range. Ribozyme-mediated trans-splicing of the trinucleotide repeats have been tried to reduce the expansion. Mutation in the DM1 gene may result in the excessive binding of transcription factors to mRNA and mRNA is sequestered in the nucleus and thus the DM protein kinase gene is not translated sufficiently (Ebralidze A et al 2004 Science 303:383). A second myotonic dystrophy gene (DM2) was mapped to a 10-cM region of human chromosome 3q21 (ZNF9). The latter does not display CTG expansion (~15 kb) seen in DM1 but large expansion (~44 kb) of the tetranucleotide repeat (CCTG). Although the amplification involves untranslated sequences, neighboring genes (chloride channel subunit 1, insulin receptor, insulin intolerance) are spliced incorrectly in mammals (Houseley JM et al 2005 Hum Mol Genet 14:873). The expanded mRNAs are not distributed normally to the cytoplasm and are not translated into the needed protein in sufficient amounts nor do they interfere with the function of nuclear RNA-binding proteins. In the brain, hyperphosphorylated short tau protein may occur. ► [muscular dystrophy](#), ► [Pompe's disease](#), ► [Werdnig-Hoffmann disease](#), ► [Duchenne periodic paralysis](#), ► [Schwartz-Jampel syndrome](#), ► [Steinert disease](#), ► [anticipation](#), ► [prenatal diagnosis](#), ► [mental retardation](#), ► [imprinting](#), ► [fragile sites](#), ► [trinucleotide repeats](#), ► [troponin](#), ► [transsplicing](#), ► [contiguous gene syndrome](#), ► [tau](#); Liquori CL et al 2001 Science 293:864; Sergeant N et al 2001 Hum Mol Genet 10:2143.

Historical vignettes

HJ Muller was the second geneticist recipient of the Nobel Prize, on 31 October 1946, for his research on the influence of X-rays on genes and chromosomes. At the Cold Spring Harbor Symposia on Quantitative Biology (9:163, in 1941) he stated:

“We are not presenting...negative results as an argument that mutations cannot be induced by chemical treatment.”

“...it is not expected that chemicals drastically affecting the mutation process while leaving the cell viable will readily be found by our rather hit-and-miss methods. But the search for such agents, as well as the study of the milder, ‘physiological’ influences that may affect the mutation process, must continue, in the expectation that it still has great possibilities before it for the furtherance both of our understanding and our control over the events within the gene”.

Timothy Taylor (archeologist) in 2001 in Nature (Lond) 411:419.

“Perhaps I have no business commenting on genetics, but what I am really interested in is an explanatory imperialism, which threatens to subsume even archeology.”

O

O: Refers to replicational origin. ►replication, ►replication fork, ►bidirectional replication

Ω (Omega): This is the insertion element present in 0 to 1 copy per mitochondrion in yeast. ►mitochondria, ►mtDNA, ►insertion elements

O Antigen: ►ABO blood group, see also O-type lipopolysaccharide-protein antigen of gram negative bacterial capsids

O Blood Group: ►ABO blood group

ω-Agatoxin: Refers to the ion channel blocking proteins present in the *Agelenopsis* spider.

Oak (*Quercus* spp.): This is a forest as well as an ornamental tree, which has many morphological varieties, $2n = 24$. The delineation of some of the numerous species may be difficult because of the not uncommon spontaneous hybridization.

Oats (*Avena* spp.): A major cereal crop with somewhat reduced acreage since farm mechanization has led to a decrease in the number of horses used in agriculture (see Fig. O1). The cultivated species (*A. sativa*) is an allohexaploid but diploid and tetraploid forms are also well known. Basic chromosome number, $x = 7$. (See <http://plants.usda.gov/java/profile?symbol=AVFA>; genes: <http://wheat.pw.usda.gov/GG2/index.shtml>).

OBA (Office of Biotechnology Activities): Information about regulations can be obtained from <http://www4.od.nih.gov/oba>.

Obesity: This condition is characterized by the accumulation of excessive body weight (primarily fat) beyond the physiologically normal range. Differences in predisposition to obesity have long been recognized by animal breeders and the different breeds of swine have large (over 100%) differences in fat content per body weight. Obesity is a health problem in humans because diabetes mellitus, hypertension, hyperlipidemia, heart disease and certain types of cancer appear to be associated with obesity. In mice obesity is regulated by a gene *ob* in chromosome 6, sequenced in 1994. It has been suggested that the 167 amino acid protein product synthesized in the adipose (fat) tissues is secreted into the bloodstream and regulates food intake by signaling to the hypothalamus. Reduction in this gene product or specific lesions in the ventromedial (basal-central) region of the hypothalamus stimulates food consumption and reduces the expenditure of energy. Mice lacking Nocturnin (a circadian deadenylase) remain lean on high fat diets, with lower body weight and reduced visceral fat. However, unlike lean lipodystrophic models, these mice do not have fatty livers and do not exhibit increased activity or reduced food intake. Data on gene expression have indicated that *Nocturnin* knockout mice have deficits in lipid metabolism or uptake, in addition to changes in glucose and insulin sensitivity (Green CB et al 2007 Proc Natl Acad Sci USA 104:9888).

It has been observed that in obese and normal mice the gut has different species of microbes (Ley RE et al 2005 Proc Natl Acad Sci USA 102:11070). Some experimental data point to the *db* (*diabetes*) gene (mouse chromosome 4) as a receptor for the *ob*-encoded factor, leptin. The *tubby* gene (mouse chromosome 7) also causes maturity-onset obesity, insulin resistance, vision and hearing deficit. Tubby is activated by signal transduction from G protein-linked receptors. Phospholipase C (PLC) releases Tubby from the phosphatidylinositol-4,5-bisphosphate of the plasma membrane and then triggers its movement to the cell nucleus where it functions as a transcription factor. The *fat* mutation in mice has a later onset than *ob*. In *ob/ob* mice the serum insulin level decreases with an increase of blood glucose level. In the *fat/fat* mice exogenously supplied insulin reduces the serum glucose level. Fat mice store 70% of their insulin as proinsulin. Apparently, the *fat* gene causes deficiency in carboxypeptidase, an enzyme that normally processes proinsulin. The protein tyrosine phosphatase-1B gene (PTP-1B) of mice is a negative regulator of insulin signaling. Mutational loss of PTP-1B activity results in

decreased phosphorylation of the insulin receptor. Insulin receptor knockout protects against obesity (Blücher M et al 2002 *Dev Cell* 3:25). Consequently, the mutant animals gain much less weight than those with the wild type allele. Phosphorylation of the insulin receptor apparently promotes glucose uptake and weight gain. In humans, obesity has been attributed to both dominant and recessive genetic factors with environmental (diet) factors accounting for about 40% of the variation in obesity. *Mahagony* (*mg*) locus has wide-ranging pleiotropic effects by suppressing obesity of the *agouti-lethal-yellow* locus. The *mg* gene encodes a transmembrane signaling receptor of 1,428 amino acids with homology to the human attractin protein produced by T lymphocytes and cross-talking between the immune system and melanocortin. Major genes in humans seem to determine 40% of the variation in body and fat mass. Heritability of increased body weight in humans may reach > 90% (Stunkard AJ 1991 *Res Publ Assoc Nerv Ment Dis* 69:205). There is a strong linkage between the growth hormone secretagogue receptor (ghrelin receptor, 3q26) and obesity (Baessler A et al 2005 *Diabetes* 54:259). Vaccination of rats with various forms of ghrelin slowed down weight gain and reduced obesity (Zorilla EP et al 2006 *Proc Natl Acad Sci USA* 103:13226). In humans, there is some indication of greater effect of either maternal or paternal body weight on the obesity of the progeny. The geneticist faces problems in measuring such a complex trait as obesity, e.g., in terms of body mass, fat mass, visceral adipose tissue amounts, metabolic rate, respiratory quotient and insulin sensitivity. Many human obesity factors have been implicated mainly on the basis of mice models and putative linkage of quantitative trait loci (QTL). A major susceptibility locus was detected in the short arm of human chromosome 10 (MLS 5.28) and minor quantitative factors appeared in chromosomes 2 (lod score 2.68) and 5 (lod score 2.93). Neuropeptide Y (NPY) appears to be a stimulant of food intake and an activator of a hypothalamic feeding receptor (Y5). A cAMP-dependent protein kinase (PKA) also plays an important role in obesity. This holoenzyme is a tetramer, containing two regulatory (R) and two catalytic (C) subunits. The catalytic function is phosphorylation of serine/threonine and the regulatory units slow down the enzyme when the level of cAMP is low. A knockout of the RII β regulatory subunit leads to the stimulation of energy expenditures in mice and they remain lean even on a diet that is normally conducive to obesity. In the inner membrane of the mammalian mitochondria, body heat is generated by uncoupling oxidative phosphorylation. Uncoupling proteins UCP1 (4q23), UCP2 (11q13) and UCP3 (11q13) also regulate obesity to some extent. UCP2 is associated with a slightly reduced tendency for obesity (Esterbauer H et al 2001 *Nature*

Genet 28:178). These proteins regulate energy balance and cold tolerance. Mice mutants in the uncoupling protein (ICP) have increased food intake but because of the increase in the rate of metabolism they do not become obese. Melanocyte regulatory factors (POMC, α -MSH, MC3-R, MC4-R) and bombesin receptor-3 (BRS-3) are modulators of energy balance and thus obesity and associated diseases. MC4-R regulates food intake and possibly energy use; MC3-R affects the efficiency of the feed and the storage of fat. Mice mutants for both these hormones eat excessively (because of MC4-R deficiency) and store fat excessively (because of MC3-R deficiency) and become quite obese. Systemic impairment of oxidative phosphorylation (OXPHOS) due to *Cre*-mediated targeted disruption, and unexpected ubiquitous reduction of mitochondrial frataxin protein expression lead to a significant reduction in total energy expenditure paralleled by increased expression of ATP citrate lyase, a rate-limiting step in de novo synthesis of fatty acids and triglycerides contributes to obesity (Pamplun D et al 2007 *Proc Natl Acad Sci USA* 104:6377). Perilipin (an adipocyte protein) modulates hormone-sensitive lipase (HSL) activity. HSL hydrolyses triacylglycerol, which stores energy in the cell. Deficiency of perilipin protects against obesity. The peptide motif CKGGRAKDC, which associates with prohibitin, a multifunctional membrane protein, targets angiogenesis in the adipose tissue and causes apoptosis. This results in resorption of white fat cells and normalizes metabolism without adverse effects (Kolonin MG et al 2004 *Nature Med* 10:625). Lymphocytic leakage – due to mutation at the mouse locus *Prox1* – also controls adult-onset obesity and lymphatic vascular disease (Harvey NL et al 2005 *Nature Genet* 37:1072). Close to 30 genetic sites are known to be involved in human obesity. Further, 16–22% of adults who are homozygous for FTO (fat mass and obesity, human chromosome 16q22.2 [mouse chromosome 8]) risk allele weighed about 3 kilograms more and had 1.67-fold increased odds of obesity when compared with those who did not inherit a risk allele (Frayling TM et al 2007 *Science* 316:889; Dina C et al 2007 *Nature Genet* 39:724).

Obesity may be controlled by appropriate exercise regimes as well as restricted food intake. Anti-obesity drugs may target appetite, intestinal fat absorption, increase energy expenditures, stimulate fat mobilization or decrease triglyceride synthesis. Some of the drugs of the dexfenfluramine family (Fen Phen, inhibit serotonin re-uptake and stimulate its release) may reduce obesity by 10% but may have life-threatening side effects in a few cases. The newer drug Sibutramine does not stimulate serotonin release and is considered safe. Current research has focused on the mechanism of action of leptin (response of the hypothalamus to it) and the level of leptin

biosynthesis or degradation. Cholecystokinin hormone receptor stimulants, glucagon-like peptide may reduce food intake. Fatty acid synthase (FAS) inhibitors may reduce food intake by inhibiting the removal of FAS from the cells and thus ensuring that the level of malonyl coenzyme A remains high. Malonyl-CoA (an appetite inhibitor) is generated from acetyl-CoA with the aid of acetyl-CoA carboxylase. During fasting lipid stores are mobilized from the adipose tissue in part by phosphorylation and inactivation of acetyl-coenzyme A carboxylase (ACC) involved in fatty acid synthesis. The pseudokinase Tribbles 3 (TRB3) also promotes lipolysis during fasting by degrading ACC by recruiting COP1 (ubiquitin ligase), a photomorphogenesis protein. Lipid metabolism and obesity may be controlled by both these pathways besides blocking or eliminating insulin signaling (Qi L et al 2006 Science 312:1763). Obesity in mice and humans may be promoted by an increase of Bacteroidetes and Firmicutes bacteria in the gut. These bacteria facilitate greater utilization of food energy resulting in increased body fat production (Tumbaugh PJ et al 2006 Nature [Lond] 444L1027). Germ-free animals – in contrast to mice with a gut microbiota – are protected against obesity that is a consequence of consuming a Western-style, high-fat, sugar-rich diet. Their persistently lean phenotype is associated with increased skeletal muscle and phosphorylated AMP-activated protein kinase (AMPK) in the liver and its downstream targets involved in fatty acid oxidation (acetyl-CoA carboxylase and carnitine-palmitoyltransferase). Moreover, germ-free knockout mice lacking fasting-induced adipose factor (Fiaf), a circulating lipoprotein lipase inhibitor whose expression is normally selectively suppressed in the gut epithelium by the microbiota, are not protected from diet-induced obesity (Bäckhed F et al 2007 Proc Natl Acad Sci USA 104:979).

Insects have developed a mechanism to avoid obesity. *Plutella xylostella* caterpillars reared for multiple generations on carbohydrate-rich foods (either a chemically defined artificial diet or a high-starch *Arabidopsis* mutant) progressively developed the ability to eat excess carbohydrate without storing it as fat, providing strong evidence that excess fat storage has a fitness cost. In contrast, caterpillars reared in carbohydrate-scarce environments (a chemically defined artificial diet or a low-starch *Arabidopsis* mutant) had a greater propensity to store ingested carbohydrate as fat. Moreover, insects reared on the low-starch *Arabidopsis* mutant evolved a preference for laying their eggs on this plant, whereas those reared on the high-starch *Arabidopsis* mutant showed no such preference. These observations provide an experimental example of metabolic adaptation in the face of changes in the nutritional

environment and suggest that changes in plant macronutrient profiles may promote host-associated population divergence (Warbrick J et al 2006 Proc Natl Acad Sci USA 103:14045).

In the twenty-first century obesity has become a serious human biological/social problem because of diabetes, heart disease and other ill effects on health. In the past centuries some degree of corpulence was regarded as a status symbol or opulence or beauty as revealed by many Renaissance Italian paintings and other masterpieces of art (see Fig. O2). In recent years there is an increased awareness and need for controlling obesity by all available means. Although the government is not supposed to intrude on personal free choice, it is becoming evident that some legislative controls are required. Precedents have been set by controlling the use of alcohol, tobacco and narcotics. Further legislative controls of food for schoolchildren, advertising high sugar- and fat-containing food for children seem to be warranted to curb the obesity epidemics. Also, schools should promote physical education and exercise for children (Mello MM et al 2006 N Engl J Med 354:2601). ▶leptin, ▶resistin, ▶histamine, ▶PYY₃₋₃₆, ▶neuropeptide Y, ▶orexin, ▶bombesin, ▶cholecystokinin, ▶frataxin, ▶melanocyte stimulating hormone, ▶melanocortin, ▶melanoma, ▶body mass index, ▶diabetes, ▶IL-6, ▶insulin, ▶insulin receptor, ▶secretagogue, ▶ghrelin, ▶obestatin, ▶adiponectin, ▶paternal transmission, ▶hypertension, ▶Prader-Willi syndrome, ▶Alström syndrome,

Obestatin: This is a peptide hormone transcribed from the ghrelin gene but its effects are opposite to those of ghrelin; it suppresses appetite, food intake and weight gain (Zhang JV et al 2005 Science 310:996). ►ghrelin, ►obesity

OBF (oct-binding factor; synonyms BOB.1, OCA-B): Regulates the lymphocyte-specific oct sequence in the promoter of the transcription of immunoglobulin genes; it is required for the development of the germinal centers. ►oct, ►immunoglobulins, ►germinal center

Objective Lens: Refers to the microscope lens next to the object to be studied. ►light microscopy

Obligate: This means restricted to a condition or necessarily of a type, e.g., obligate parasite, obligate anaerobe. The latter can thrive only in the absence of air.

Oblique Crossing Over: In the case of adjacent (tandem) duplications in homologous chromosomes pairing may take place in more than one register and crossing over may yield unequal products (see Fig. O3). ►unequal crossing over

Figure O3. Oblique crossing over

Obsessive-Compulsive Disorder (OCD): This is a type of schizophrenic behavior bearing some resemblance to the Tourette syndrome (see Fig. O4).

Figure O4. The red marked spots of the brain indicate some of the approximate areas of successful therapeutic stimulation. Other points (not shown here) were also used for the same purpose

A major dominant gene with minor modifiers determines this condition without difference in the two sexes. In some psychotherapy and electroconvulsive therapy resistant patients, who exhibit overactivity in the subgenual cingulate region of the brain (Brodmann area 25), electrical stimulation applied deep into the region was remarkably successful in reversing the condition in a limited trial (Mayberg HS et al 2005 Neuron 454:6512). ►schizophrenia, ►panic disorder, ►Tourette syndrome; Hanna GL et al 2002 Am J Med Genet 114:541.

OCA-B: This is the same as OBF or Bob. ►OBF

Occam's Razor (Ockham's razor): This is the philosophical precept of William Ockham [1280–1349], a rebellious clergyman and a venerabilis inceptor [= reverend innovator]: “*pluralites non est ponenda sine necessitate*”, meaning that multiple alternatives should not be offered in logical argumentation but the simplest yet adequate explanation should be chosen. ►maximal parsimony

Occipital Horn Syndrome (cutis laxa): ►Menkes syndrome, ►cutis laxa

Occluded Virus Particle: The virus is surrounded by proteinacious material that protects it from the adverse environment, e.g., when the insect host dies and decomposes. When the insect eats plant material the alkaline gut fluid dissolves the occlusion and the infectious (baculovirus) particles are released. The lipoprotein viral envelope fuses with the gut cell walls

and the nucleocapsids are transmitted to the cytoplasm and eventually to the cell nucleus. ▶[baculoviruses](#); Hu Z et al 1999 J Gen Virol 80(pt 4):1045; Braunagel SC et al 2003 Proc Natl Acad Sci USA 100:9797.

Occlusion: Transcription from one promoter reduces transcription from a downstream promoter. ▶[downstream](#), ▶[promoter](#), ▶[transcription](#)

Occupational Hazard: Refers to the presence of genotoxic (carcinogenic) agents at the workplace. Monitoring includes urine analysis for chemicals, sisterchromatid exchange, abnormal sperm count or deformed sperm or SNIPS, etc. ▶[mutation detection](#), ▶[epidemiology](#)

Occupational and Safety and Health Administration: ▶[OSHA](#)

Occurrence Risk: Refers to the chance that an offspring of a particular couple will express or become a carrier of a gene. ▶[genetic risk](#), ▶[recurrence risk](#)

Ocellus (plural ocelli): This is a simple light sensor (eyelet, eyespot) on the top of the head of insects (see tiny arrows in Fig. O5), behind the compound eyes (see Fig. O5). ▶[compound eyes](#), ▶[ommatidium](#), ▶[rhabdomere](#), ▶[morphogenesis in *Drosophila*](#)

Figure O5. Ocelli in insects

Ochre: Denotes chain-terminator codon (UAA).

Ochre Suppressor: Refers to mutation in the anticodon of tRNA that permits the insertion of an amino acid at the position of a normally chain terminating UAA RNA codon; ochre suppressors frequently suppress amber (UAG) mutations. ▶[code genetic](#), ▶[nonsense codon](#), ▶[suppressor tRNA](#)

Ochronosis: This is the blue pigmentation in alkaptonuria. ▶[alkaptonuria](#)

ω-Conotoxins: These are *Conus* snail inhibitors of calcium ion channels. ▶[ion channels](#)

Oct: This is a mammalian gene regulatory protein (helix-turn-helix transcription factors) with octa recognition sequence: ATTTGCAT. Oct-1 and Oct-2 regulate B cell differentiation. Oct3/4 mediates differentiation and dedifferentiation of embryonic stem cells. The Oct-6 transcription factor regulates Schwann cell

differentiation. The presence of Oct-1 allele may lead to a fourfold increase in susceptibility to the cerebral form of malaria. ▶[Schwann cell](#), ▶[lymphocytes](#), ▶[OBF](#), ▶[B cell](#), ▶[immunoglobulins](#), ▶[Oct-2](#), ▶[Octa](#), ▶[malaria](#), ▶[octamer](#); Pesce M, Schöler HR 2001 Stem Cells 19:271.

Oct-2: A lymphoid transcription factor that is similar to Oct-1; both respond to BOB.1/OBF.1 activators. ▶[OBF](#), ▶[OCT](#)

Octa: This is an 8-base sequence (ATTTGCAT) in the promoter of H2B histone gene and some other genes. Several slightly different octa sequences are found in the promoter regions of various genes. (Octo in Latin, οκτώ in Greek: number 8, Oct-1). ▶[OCT](#)

Octad: This means comprising eight elements, e.g., the spores in an ascus if meiosis is followed by an immediate mitotic step as in *Neurospora*, *Ascobolus*, etc. ▶[tetrad analysis](#)

Octadecanoic Acid (stearic acid): This is an inducible plant defense molecule against insects. ▶[sphingolipids](#)

Octamers: These are conserved key elements in the promoter of immunoglobulin genes where several transcription factors bind. ▶[octa](#), ▶[OCT](#), ▶[immunoglobulins](#); Matthias P 1998 Semin Immunol 10:155.

Octaploid: This is a cell nucleus carrying eight genomes, 8x. ▶[polyloid](#)

Octopine: This derivative of arginine is synthesized by a Ti plasmid gene (*ocs*) in *Agrobacterium* strain Ach 5 (see Fig. O6). ▶[opines](#), ▶[Agrobacterium](#)

Figure O6. Octopine

Ocular: This refers to the microscope lens next to the viewer's eye. ▶[objective](#)

Ocular Albinism: ▶[albinism](#)

Ocular Cicatricial Pemphigoid: This is an autosomal dominant autoimmune disease of the eye and possibly of other mucous membranes. It may be associated with defects in the HLA system. ▶[eye diseases](#), ▶[autoimmune disease](#), ▶[HLA](#)

Oculocutaneous Albinism: Several forms of the recessive disease are known. Type I (11q14-q21) is

tyrosinase negative recessive whereas types II (15q11.2-q121) and III (9p23) are tyrosinase positive (brown). There is another brown type at 15q. The most prevalent is type II, its incidence is $\sim 1/1,100$ among the Ibos of Nigeria, $\sim 1/10,000$ among US blacks and $\sim 1/36,000$ among the general population of the US. ► [albinism](#)

Oculodentodigital Dysplasia: An autosomal dominant disorder characterized by defects in the eyes (microphthalmos), small teeth and polydactyly or syndactyly. Its mutation rate reveals a large paternal effect. The basic defect may be in the connexin 43 gene (6q22-q23) that may cause disturbance in the gap junctions that are required for the exchange of small ions and signaling molecules. ► [eye diseases](#), ► [microphthalmos](#), ► [polydactyly](#), ► [syndactyly](#), ► [connexins](#), ► [gap junction](#); Paznekas WA et al 2003 Am J Hum Genet 72:408.

O.D.: Optical density indicates the absorption of light at a particular wavelength by a compound in a spectrophotometer. O.D. can be used to characterize a molecule, e.g., pure nucleic acids have maximal absorption at 260 nm but contamination and the solvent may alter the absorption pattern. ► [DNA measurements](#), ► [extinction](#)

Odds Ratio (OR): A comparison of the effect of a treatment or exposure on a particular group (of a certain genotype) versus the same treatment or exposure on another different group. The OR may reveal the response of the organism of a certain genotype to the particular exposure. The OR can be estimated statistically by a two-by-two contingency table and as ad/bc . Greater differences from 1 (+/–) indicate stronger association. ► [association test](#), ► [lod score](#)

Odontoblast: Refers to the connective tissue cell that forms dentin and dental pulp of the teeth.

Odor-Sensing: ► [olfactogenetics](#), ► [pheromones](#); Hurst JL et al 2001 Nature [Lond] 414:631; Jacob S et al 2002 Nature Genet 30:175; Hallem EA, Carlson JR 2006 Cell 125:143.

ODP (origin decision point): This is a checkpoint for the initiation of replication. It precedes the restriction point. ► [R point](#); Wu JR, Gilbert DM 2000 FEBS Lett 484:108.

Oedipus Complex: According to Freudian theory, during adolescence a child may become more attached to the parent of the opposite sex, and if the condition persists it may lead to neurotic behavior.

Oenocytes: These insect organs accumulate lipid droplets during starvation and cooperate with fat

bodies in regulating lipid metabolism (Gutierrez E et al 2007 Nature [Lond] 445:275). ► [fat body](#)

Oenothera (Onagraceae, $x = 7$): Several species, diploid and polyploid have been used for the cytological study of multiple translocations and the nature and inheritance of plastid genes. ► [gaudens](#), ► [translocation](#), ► [complex heterozygote](#), ► [megaspore competition](#), ► [zygotic lethal](#); Cleland RE 1972 Oenothera: Cytogenetics and Evolution, Acad. Press, New York; Hupfer H et al 2000 Mol Gen Genet 263:581; Mracek J et al 2006 Genomics 2006 88:372.

Oestrogen (estrogen, estradiol): This is a steroid hormone. ► [animal hormones](#), ► [estradiol](#)

Oestrus (estrus): Refers to the periodically recurrent sexual receptivity, concomitant with sexual urge (heat) in mammals, except humans. In mice it lasts for ~ 3 –4 days, depending on crowding, exposure to male pheromones or hormone treatment and the daily light/dark cycles. ► [uterus](#)

OFAGE (orthogonal-field alternation gel electrophoresis): This device is used to isolate small chromosomal size DNA of lower eukaryotes. ► [pulsed field electrophoresis](#)

Offermann Hypothesis: Purported to provide a mechanism for recombination within a short chromosomal region that would appear to be intragenic. It was assumed that actually recombination separated two genes, which were involved in position effect. These loci were not supposed to have any detectable phenotype themselves, except the position effect on the neighbor. This idea emerged in 1935, years before pseudoallelism has been discovered in 1940 by C.P. Oliver. ► [pseudoallelism](#); Carlson EA 1966 The Gene: A Critical History. Saunders, Philadelphia, PA.

Offspring-Parent Regression: ► [correlation](#)

O-GlcNAc Transferase (OGT): This is an indispensable cellular enzyme mediating post-transcriptional glycosylation of many different proteins involved in regulatory functions. (See Hanover JA 2001 FASEB J 15:1865)
